INFORM 7

The Program

Complete Program

Build 5Z71 Graham Nelson

Inform is a natural-language design system for interactive fiction, first created in 1993. To most users it seems a single unified tool, but in fact is made up of core software, common to all platforms, combined with substantial user interfaces written independently for Mac OS X, Windows and Linux, and with documentation and examples. The core material is in turn divided into:

Chapters 1 to 14: the source code to the NI compiler, written in C

Appendix A: the Standard Rules, written in Inform 7

Appendix B: the template layer, written in Inform 6

Each of these chapter blocks is divided up into one or more named sections, which have both full names ("Grammar Lines") and abbreviations (`12/gl`*, the 12 signifying Chapter 12). Finally, each section is divided into numbered "paragraphs", some named and others not. Code can thus be approximately located by "postal codes" such as* `12/gl`*.§7.*

Of its nature, Inform must perform a computational task which is difficult to specify formally, particularly since part of its aim is to cope well with incorrect input from an inexperienced user. It has become a complex program some 120,000 lines in length, and like all such it must mitigate its complexity using internal stylistic conventions and principles of organisation. To this end it follows the "literate programming" dogma of Donald Knuth, an idea which had in any case influenced Inform's own design. In LP, a single source ("web") is both "tangled" into a functional form and also "woven" into a typeset form suitable for human readers. Inform uses its own LP tool, `inweb`*, an adaptation of Knuth's* `CWEB` *which scales better to large multi-target projects.*

The Inform project's main goal is to publish the entire core Inform code base, beginning in April 2008 with public drafts of Appendices A and B, approximately 600pp of material. These use only the simplest form of LP where tangling is minimal, and the reader needs no previous experience of the genre.

Preface P/pref

Purpose
An introduction to the reader.

P/pref.§2 Build number; §3 Basic method; §4 Organization into chapters; §5 Choice of language

§**1.** Inform 7 is a free open-source system for the design of interactive fiction. This is the source code to NI, which is the component of I7 used for turning a natural language description of a model world into a valid implementation in Inform 6 (I6). This is one of the two uninteractive steps on the assembly line:

$$\textit{Natural language} \longrightarrow \textbf{NI} \longrightarrow \textbf{I6} \longrightarrow \begin{cases} \textit{Z-machine story file} \\ \textit{Glulx story file} \end{cases}$$

The Inform user interface automates this process and also supplies both ends: editing the natural language source and running the appropriate interpreter to play the resulting story file. The three user interfaces, by Andrew Hunter for Mac OS X, by David Kinder for Windows, and by Philip Chimento and Adam Thornton for Linux, are not documented here.

There are a further three substantial software layers needed to use I7:

(i) the Standard Rules file, written in I7 source text but with certain permitted additional syntaxes: this is formally an Extension, though its presence is essential;

(ii) the `.i6` files, written in a metalanguage resembling that of I6, which serves both as a repository of useful I6 routines for NI-compiled programs, and also as a description at the top level of what NI should do and in what order;

(iii) the "natural" variant of the I6 library, which is fundamentally the standard I6 library but with large parts of the action verb subroutines removed, and with numerous minor modifications and hooks added to the parser and the actions engine.

Any reader who has used I6 can take (iii) for granted, but a reading of (i) and (ii) might well be more useful in giving an appreciation of I7's internals than reading the NI source would be.

This is not intended as a manual for Inform 7: *Writing with Inform* and *The Inform Recipe Book*, the interleaved volumes of documentation included in the application and also published online, are the user guide. Nor is there much comment here on how the design was made: for some of the early history, see the "white paper" for the Inform 7 project, *Natural Language, Semantic Analysis and Interactive Fiction*, which covers the basic decisions made. The commentary in the source code assumes that the overall strategy is wise and gets on with its practical implementation.

§**2. Build number.** Each time the master copy of NI is modified and recompiled, the build number (digit-letter-digit-digit) is advanced. Build numbers do not reflect a hierarchical branching of the source, but are simply a way to encode a large number in four printable digits. Letters I and O are skipped, and the tailing two digits run from 01 to 99.

Build 1A01 was the first rough draft of a completed compiler: but it did not synchronise fully with the OS X Inform application until 1G22 and private beta-testing did not begin until 1J34. Other milestones include time (1B92), tables (1C86), component parts (1E60), indexing (1F46), systematic memory allocation (1J53), pattern matching (1M11), the map index (1P97), extension documentation support (1S39) and activities (1T89). The first round of testing, a heroic effort by Emily Short and Sonja Kesserich, came informally to an end at around the 1V50 build, after which a general rewriting exercise began. Minor changes needed for David Kinder's Windows port began to be made with 1W80, but the main aims were to increase speed and to improve clarity of source code. Hashing algorithms adapted to word-based syntax were introduced in 1Z50; the prototype parser was then comprehensively rewritten using a unified system to handle ambiguities and avoid blind alleys. A time trial of 2D52 against 1V59 on the same, very large, source text showed a speed increase of a factor of four. A second stage of rewriting, to generalise binary predicates and improve grammatical accuracy, began with 2D70. By the time of the first public beta release, 3K27, the testing tool `inform-test` had been written (it subsequently evolved into today's `intest`), and Emily Short's extensive suite of Examples had been worked into the verification process for builds. The history since 3K27 is recorded in the published change log.

```
define NI_VERSION "Inform 7"
define NI_BUILD "[[Build Number]]"
```

§**3. Basic method.** NI is a large but simple program. First, it reads the source text and breaks it up lexically into words, quoted matter and punctuation. Then it divides this stream of words into sentences, marking some out as headings and others as requests to include extensions, requests which are immediately carried out. When there is nothing further to input, sentences are sorted into assertions (statements about the initial state of the world) and rules (instructions concerning play). Assertions are generally copular sentences relating things together, such as "two coins are in a closed box", and these are parsed first into "meaning list" tree structures and thence into propositions in predicate calculus which are declared to be true at the start of play. Each such proposition is then interpreted to extract single facts called "inferences", and reasonable "common sense" guesses are made to add further facts, which have a lower level of certainty. When all assertions have been processed, the many inferences are reconciled to construct a spatial model of the world which, following Occam's razor, is as simple as it can be, consistent with the inferences. Only if this can be done without inconsistency are the remaining data structures built: tables defined in the source, and the parsing grammar. At last the rules are identified, placed into relevant rulebooks, sorted by scope of applicability, and compiled into I6 routines. The final task is to produce a report and an index.

Though Inform uses propositions in predicate calculus as an intermediate state to hold the meaning of sentences, it does not store knowledge that way; though it makes elementary deductions and substitutions, it does not contain a theorem-prover by unification. In the 1960s divide between the "scruffy" school of storing domain-specific knowledge (McCarthy, Minksy, Papert, et al.) versus the "neat" school of purely propositional logic (Robinson, Kowalski, Colmerauer, et al.), Inform is scruffy. McCarthy thought that a program with "common sense" is one which "automatically deduces for itself a sufficiently wide class of immediate consequences of anything it is told and what it already knows". He wrote that back in 1959 and the "neat" methods have become astonishingly powerful since then – verifying the proof of the Prime Number Theorem via contour integration, for instance – but where the programmer knows in advance what sort of knowledge the program will be dealing with, I think the scruffy methods still have it. At any rate, Inform is a working program for its end users, not an experiment in AI.

§**4. Organization into chapters.** "I can't help feeling," wrote Michael Frayn recently, "that if someone had asked me before the universe began how it would turn out, I should have guessed something a bit less like an old curiosity shop and a bit more like a formal French garden – an orderly arrangement of straight avenues, circular walks, and geometrically shaped trees and hedges." I have an uneasy feeling that the same might be said about Inform, but at its most basic level, it is organised in six layers:

(L1) services for memory management, output streams, file input/output, and the handling of text as a sequence of words (chapters 1 to 3);

(L2) the A-parser, which gathers the source text from its various locations and divides it into sentences whose basic form can be recognised (chapter 4);

(L3) the S-parser, which resolves smaller excerpts of text into meanings, and the necessary apparatus to describe, manipulate and compile these meanings (chapters 5 to 7);

(L4) the world-builder, which uses the A-parser and S-parser in combination to break down the assertions in the source text to see what facts can be inferred about the initial state of the world, and then assembles those into a model, compiling it to a suitable Inform 6 description (chapters 8 to 10);

(L5) the change agent, compiling the phrases which are the means by which the state of the model world changes at run-time; and organising the rules which use those phrases, and the rulebooks holding those rules; and the actions and activities which structure those rulebooks, and the run-time grammar of commands which invoke those actions (chapters 11 to 13);

(L6) a thin control layer on top, following instructions from the command line parameters and from the "template" which lays out Inform's sequence of operation (chapter 14).

§**5. Choice of language.** NI is written in a literate programming extension of C called `inweb`. Besides interspersing documentation, this also provides concise syntax for parsing natural language; further apparent extensions, for logging to the debugging log and for automated memory allocation, are in fact provided by macros which are defined in the NI source.

To compile NI requires use of the Inform Tools, and in particular of `inweb`. A manual for each of the tools is included in the NI source (as documentation without code). Having compiled NI, it is important to check the result with `intest`: testing of bug fixes requires each change to be checked against a corpus of about 1200 test source texts. As of November 2008, this takes more than 3 minutes even using all four processors of a quad-3 GHz Mac Pro: it takes up to an hour on a Power PC-equipped iMac G4.

Thematic Index P/thix

Purpose

A gazetteer of interesting places to visit for the traveller who embarks into the Inform source code.

---

§**1.** Literate programs are traditionally typeset with an index, covering (mainly) each use of each identifier, and also some general concepts. In an age of highly searchable PDF files, that no longer seems helpful. Instead, this section is designed to help people who only want information on particular areas.

§**2. How NI interfaces with the Inform application.** These are independent programs and communicate at arm's length: the host application (usually providing a user interface) issues instructions at the command line when it launches NI, and then reads and acts upon its output. Each program has expectations about how the other will behave: these evolved gradually over the period 2003-07, and were for a long time never written down. The following indexes passages in the NI source which document these miscellaneous interface issues:

---

§**3. Miscellany.**

Licence and Copyright Declaration P/legal

Purpose

A verbatim copy of the Artistic License 2.0, which governs the use and distribution of Inform 7 materials.

---

§**1. Declaration of copyright.** The Inform 6 compiler and its associated library are copyright (c) Graham Nelson 1993-2007. The following materials associated with the Inform 7 project are copyright (c) Graham Nelson 2003-2007: the source code to the NI compiler; the I6T template files; the "natural" version of the I6 library; the icons, images and other non-executable resources supplied for use within Inform user interfaces; the Inform 7 documentation and website, including the Examples; the Inform Tools Suite; and the test cases used for regression-testing with `intest`, their associated material and ideal results. The *Inform [6] Designer's Manual, Fourth Edition* (DM4) is copyright (c) Graham Nelson 2001. We will call this whole body of intellectual property, with the exception of the typeset and printed form of the DM4, "the Package".

GN is the primary author of the Package, but not the only one: indeed the examples were very largely written by Emily Short, and others have also made modest contributions. However, GN holds the copyright to all of it so that there is a single point of reference for licencing of Inform.

Note that this does *not* include the officially recognised Inform user interface applications: the authors of these programs retain their own copyrights and are responsible for their own licencing. (It is a condition to be officially recognised by the Inform project that some form of free licence be used: in practice, most have chosen the GPL version 2.)

§**2. The former Inform licence, 1993-2007.** The Package was previously governed by a short, largely free but in some ways restrictive licence. (The text of this was published in the DM4, which is freely browsable online.)

The new licence is both more explicit and more liberal. The change was made for cultural reasons: over those years the Internet became a highly litigious domain, where even those who espouse freedoms are obsessed with the terms of licenses. Some users are now frightened off by any retention of rights by the author of software, worrying that the rug might be pulled at any moment. Some institutions enforce their ideological position by refusing to distribute software under a licence which they deem impure: for instance, under the old licence Inform could not be aggregated with Debian Linux, even though it had been completely free and open for 15 years. Also, there are some possible complications about the way NI and other components combine with GPL-licensed software for the user interfaces, and I feel reluctantly compelled to finally include a disclaimer of warranty, some degree of anti-patent-troll protection, and so forth – something I dislike doing since it implicitly acknowledges some validity in such distasteful legal claims.

There are two practical differences between the old and new licences. First, the new licence removes the requirement that any work of IF compiled by Inform should name "Inform" in its banner text. Authors are now legally free to suppress the banner text altogether, though I hope they won't: it's only a small gesture of respect to all those who have worked on Inform, and costs nothing. Second, the old licence forbade (at any rate did not permit) the making of a modified version of Inform, whereas the new licence largely permits this (see below).

§**3. The current licence, 2008-.** As from the first publication on the Inform website of the source code to Inform 7, in 2008:

(a) The Package is hereby placed under the Artistic License 2.0.
(b) For the avoidance of doubt, the Author additionally grants the right for all users of the Package to make unlimited use of story files produced by the Package.

To clarify (b): the structure of Inform means that it copies large pieces of the I6 library and the I6T template files almost verbatim into the I6 source code used to make a story file. Someone might then worry that any resulting story file is therefore a derivative work of the Package itself, and so inherits the Artistic License 2.0. The Author wishes to clarify that this is not the case, and that *people using Inform to make a story file can sell, distribute, modify or otherwise use it exactly as they please, and under any licence(s) they choose.* (The same issue arises with the Free Software Foundation's `bison`, and they solve it in the same way, by making an additional grant of rights on top of the licence for `bison` itself.)

§**4.** The Artistic License 2.0, used by Perl among other notable projects, is widely considered to be one offering generous permissions for the user, and was chosen because:

(a) it is recognised by the Open Source Initiative as an open source licence;
(b) it is recognised by the Free Software Foundation as a guarantee that the software is free not only in the economic way, but also in a more libertarian sense;
(c) by freely allowing modifications and derivative works, but requiring any such to be issued under different names, it allows the authors to retain the moral right of authorship: the ability to decide what is, and is not, the Inform design.

The licence is the sole legal document governing these matters, of course, but our interpretation of clause (9) is that, in particular, it is legal to distribute an aggregation of the Package along with any of the recognised user interface application(s) and also with Extensions by third parties which are subject to the Creative Commons Attribution licence (such as those published on the Inform website), and to call the result "Inform".

The verbatim text of the licence now follows. It is copyrighted by the Perl Foundation, 2006, whose work in creating it we acknowledge with thanks. (The boldface section numbers in the typeset form of this preface are just typography, and not a part of the licence: but the clause numbers, "(10)" and so forth, are. The American spelling "license" is used, since that's how the Foundation wrote it.)

§**5. Preamble.** This license establishes the terms under which a given free software Package may be copied, modified, distributed, and/or redistributed. The intent is that the Copyright Holder maintains some artistic control over the development of that Package while still keeping the Package available as open source and free software.

You are always permitted to make arrangements wholly outside of this license directly with the Copyright Holder of a given Package. If the terms of this license do not permit the full use that you propose to make of the Package, you should contact the Copyright Holder and seek a different licensing arrangement.

§**6. Definitions.** *Copyright Holder* means the individual(s) or organization(s) named in the copyright notice for the entire Package. *Contributor* means any party that has contributed code or other material to the Package, in accordance with the Copyright Holder's procedures. *You* and *your* means any person who would like to copy, distribute, or modify the Package. *Package* means the collection of files distributed by the Copyright Holder, and derivatives of that collection and/or of those files. A given Package may consist of either the Standard Version, or a Modified Version. *Distribute* means providing a copy of the Package or making it accessible to anyone else, or in the case of a company or organization, to others outside of your company or organization. *Distributor Fee* means any fee that you charge for Distributing this Package or providing support for this Package to another party. It does not mean licensing fees. *Standard Version* refers to the Package if it has not been modified, or has been modified only in ways explicitly requested by the Copyright Holder. *Modified Version* means the Package, if it has been changed, and such changes were not explicitly requested by the Copyright Holder. *Original License* means this Artistic License as Distributed with the Standard Version of the Package, in its current version or as it may be modified by The Perl Foundation in the future. *Source* form means the source code, documentation source, and configuration files for the Package. *Compiled* form means the compiled bytecode, object code, binary, or any other form resulting from mechanical transformation or translation of the Source form.

§**7. Permission for Use and Modification Without Distribution.**

(1) You are permitted to use the Standard Version and create and use Modified Versions for any purpose without restriction, provided that you do not Distribute the Modified Version.

§**8. Permissions for Redistribution of the Standard Version.**

(2) You may Distribute verbatim copies of the Source form of the Standard Version of this Package in any medium without restriction, either gratis or for a Distributor Fee, provided that you duplicate all of the original copyright notices and associated disclaimers. At your discretion, such verbatim copies may or may not include a Compiled form of the Package.

(3) You may apply any bug fixes, portability changes, and other modifications made available from the Copyright Holder. The resulting Package will still be considered the Standard Version, and as such will be subject to the Original License.

§**9. Distribution of Modified Versions of the Package as Source.**

(4) You may Distribute your Modified Version as Source (either gratis or for a Distributor Fee, and with or without a Compiled form of the Modified Version) provided that you clearly document how it differs from the Standard Version, including, but not limited to, documenting any non-standard features, executables, or modules, and provided that you do at least ONE of the following:

(a) make the Modified Version available to the Copyright Holder of the Standard Version, under the Original License, so that the Copyright Holder may include your modifications in the Standard Version.

(b) ensure that installation of your Modified Version does not prevent the user installing or running the Standard Version. In addition, the Modified Version must bear a name that is different from the name of the Standard Version.

(c) allow anyone who receives a copy of the Modified Version to make the Source form of the Modified Version available to others under

(i) the Original License or

(ii) a license that permits the licensee to freely copy, modify and redistribute the Modified Version using the same licensing terms that apply to the copy that the licensee received, and requires that the Source form of the Modified Version, and of any works derived from it, be made freely available in that license fees are prohibited but Distributor Fees are allowed.

§10. Distribution of Compiled Forms of the Standard Version or Modified Versions without the Source.

(5) You may Distribute Compiled forms of the Standard Version without the Source, provided that you include complete instructions on how to get the Source of the Standard Version. Such instructions must be valid at the time of your distribution. If these instructions, at any time while you are carrying out such distribution, become invalid, you must provide new instructions on demand or cease further distribution. If you provide valid instructions or cease distribution within thirty days after you become aware that the instructions are invalid, then you do not forfeit any of your rights under this license.

(6) You may Distribute a Modified Version in Compiled form without the Source, provided that you comply with Section 4 with respect to the Source of the Modified Version.

§11. Aggregating or Linking the Package.

(7) You may aggregate the Package (either the Standard Version or Modified Version) with other packages and Distribute the resulting aggregation provided that you do not charge a licensing fee for the Package. Distributor Fees are permitted, and licensing fees for other components in the aggregation are permitted. The terms of this license apply to the use and Distribution of the Standard or Modified Versions as included in the aggregation.

(8) You are permitted to link Modified and Standard Versions with other works, to embed the Package in a larger work of your own, or to build stand-alone binary or bytecode versions of applications that include the Package, and Distribute the result without restriction, provided the result does not expose a direct interface to the Package.

§12. Items That are Not Considered Part of a Modified Version.

(9) Works (including, but not limited to, modules and scripts) that merely extend or make use of the Package, do not, by themselves, cause the Package to be a Modified Version. In addition, such works are not considered parts of the Package itself, and are not subject to the terms of this license.

§13. General Provisions.

(10) Any use, modification, and distribution of the Standard or Modified Versions is governed by this Artistic License. By using, modifying or distributing the Package, you accept this license. Do not use, modify, or distribute the Package, if you do not accept this license.

(11) If your Modified Version has been derived from a Modified Version made by someone other than you, you are nevertheless required to ensure that your Modified Version complies with the requirements of this license.

(12) This license does not grant you the right to use any trademark, service mark, tradename, or logo of the Copyright Holder.

(13) This license includes the non-exclusive, worldwide, free-of-charge patent license to make, have made, use, offer to sell, sell, import and otherwise transfer the Package with respect to any patent claims licensable by the Copyright Holder that are necessarily infringed by the Package. If you institute patent litigation (including a cross-claim or counterclaim) against any party alleging that the Package constitutes direct or contributory patent infringement, then this Artistic License to you shall terminate on the date that such litigation is filed.

(14) Disclaimer of Warranty: THE PACKAGE IS PROVIDED BY THE COPYRIGHT HOLDER AND CONTRIBUTORS "AS IS" AND WITHOUT ANY EXPRESS OR IMPLIED WARRANTIES. THE IMPLIED WARRANTIES OF MERCHANTABILITY, FITNESS FOR A PARTICULAR PURPOSE, OR NON-INFRINGEMENT ARE DISCLAIMED TO THE EXTENT PERMITTED BY YOUR LOCAL LAW. UNLESS REQUIRED BY LAW, NO COPYRIGHT HOLDER OR CONTRIBUTOR WILL BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL, OR CONSEQUENTIAL DAMAGES ARISING IN ANY WAY OUT OF THE USE OF THE PACKAGE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

§**14.** That final burst of shouting concludes the verbatim text of the Artistic License 2.0, and we can now return to your scheduled program.

BNF Grammar P/bnfg

Purpose

A collated BNF grammar for the syntax of the language in which Inform source text is written.

---

§**1.** The following is derived by `inweb` from documentation, not code, and is intended primarily to provide a contents page showing how to find which sections handle which grammatical constructs. While this is close to being a formal syntactic description of I7, semantic considerations are in practice more important. For instance, it is syntactically valid for an action pattern to be used as a value, but one would not normally expect, say, "taking something portable" to be something which can be evaluated: but in sentences like "Taking something portable is permitted behaviour", the same words are construed as a referential noun phrase. Similarly, the description below does not explain how to resolve ambiguities (though in most cases productions are checked in the order shown). Finally, note that a number of the syntaxes below are undocumented in the public manual for Inform. This is intentional: they are provided only for the bootstrapping process which the Standard Rules goes through, and are not for public use. They may change without notice.

The notation used is mostly standard: see the Wikipedia page on EBNF for details. In particular "::=" can be read as "matches", and each angle-bracketed construction is followed by one or more possibilities. (A vertical stroke means "or".) Square brackets mean that material is optional. Braces mean "0 or more": thus "**on {and on}**" matches the texts "on", "on and on", "on and on and on", ...

Bold-face words in lower case are literal words, and bold-face parentheses are literal parentheses. Bold-face small caps are used for lexically defined patterns: the meaning of these is mostly obvious, or can be found elsewhere. (For instance, an I6 identifier is a string of 1 to 31 characters consisting of digits, upper or lower case unaccented letters or underscore signs, such that the first character must not be a digit.) Lower-case roman type denotes a name: thus "world-object" means the name of a world-object, which might be a thing, room, direction or region. Lower-case italic type denotes an inflected usage: thus *verb-usage* might match "has not been" or "carried" or "was supported by". Finally, the subscripts after angle-bracketed constructions refer to the NI source code: for instance, "5/lit" means the section "Literal Productions" in Chapter 5.

§**2. Literal values.** That is, those which can be determined as constants by lexical means alone, in the same way that a run of digits not starting perhaps with a minus sign but not a 0 can be recognised as a literal number.

---

§**3. Physical descriptions.** These are general descriptions of categories of physical things or places. A detail currently left vague, to avoid doubling the size of the grammar, is that in some contexts a physical description is allowed to consist of adjectives without a noun (as in the grammar written below, which is used most often), whereas in a few other cases a noun is required. (I construe this as a semantic rather than syntactic requirement, and so give the more general form of the grammar.)

---

§**4. Type expressions.** This is a difficult concept to coin a name for. These are not constant in value, but constant in identification. In particular, we can use these for deciding specificity. For instance, the literal object "Spanish saddle" is a type expression because it can be determined at compile time to be more specific than, say, the kind "equestrian kit": but the global variable "latest horse show prize" is not a type expression, since we can't judge its specificity without knowing the current value, and that's no use because it is undetermined at compile time.

§5. Values and conditions.

§**6. List punctuation.** Note the optional serial comma, always permitted.

---

§**7. Action patterns.** The most important and unconventional form of condition in I7: a description matching a range of possible actions, which is deemed true if the current action fits.

---

§**8. Source file layout.** There are two kinds of source file: the main source text, and an extension.

---

§**9.** Extension files have a similar make-up, but use different titling, and end differently too: with an explicit closing sentence and then, optionally, some documentation and examples.

---

§**10. Paragraphs.** Paragraphs are composed of one or more sentences of any kind in any order, with two exceptional forms: headings and tables.

§11. Whole-paragraph sentences.

§**12. Rules and phrase definitions.**

---

§**13. Assertion sentences.** This is the general form that almost all declarative sentences in I7 take: though there are a number of miscellaneous exceptional sentences in the next section, they only turn up occasionally.

---

§**14. Exceptional declarative sentences.** These look superficially like assertions, but are in fact parsed as exceptional cases. The net effect is that I7 behaves as if it has certain reserved verbs and prepositions, though in fact for various reasons this is not how such sentences are implemented.

§**15. Imperative sentences.** A miscellany of ways to instruct I7 this way and that, using an imperative verb rather than an SVO sentence.

1 Definitions

`1/basic`: *Basic Definitions.w* To make basic definitions used throughout NI.

`1/plat`: *Platform-Specific Definitions.w* To provide any adaptations needed for NI to work on different "platforms", or operating systems: for instance, styles of writing filenames specific to Linux, Windows or Mac OS X are specified here. The only platform dependencies in the whole of NI are contained in this section.

Basic Definitions 1/basic

Purpose

To make basic definitions used throughout NI.

1/basic.¶5 File Input/Output; ¶6 Encodings and formats; ¶7-0 Output file handles

---

Definitions

¶1. We first include the standard C library, using most of the basic repertoire of routines for handling simple data. `stdarg.h`, perhaps the least-used of these, is needed because a variable-argument function (an NI-specific form of `printf`), will be defined in Chapter 2 to handle the debugging log.

```
#include <stdio.h>
#include <ctype.h>
#include <math.h>
#include <stdarg.h>
#include <stdlib.h>
#include <string.h>
#include <time.h>
```

¶2. As in the Inform 6 source code, the following conventional definitions are used for values whenever integer variables are used as flags. (We only use `NOT_APPLICABLE` very occasionally.)

```
define TRUE 1
define FALSE 0
define NOT_APPLICABLE 2
```

¶3. These flags are set by command-line parameters. `for_release` will be set when NI is used in a run started by clicking on the Release button in the application. `fix_rng_at_start_of_play` is not used by the application, but the `intest` program makes use of this feature to make repeated tests of the Z-machine story file produce identical sequences of random numbers: without this, we would have difficulty comparing a transcript of text produced by the story file on one compilation from another.

`story_filename_extension` is also set as a result of information passed from the application via the command line to NI. In order for NI to write good releasing instructions, it needs to know the story file format (".z5", ".z8", etc.) of the finally produced story file. But since NI compiles only to Inform 6 code, and does not run I6 itself, it has no way of telling what the application intends to do on this. So the application is required to give NI advance notice of this via a command-line option.

```
int for_release = FALSE;                    Omit sections of source text marked not for release
int existing_story_file = FALSE;            Ignore source text to blorb existing story file?
int fix_rng_at_start_of_play = FALSE;       Compile I6 code which seeds the RNG
int rng_seed_at_start_of_play = 0;          The seed value, or 0 if not seeded
int census_mode = FALSE;                    NI running only to update extension documentation
char *story_filename_extension = NULL;      What story file we will eventually have
int show_progress_indicator = TRUE;         Produce percentage of progress messages
```

¶4. Broadly speaking, what NI does can be divided into two halves: in the first half, it reads all the assertions, makes all the objects and global variables and constructs the model world; in the second half, it compiles the phrases and grammar to go with it. `model_world_constructed` records which of these halves we are currently in: `FALSE` in the first half, `TRUE` in the second.

If there were a third stage, it would be indexing, and during that period `indexing_stage` is `TRUE`. But by that time the compilation of Inform 6 code is complete.

```
int text_loaded_from_source = FALSE;                    Lexical scanning is done
int model_world_constructed = FALSE;                    World model is constructed
int indexing_stage = FALSE;                             Everything is done except indexing
```

¶5. File Input/Output. This seems a good point to note that NI follows Unix Standard I/O conventions only up to a point. Text printed to `stdout` is descriptive of the output, but is not the primary output itself (i.e., is not the I6 translated code). Nor is the natural language original read from `stdin`. But we do follow convention by writing errors to `stderr`. Standard I/O is a good idea for tools to be used in pipelines, but NI is not a good candidate for such use because of the number of auxiliary files involved in any translation – the index, the debugging log, etc. Indeed, a true picture of file input/output by NI is more like the following: note the absence of `stdin`.

Primary source text		Standard Rules
UUID File		*Other extensions
		Template code (`.i6t` files)
		Extensions dictionary (in)
	...go into NI and out come...	
Inform 6 code	`stdout` console text	Extensions dictionary (out)
Release blurb	*`stderr` console errors	Extensions documentation (HTML files)
iFiction record	*EPS map file	
Headings file	*Trace log	
Debugging log		
Problems file		
Index (HTML files)		

Here files in the left-hand column belong to an Inform 7 "project": for a project called Kensington, they would all be files inside the `Kensington.inform` folder. Files in the middle column are stored in standard places on the user's machine: for instance, on Mac OS X the trace log and EPS file are placed on the Desktop. Files in the right-hand column are the private property of NI and live either inside the Inform 7 application, or else in an area of the user's file system which is maintained by NI without the user's direct involvement. Lastly, files marked with an asterisk are not accessed on every run of NI.

¶6. Encodings and formats. NI uses several different encodings of text, which coincide on the encoding of the standard range of ASCII characters between `0x0020` and `0x007E`.

File	Usage	Format	Encoding
Primary source text	in	Text	Unicode UTF-8 with or without BOM
Standard Rules	in	Text	Unicode UTF-8 with or without BOM
Other extensions	in	Text	Unicode UTF-8 with or without BOM
UUID File	in	Text	ASCII
Template code	in	I6 source	ISO Latin-1
Extensions dictionary	in/out	Text	ISO Latin-1
Inform 6 code	out	I6 source	ISO Latin-1
`stdout` console text	out	Text	ASCII
*`stderr` console errors	out	Text	ASCII
Extensions documentation	out	HTML	Unicode UTF-8 without BOM
Release blurb	out	Blurb file	ISO Latin-1
iFiction record	out	XML	Unicode UTF-8 without BOM
Headings file	out	XML	Unicode UTF-8 without BOM
Pictures manifest	out	XML	Unicode UTF-8 without BOM
Debugging log	out	Text	ISO Latin-1
*Trace log	out	Text	ISO Latin-1
Problems file	out	HTML	Unicode UTF-8 without BOM
Index (HTML files)	out	HTML	Unicode UTF-8 without BOM
*EPS map file	out	EPS	ISO Latin-1

The primary source text and extension files may have any of the standard line delimiters, including the little-implemented Unicode line divider. I6 files may have any of the non-Unicode line delimiters. Files written by NI use `'\n'` as line delimiter, the meaning of which varies from platform to platform.

Strings inside NI encode text as ISO Latin-1. Unicode characters beyond `0x00FF` are stored using escapes in the form `"[unicode 654]"`, where the character number is decimal.

It's convenient to define constants to refer to our two text encodings.

```
define UTF8_ENC 1                    Write as UTF-8 without BOM
define ISO_ENC 2                     Write as ISO Latin-1 (i.e., no conversion needed)
```

¶7. Output file handles. By convention, the file handles to which Inform's auxiliary outputs are written – any errors, debugging information, and so on – have short names: `dl`, for example. But note that these are variables and NI does vary them: for instance, it copies Problem messages both to `stderr` and to the debugging log, and it does this by setting `problems_file` to each in turn and printing the message twice. (Well, in fact it formats the message differently depending on the destination, but this is the idea.) The definitive file handles are in longer-named variables such as `debug_log_file`.

There is no short-named file handle for the I6 code output because it is instead passed as a function argument through most of the output routines, and invariably called `of`.

The "debugging log" gives a richly verbose account of what NI is doing. This (ISO Latin-1) plain text file exists to debug NI, *not* to help designers debug their own games. Almost every data structure has a corresponding routine to pretty-print a representation of it to the debug log. This is a plain text file. The "trace log" is a much simpler version, used for extracts only and only on request.

NI also creates a report which *is* for the eyes of designers: its report of Problems, which despite the name often simply says that all is well. Many parts of NI also check the error count to see if things are going well or badly, so we'll define that here too.

The index contains several files, each of which is written in turn: the file handle `ifl` is the currently open one, and is null until we reach indexing (if we do).

The file handle `inform6_file` is NI's output, which is a program written in Inform 6. We define this here so that error handling can close it if the program exits prematurely.

```
STREAM debug_log_file_struct;                          The actual debugging log file
STREAM inform6_file_struct;                            The actual I6 code file
STREAM trace_log_struct;                               The actual trace log file (if created)
STREAM problems_file_struct;                           The actual report of Problems file
STREAM index_file_struct;                              The current index file being written
STREAM telemetry_file_struct;                          The actual telemetry file (if created)

STREAM *debug_log_file = &debug_log_file_struct;       The actual debugging log file
STREAM *inform6_file = &inform6_file_struct;           The actual I6 code file
STREAM *trace_log = &trace_log_struct;                 The actual trace log file (if created)
STREAM *problems_file = &problems_file_struct;         The actual report of Problems file
STREAM *telemetry_file = &telemetry_file_struct;       The actual debugging log file

STREAM *dl = NULL;                                     Current destination of debugging text
STREAM *trl = NULL;                                    Current destination of trace log text
STREAM *ifl = NULL;                                    Current destination of index text
STREAM *probl = NULL;                                  Current destination of problem message text
STREAM *telmy = NULL;                                  Current destination of telemetry text

int problem_count = 0;                                 The number of Problem messages so far produced
int it_is_not_worth_adding = FALSE;                    To suppress the "It may be worth adding..."
int trace_sentences = FALSE;                           Currently debugging text to trace rather than log
int logging_to_I6_text = FALSE;                        Used for internal test cases
```

¶8. The top-level control of NI, telling it what sequence of tasks to perform, is done by a metalanguage interpreter which works through a series of template files with the `.i6t` filename extension (see Chapter 14). Setting the following flag causes this interpreter to shut down gracefully and exit NI.

```
int abort_I6T_interpreter = FALSE;
```

---

§**1.** This section has no body, and exists only to make definitions, so there is no code here.

Platform-Specific Definitions 1/plat

Purpose

To provide any adaptations needed for NI to work on different "platforms", or operating systems: for instance, styles of writing filenames specific to Linux, Windows or Mac OS X are specified here. The only platform dependencies in the whole of NI are contained in this section.

Definitions

¶1. We have, at present, three sets of platform definitions: to compile NI, you should either modify the text below so that the default platform is yours, or else predefine one of `PLATFORM_WINDOWS`, `PLATFORM_UNIX` or `PLATFORM_MACOSX`. (We allow for that predefinition so that `autoconf`-like tools can be used to build NI on Unix platforms.) Similarly, predefinition can be used to set the `CPU_WORDSIZE_MULTIPLIER`: this is CPU's word size as a number of bits divided by 32, so in other words, define this as 2 to compile a form of NI which works on 64-bit processors. (NI does not run on 16-bit processors.)

```
#ifndef PLATFORM_MACOSX
#ifndef PLATFORM_WINDOWS
#ifndef PLATFORM_UNIX
#define PLATFORM_MACOSX                          the original home for NI, and still the default
#endif
#endif
#endif

#ifndef CPU_WORDSIZE_MULTIPLIER
#define CPU_WORDSIZE_MULTIPLIER 1                the CPU word size is by default 32 bits
#endif
```

---

§**1.** We now come to the blocks of definitions chosen by the above. The principal differences lie in (i) where NI expects to find user-installed extensions, etc.; (ii) where to write the handful of files output during compilation but not stored inside a project; (iii) how to tweak HTML to look better on this platform; and (iv) how the filing system works and how to scan directories inside it.

Note that we use the C preprocessor's `#define` below, and also make use of `#ifdef`, rather than the higher-level `inweb` definition function `@d`: this is because `inweb` does not allow conditional definitions, and looks down on them as hacky expediencies.

§**2. Mac OS X.** These settings are suitable for using NI with Andrew Hunter's Inform 7 application for OS X. NI reads and writes extension-related material, etc., to an `Inform` folder inside `Library` in the user's home folder. (As we shall see, NI creates this if need be.) The trace and EPS files are written to the desktop.

```
#ifdef PLATFORM_MACOSX
#define FOLDER_SEPARATOR '/'
#define INFORM_FOLDER_RELATIVE_TO_HOME "Library/"
#define HOME_LIBRARY "/Library/Inform/Extensions"
#define HOME_DOCS "/Library/Inform/Documentation"
#define HOME_TEMPLATES "/Library/Inform/Templates"
#define TRACEFILE "/Library/Inform/Inform_Trace.txt"
#define TELEMETRYFILE "/Library/Inform/Telemetry"
#define OPTIONSFILE "/Library/Inform/Options.txt"
#define ICON_EXT "tif"
#define DEFAULT_HTML_FONT \
    "face=\"lucida grande,geneva,arial,tahoma,verdana,helvetica,helv\" size=2"
#define POSIX_DIRECTORY_HANDLING
#define EPS_FILE_DESTINATION "/Desktop/Inform Map.eps"
void set_platform_specific_eps_filename(char *to) {
    char *home = (char *) (getenv("HOME"));
    if (home == NULL) {
        strcpy(to, "/Inform Map.eps");
    } else {
        strcpy(to, home);
        strcat(to, EPS_FILE_DESTINATION);
    }
}
#define EXTENSIONS_MODEL_HTML "ExtensionsModel.html"
#define EXTENSION_FILE_MODEL_HTML "ExtensionFileModel.html"
#define JAVASCRIPT_MODEL 1
typedef long int pointer_sized_int;
#endif
```

The function set_platform_specific_eps_filename is called from 2/files.

§**3. Microsoft Windows.** The Windows Inform 7 application, by David Kinder, prefers to control the appearance of HTML in its panels using its own CSS arrangements, and so NI does not assert the font to be used in this case. NI reads and writes extension-related material, etc., to an `Inform` folder in the user's My Documents folder. (As we shall see, NI creates this if need be.) The trace and EPS files are written to the desktop.

```
#ifdef PLATFORM_WINDOWS
#define LOCALE_IS_ISO
#define FOLDER_SEPARATOR '\\'
#define INFORM_FOLDER_RELATIVE_TO_HOME ""
#define HOME_LIBRARY "\\Inform\\Extensions"
#define HOME_DOCS "\\Inform\\Documentation"
#define HOME_TEMPLATES "\\Inform\\Templates"
#define TRACEFILE "\\Inform\\Inform_Trace.txt"
#define TELEMETRYFILE "\\Inform\\Telemetry"
#define OPTIONSFILE "\\Inform\\Options.txt"
#define DEFAULT_HTML_FONT "size=2"
#define WINDOWS_DIRECTORY_HANDLING
#define EPS_FILE_DESTINATION "\\Inform Map.eps"
```

```
void set_platform_specific_eps_filename(char *to) {
    char *home = (char *) (getenv("HOME"));
    char *desktop = (char *) (getenv("DESKTOP"));
    if (desktop == NULL) desktop = home;
    if (desktop == NULL) desktop = "";
    strcpy(to, desktop);
    strcat(to, EPS_FILE_DESTINATION);
}
#define EXTENSIONS_MODEL_HTML "WinExtensionsModel.html"
#define EXTENSION_FILE_MODEL_HTML "WinExtensionFileModel.html"
#define JAVASCRIPT_MODEL 2
typedef long int pointer_sized_int;
#endif
```

The function set_platform_specific_eps_filename is called from 2/files.

§4. **A Windows-safe form of `isdigit`.** Annoyingly, the C specification allows the implementation to have `char` either signed or unsigned. On Windows it's generally signed. Now, consider what happens with a character value of acute-e. This has an `unsigned char` value of 233. When stored in a `char` on Windows, this becomes a value of `-23`. When this is passed to `isdigit()`, we need to consider the prototype for `isdigit()`:

```
int isdigit(int);
```

So, when casting to int we get `-23`, not `233`. Unfortunately the return value from `isdigit()` is only defined by the C specification for values in the range 0 to 255 (and also EOF), so the return value for `-23` is undefined. Unfortunately with Windows GCC, `isdigit(-23)` returns a non-zero value.

```
#ifdef PLATFORM_WINDOWS
int isdigit(int c) {
    return ((c >= '0') && (c <= '9')) ? 1 : 0;
}
#endif
```

§5. **Generic Unix.** These settings are used both for the Linux versions of NI (both command-line, by Adam Thornton, and for Ubuntu, Fedora, Debian and so forth, by Philip Chimento) and also for Solaris variants: they can probably be used for any Unix-based system.

```
#ifdef PLATFORM_UNIX
#include <strings.h>
#include <math.h>
#define FOLDER_SEPARATOR '/'
#define INFORM_FOLDER_RELATIVE_TO_HOME ""
#define HOME_LIBRARY "/Inform/Extensions"
#define HOME_DOCS "/Inform/Documentation"
#define HOME_TEMPLATES "/Inform/Templates"
#define TRACEFILE "/Inform/Inform_Trace.txt"
#define TELEMETRYFILE "/Inform/Telemetry"
#define OPTIONSFILE "/Inform/Options.txt"
#define DEFAULT_HTML_FONT \
    "face=\"lucida grande,geneva,arial,tahoma,verdana,helvetica,helv\" size=2"
#define POSIX_DIRECTORY_HANDLING
#define EPS_FILE_DESTINATION "/Inform Map.eps"
void set_platform_specific_eps_filename(char *to) {
    char *home = (char *) (getenv("HOME"));
    char *desktop = (char *) (getenv("DESKTOP"));
```

```
    if (desktop == NULL) desktop = home;
    strcpy(to, desktop);
    strcat(to, EPS_FILE_DESTINATION);
}
#define EXTENSIONS_MODEL_HTML "ExtensionsModel.html"
#define EXTENSION_FILE_MODEL_HTML "ExtensionFileModel.html"
#define JAVASCRIPT_MODEL 0
typedef long int pointer_sized_int;
#endif
```

The function set_platform_specific_eps_filename is called from 2/files.

§**6.** The "icon extension" is used for only two icons, the orange jump to source icon and the grey magnifying glass. These are rendered inside the Inform 7 application in both TIFF and PNG formats: TIFF looks better on OS X, but other platform browsers mostly cannot render TIFFs.

```
#ifndef ICON_EXT
#define ICON_EXT "png"                    File extension of the icons in the HTML index
#endif
```

§**7. Directory handling.** NI would ideally handle all directory activities – scanning directories to see what files are there, creating new directories, etc. – using the standard POSIX environment, which is supposed to make such things platform-independent. In practice Windows provides POSIX-like facilities but with sufficient differences that we have instead written the necessary routines twice: and in the rest of NI we treat the pointer to a directory structure as a `void *` to avoid making any assumptions about what the structure behind it actually is. First: "pure" POSIX.

```
#ifdef POSIX_DIRECTORY_HANDLING
#include <sys/stat.h>
#include <sys/types.h>
#include <errno.h>
#include <dirent.h>

int platform_specific_mkdir(char *path_to_folder) {
    int rv;
    errno = 0;
    rv = mkdir(path_to_folder, S_IRWXU | S_IRWXG | S_IROTH | S_IXOTH);
    if (rv == 0) return TRUE;
    if (errno == EEXIST) return TRUE;
    STREAM_WRITE(STDERR, "Failed to create folder <%s>\n", path_to_folder);
    return FALSE;
}

void *platform_specific_opendir(char *path_to_folder) {
    DIR *dirp = opendir(path_to_folder);
    return (void *) dirp;
}

int platform_specific_readdir(void *folder, char *path_to_folder,
    char *leafname) {
    char path_to[2*MAX_FILENAME_LENGTH+2];
    struct stat file_status;
    int rv;
    DIR *dirp = (DIR *) folder;
    struct dirent *dp;
```

```
    if ((dp = readdir(dirp)) == NULL) return FALSE;
    sprintf(path_to, "%s%c%s", path_to_folder, FOLDER_SEPARATOR, dp->d_name);
    rv = stat(path_to, &file_status);
    if (rv != 0) {
        STREAM_WRITE(STDERR, "Stat failed on %s\n", path_to);
        return FALSE;
    }
    if (S_ISDIR(file_status.st_mode)) sprintf(leafname, "%s/", dp->d_name);
    else strcpy(leafname, dp->d_name);
    return TRUE;
}
void platform_specific_closedir(void *folder) {
    DIR *dirp = (DIR *) folder;
    closedir(dirp);
}
#endif
```

The function platform_specific_mkdir is called from 2/files and 10/bib.
The function platform_specific_opendir is called from 2/files.
The function platform_specific_readdir is called from 2/files.
The function platform_specific_closedir is called from 2/files.

§**8.** Now for the Windows versions of these same functions, though they are not very different.

```
#ifdef WINDOWS_DIRECTORY_HANDLING
#include <sys/stat.h>
#include <dirent.h>
#include <errno.h>
#include <io.h>
int platform_specific_mkdir(char *path_to_folder) {
    int rv;
    errno = 0;
    rv = _mkdir(path_to_folder);
    if (rv == 0) return TRUE;
    if (errno == EEXIST) return TRUE;
    STREAM_WRITE(STDERR, "Failed to create folder <%s>\n", path_to_folder);
    return FALSE;
}
void *platform_specific_opendir(char *path_to_folder) {
    DIR *dirp = opendir(path_to_folder);
    return (void *) dirp;
}
int platform_specific_readdir(void *folder, char *path_to_folder,
    char *leafname) {
    char path_to[2*MAX_FILENAME_LENGTH+2];
    struct _stat file_status;
    int rv;
    DIR *dirp = (DIR *) folder;
    struct dirent *dp;
    if ((dp = readdir(dirp)) == NULL) return FALSE;
    sprintf(path_to, "%s%c%s", path_to_folder, FOLDER_SEPARATOR, dp->d_name);
    rv = _stat(path_to, &file_status);
```

```
    if (rv != 0) {
        STREAM_WRITE(STDERR, "Stat failed on %s\n", path_to);
        return FALSE;
    }
    if (S_ISDIR(file_status.st_mode)) sprintf(leafname, "%s/", dp->d_name);
    else strcpy(leafname, dp->d_name);
    return TRUE;
}

void platform_specific_closedir(void *folder) {
    DIR *dirp = (DIR *) folder;
    closedir(dirp);
}

#endif
```

The function platform_specific_mkdir is called from 2/files and 10/bib.

The function platform_specific_opendir is called from 2/files.

The function platform_specific_readdir is called from 2/files.

The function platform_specific_closedir is called from 2/files.

§**9. Locale issues.** The following is intended to handle possible differences of text encoding in filenames, which (for Unix-based systems) depend on the current locale. The default is UTF-8 since Mac OS X, and probably most other modern Unixes, use this.

```
#ifndef LOCALE_IS_ISO
#ifndef LOCALE_IS_UTF8
#define LOCALE_IS_UTF8 1
#endif
#endif
```

§**10.** The function `iso_fopen` should behave exactly like `fopen`, but encoding the filename as ISO Latin-1 text. Thus, it can actually be just `fopen` on platforms whose locale uses ISO as its filename encoding; but on platforms with UTF-8 encoding of filenames, transcoding is needed.

The function `iso_fopen_caseless` is used when Inform wants to cope well if the casing (upper vs. lower case, that is) in the filename might not be right. On a caseless-read filing system such as that of Mac OS X (default) or Windows, there is no issue. But for a cased filing system, we may need to provide something.

```
FILE *iso_fopen(char *pathname, char *usage) {
    char transcoded_pathname[2*MAX_FILENAME_LENGTH];
    transcode_ISO_string_to_locale(pathname, transcoded_pathname);
    return fopen(transcoded_pathname, usage);
}

FILE *iso_fopen_caseless(char *pathname, char *usage) {
    char transcoded_pathname[2*MAX_FILENAME_LENGTH];
    transcode_ISO_string_to_locale(pathname, transcoded_pathname);
    return ci_fopen(transcoded_pathname, usage);
}
```

The function iso_fopen is called from 2/strm, 2/dl, 3/read, 4/ext, 4/excen, 4/edict, 4/edoc, 10/ifid, 10/bib, 10/fig, 10/sfx and 14/i6t.

The function iso_fopen_caseless is called from 3/read and 4/excen.

§**11.** And the locale-dependent part is:

```
#ifdef LOCALE_IS_ISO
void transcode_ISO_string_to_locale(char *from, char *to) {
    strcpy(to, from);
}
#endif
#ifdef LOCALE_IS_UTF8
void transcode_ISO_string_to_locale(char *from, char *to) {
    transcode_ISO_string_to_UTF8(from, to);
}
#endif
```

The function transcode_ISO_string_to_locale is called from 2/files and 4/excen.

§**12.** Here we read a line from a file whose encoding is that of filenames in the locale. If the locale uses ISO, it's sufficient to call NI's standard `truncated_iso_fgets` instead: but for UTF-8 locales, we need the following.

These matters are beyond evil. In testing, I discovered, for instance, that under Mac OS X the leafname in a `dirent` would encode c-cedilla not as `E7` ("Latin Small Letter C With Cedilla") but as the sequence `63 0327` (lower case c, followed by "Combining Cedilla"); while this pointless digraph fed back into `fopen` would fail to match the original again, and this caused extensions whose names contained a c-cedilla to fail to be documented properly.

```
#ifdef LOCALE_IS_ISO
int truncated_locale_fgets(FILE *F, char *buffer, int limit) {
    return truncated_iso_fgets(F, buffer, limit);
}
#endif
#ifdef LOCALE_IS_UTF8
int truncated_locale_fgets(FILE *F, char *buffer, int limit) {
    int len=0, c;
    if (buffer == NULL) return -1;
    if (feof(F)) return -1;
    while ((c = utf8_fgetc(F, FALSE)) != EOF) {
        if (len >= limit) break;
        if ((c == '\x0a') || (c == '\x0d')) break;
        if ((c >= 0x0300) && (c <= 0x036F) && (len > 0))
            c = combining_accent(c, buffer[--len]);
        buffer[len++] = c;
    }
    buffer[len++] = 0;
    return len;
}
#endif
```

The function truncated_locale_fgets is called from 4/excen.

§**13.** That concludes the platform-specific material, and from here on NI contains no conditional compilations.

2 Memory, Files, Problems and Logs

`2/mem`: *Memory.w* To allocate memory suitable for the dynamic creation of objects of different sizes, placing some larger objects automatically into doubly linked lists and assigning each a unique allocation ID number.

`2/strm`: *Streams.w* Support for writing structured textual output, perhaps to the screen, to a file, or to a flexible-sized area of memory.

`2/files`: *Filenames.w* Given the different environments in which we might be running, and the large range of files we may need from within a project folder, it's useful to have a section of code simply to deduce filenames.

`2/cifn`: *Case-Insensitive Filenames.w* On some of the Unix-derived file systems on which Inform runs, filenames are case-sensitive, so that FISH and fish might be different files. This makes extension files, installed by the user, prone to being missed. The code in this section provides a routine to carry out file opening as if filenames are case-insensitive, and is used only for extensions.

`2/image`: *Image Dimensions.w* These utility routines, contributed by Toby Nelson, look at the headers of JPEG and PNG files to find the pixel dimensions of any images supplied by the user for cover art and figures.

`2/sounds`: *Sound Durations.w* These utility routines, again by Toby Nelson, look at the headers of AIFF and OGG files to find the durations, and verify that they are what they purport to be.

`2/isn`: *Make Inform 6 Names.w* To construct valid Inform 6 identifiers, dictionary word constants and double-quoted string constants as needed.

`2/lns`: *Inform 6 Labels.w* I7 is has no Dijkstra-like conscience about compiling code which is full of I6 `jump` statements, and these require labels to jump to. This section provides those labels, and other related unique-ID-number counters.

`2/html`: *HTML Files.w* To provide utilities for writing HTML files such as the problems report, the extension documentation, the index files and so forth.

`2/java`: *Javascript Pastes.w* To write valid HTML for a paste icon which, when clicked, calls a Javascript function which will paste Inform source text into the Source panel of the application.

`2/hdoc`: *HTML Documentation.w* To translate a passage of source text into HTML-format documentation, for use in the automatically generated documentation pages on each installed extension.

`2/index`: *Index File Services.w* To provide routines to help build the various HTML index files, none of which are actually created in this section.

`2/lexi`: *Lexicon Index.w* To construct the Lexicon portion of the Phrasebook page of the Index, which gives brief definitions and references for nouns, adjectives and verbs used in source text for the current project.

`2/prog`: *Progress Percentages.w* This tiny section, the Lichtenstein of Inform, prints percentage of completion estimates onto `stderr` so that the host application can intercept them and update its graphical progress bar.

`2/prob0`: *Problems, Level 0.w* To handle fatal errors.

`2/prob1`: *Problems, Level 1.w* To render problem messages either as plain text or HTML, and write them out to files.

`2/prob2`: *Problems, Level 2.w* To assemble and format problem messages within the problem buffer.

`2/prob3`: *Problems, Level 3.w* Here we provide some convenient semi-standardised problem messages, which also serve as examples of how to use the Level 2 problem message routines.

`2/dl`: *Debugging Log.w* To write to the debugging log, a plain text file which traces what NI is doing, in order to assist those lost souls debugging it.

Memory 2/mem

Purpose

To allocate memory suitable for the dynamic creation of objects of different sizes, placing some larger objects automatically into doubly linked lists and assigning each a unique allocation ID number.

Template interpreter commands

```
2   {-callv:start_memory}
10   {-callv:free_memory}
34   {-callv:debug_memory_statistics}
```

Definitions

¶1. Statistics about Inform's memory usage change a little with each build, but in February 2009 it needed around 23 MB of memory to compile the medium-sized finished work "Bronze", which has a slightly over 40,000-word source text. Of that memory, about one-third was used by a small number of large buffers allocated as needed – what Inform calls "simple memory allocations". (Almost all of that space was needed by the lexer, to store the source text itself and its analysis; the other simple memory allocations were tiny by comparison.) The remaining two-thirds of memory consisted of some 357,285 objects of 112 different types and sizes. Like the chemical elements, these have very different natural abundances – the three most abundant being `specification`, `phrase` and `invocation`, each accounting for about 9% of Inform's memory, while the rarest 56 types accounted for less than 0.1% of memory each.

Our memory system is convenient and also, with luck, reduces errors due to wrongly implementing standard things like object creation and forming linked lists: but there is a price to pay. Safety measures such as the firebreaks of 0s between objects, together with the granularity of block sizes allocated, make an overhead of about 11%, that is, the total number of bytes allocated is 11% higher because of them. Similarly, profiling suggests that the processor spends about 5% of its time in the routines below. I think this is an acceptable bargain. (It's hard to know what is considered good practice, because nowadays memory allocation is often automatic so that programmers wrongly think of it as instantaneous, but for comparison, Knuth notes at section 114 of *TEX: the Program* that TEX spends 9% of its time allocating memory, and 6% deallocating it.)

¶2. The objects we allocate in memory come in two forms: managed and unmanaged. Managed structures, generally the larger ones with longer-term importance, are automatically placed into a doubly-linked list for each type, and are given unique "allocation ID numbers" (within that type) counting upwards from 0. Macros are provided for efficient looping forwards or backwards through the objects in existence.

Unmanaged structures, generally smaller ones or with shorter-term importance, are simply provided on request. They can't be looped over and have no IDs.

As is inevitable, managed structures take up slightly more memory, and take slightly more time to create. Every structure needing to be managed will have to have extra elements holding the necessary links and ID number. We define these elements with a macro (concealing its meaning from all other sections):

```
define MEMORY_MANAGEMENT
    int allocation_id;                    Numbered from 0 upwards in creation order
    void *next_structure;                 Next object in double-linked list
    void *prev_structure;                 Previous object in double-linked list
```

¶3. As an immediate example, we will hold details of our "simple memory allocations" within `simple_memory_claim` objects. We do this in order to make sure that anything we request from the operating system using `malloc` and `calloc` is eventually given back with `free`. The book-keeping for that requires the following tiny structure:

```
typedef struct simple_memory_claim {
    void *memory_claimed;                    position in memory of the array allocated
    int extent_of_claim;                     total number of bytes making it up
    MEMORY_MANAGEMENT
} simple_memory_claim;
```

The structure simple_memory_claim is private to this section.

¶4. Now to enumerate the "memory types" of objects, each corresponding to a different C structure defined by a `typedef` somewhere in Inform's source code. There is no significance to the order in which structures are registered with the memory system, but `NO_MEMORY_TYPES` must be 1 more than the highest MT number, so *do not add to this list without incrementing it*. There can in principle be up to 1000 memory types.

If a structure – say, `whatsit` – is to be managed, we should define the constant `whatsit_MT`, and if not we should define `whatsit_array_MT`.

§**1. Allocation status.** For each type of object to be allocated, a single structure of the following design is maintained. Managed types have `no_allocated_together` set to 1, and the doubly linked list is of the objects themselves. Unmanaged types are allocated in small arrays, typically of 100 objects at a time: in that case `no_allocated_together` is set to the number of objects in each completed array (so, typically 100) and the doubly linked list is of the arrays. (Inform handles an unmanaged structure `whatsit` by handling a managed structure of its own devising, `whatsit_array`, which consists of arrays of `whatsit`.)

```
typedef struct allocation_status_structure {
    actually needed for allocation purposes:
    int objects_allocated;                    total number of objects (or arrays) ever allocated
    void *first_in_memory;                    head of doubly linked list
    void *last_in_memory;                     tail of doubly linked list
    used only to provide statistics for the debugging log:
    char *name_of_type;                       e.g., "lexicon_entry_MT"
    int bytes_allocated;                      total allocation for this type of object, not counting overhead
    int objects_count;                        total number currently in existence (i.e., undeleted)
    int no_allocated_together;                number of objects in each array of this type of object
} allocation_status_structure;
```

The structure allocation_status_structure is private to this section.

§**2.** The memory allocator itself needs some memory, but only a fixed-size and fairly small array of the structures defined above. The allocator can safely begin as soon as this is initialised.

```
allocation_status_structure alloc_status[NO_MEMORY_TYPES];

void start_memory(void) {
    int i;
    for (i=0; i<NO_MEMORY_TYPES; i++) {
        alloc_status[i].first_in_memory = NULL;
        alloc_status[i].last_in_memory = NULL;
        alloc_status[i].objects_allocated = 0;
        alloc_status[i].objects_count = 0;
        alloc_status[i].bytes_allocated = 0;
        alloc_status[i].no_allocated_together = 1;
        alloc_status[i].name_of_type = "unused";
    }
}
```

The function start_memory is invoked by a command in a `.i6t` template file.

§**3. Architecture.** The memory manager is built in three levels, with its interface to the rest of Inform being entirely at level 3 (except that when Inform shuts down it calls a level 1 routine to free everything). Each level uses the one below it.

(3) Managing linked lists of large objects, within which objects can be created at any point, and from which objects can be deleted; and providing a way to create new small objects of any given type.
(2) Allocating some thousands of memory frames, each holding one large object or an array of small objects.
(1) Allocating and freeing a few dozen large blocks of contiguous memory.

§**4. Level 1: memory blocks.** Memory is allocated in blocks, within which objects are allocated as needed. The "safety margin" is the number of spare bytes left blank at the end of each object: this is done because we want to be paranoid about compilers on different architectures aligning structures to different boundaries (multiples of 4, 8, 16, etc.). Each block also ends with a firebreak of zeroes, which ought never to be touched: we want to minimise the chance of a mistake causing a memory exception which crashes the compiler, because if that happens it will be difficult to recover the circumstances from the debugging log.

```
define SAFETY_MARGIN 32
define BLANK_END_SIZE 128
```

§**5.** At present `MEMORY_GRANULARITY` is 200K on 32-bit CPUs, or 400K on 64-bit ones. This is the quantity of memory allocated by each individual `malloc` call.

After `MAX_BLOCKS_ALLOWED` blocks, we throw in the towel: Inform must have fallen into an endless loop which creates endless new objects somewhere. (If this ever happens, it would be a bug in Inform, I hasten to say: the point of this mechanism is to be able to recover. Without this safety measure, OS X in particular would grind slowly to a halt, never refusing a `malloc`, until the user was unable to get the GUI responsive enough to kill the Inform process.) The threshold is just under 2GB for 32-bit platforms, since more than that is probably impossible to handle in a 32-bit address space in any event. The actual record memory usage ever recorded for a genuine Inform project is 250MB, but that was before reworking of Inform's data structures reduced memory consumption by a factor of three. So the threshold is high enough that it won't be reached. In February 2009, "Bronze" used 81 blocks.

```
define MAX_BLOCKS_ALLOWED 10000
define MEMORY_GRANULARITY 200*1024*CPU_WORDSIZE_MULTIPLIER        which must be divisible by 1024

int no_blocks_allocated = 0;
int no_frames_allocated = 0;                                      a much larger number, used only for the debugging log
```

§**6.** Memory blocks are stored in a linked list, and we keep track of the size of the current block: that is, the block at the tail of the list. Each memory block consists of a header structure, followed by `SAFETY_MARGIN` null bytes, followed by actual data.

```
typedef struct memblock_header {
    int block_number;
    struct memblock_header *next;
    char *the_memory;
} memblock_header;
memblock_header *first_memblock_header = NULL;                    head of list of memory blocks
memblock_header *current_memblock_header = NULL;                  tail of list of memory blocks
int used_in_current_memblock = 0;                  number of bytes so far used in the tail memory block
```

The structure memblock_header is private to this section.

§**7.** The actual allocation and deallocation is performed by the following pair of routines.

```
void allocate_another_block(void) {
    unsigned char *cp;
    memblock_header *mh;
    ⟨Allocate and zero out a block of memory, making cp point to it 8⟩;
    mh = (memblock_header *) cp;
    used_in_current_memblock = sizeof(memblock_header) + SAFETY_MARGIN;
    mh->the_memory = (void *) (cp + used_in_current_memblock);
    ⟨Add new block to the tail of the list of memory blocks 9⟩;
    LOGIF(MEMORY_ALLOCATION, "AOB->the_memory: %08x\n", (pointer_sized_int) mh->the_memory);
}
```

§**8.** Note that `cp` and `mh` are set to the same value: they merely have different pointer types as far as the C compiler is concerned.

⟨Allocate and zero out a block of memory, making cp point to it 8⟩ ≡

```
    int i;
    if (no_blocks_allocated++ >= MAX_BLOCKS_ALLOWED)
        internal_error(
            "the memory manager has halted Inform, which seems to be generating "
            "endless structures. Presumably it is trapped in a loop");
    check_memory_integrity();
    LOGIF(MEMORY_ALLOCATION, "Allocating memory block %d (total objects now %d)\n",
        no_blocks_allocated, no_frames_allocated);
    cp = (unsigned char *) (malloc(MEMORY_GRANULARITY));
    if (cp == NULL) fatal_error("Run out of memory: malloc failed");
    LOGIF(MEMORY_ALLOCATION, "AOB: %08x to %08x\n",
        (pointer_sized_int) cp, (pointer_sized_int) cp+MEMORY_GRANULARITY);
    for (i=0; i<MEMORY_GRANULARITY; i++) cp[i] = 0;
```

This code is used in §7.

§**9.** As can be seen, memory block numbers count upwards from 0 in order of their allocation.

⟨Add new block to the tail of the list of memory blocks 9⟩ ≡
```
    if (current_memblock_header == NULL) {
        mh->block_number = 0;
        first_memblock_header = mh;
    } else {
        mh->block_number = current_memblock_header->block_number + 1;
        current_memblock_header->next = mh;
    }
    current_memblock_header = mh;
```

This code is used in §7.

§**10.** Freeing all this memory again is just a matter of freeing each block in turn, but of course being careful to avoid following links in a just-freed block.

```
void free_memory(void) {
    I7_free_all_remaining();
    memblock_header *mh = first_memblock_header;
    while (mh != NULL) {
        memblock_header *next_mh = mh->next;
        void *p = (void *) mh;
        free(p);
        mh = next_mh;
    }
}
```

The function free_memory is invoked by a command in a `.i6t` template file.

§**11. Level 2: memory frames and integrity checking.** Within these extensive blocks of contiguous memory, we place the actual objects in between "memory frames", which are only used at present to police the integrity of memory: again, finding obscure and irritating memory-corruption bugs is more important to us than saving bytes. Each memory frame wraps either a single large object, or a single array of small objects.

In February 2009, "Bronze" used around 48,000 memory frames.

```
define INTEGRITY_NUMBER 0x12345678                    a value unlikely to be in memory just by chance

typedef struct memory_frame {
    int integrity_check;                              this should always contain the INTEGRITY_NUMBER
    struct memory_frame *next_frame;                  next frame in the list of memory frames
    int mem_type;                                     type of object stored in this frame
    int allocation_id;                                allocation ID number of object stored in this frame
} memory_frame;
```

The structure memory_frame is private to this section.

§**12.** There is a single linked list of all the memory frames, perhaps of about 10000 entries in length, beginning here. (These frames live in different memory blocks, but we don't need to worry about that.)

```
memory_frame *first_memory_frame = NULL;              earliest memory frame ever allocated
memory_frame *last_memory_frame = NULL;               most recent memory frame allocated
```

§**13.** If the integrity numbers of every frame are still intact, then it is pretty unlikely that any bug has caused memory to overwrite one frame into another. `check_memory_integrity` might on very large runs be run often, if we didn't prevent this: since the number of calls would be roughly proportional to memory usage, we would implicitly have an $O(n^2)$ running time in the amount of storage n allocated.

```
int calls_to_cmi = 0;
void check_memory_integrity(void) {
    int c = calls_to_cmi++;
    if (!((c<10) || (c == 100) || (c == 1000) || (c == 10000))) return;
    LOGIF(MEMORY_ALLOCATION, "Beginning memory integrity check: ");
    memory_frame *mf;
    for (c = 0, mf = first_memory_frame; mf; c++, mf = mf->next_frame)
        if (mf->integrity_check != INTEGRITY_NUMBER) {
            LOG("*** Memory integrity check failed. Recent frames: ***\n");
            debug_memory_frames(c-20, c-1);
            internal_error("Memory manager failed integrity check");
        }
    LOGIF(MEMORY_ALLOCATION, "*** Succeeded ***\n");
}
void debug_memory_frames(int from, int to) {
    int c;
    memory_frame *mf;
    for (c = 0, mf = first_memory_frame; (mf) && (c <= to); c++, mf = mf->next_frame)
        if (c >= from) {
            char *desc = "corrupt";
            if (mf->integrity_check == INTEGRITY_NUMBER)
                desc = alloc_status[mf->mem_type].name_of_type;
            LOG("Frame at %08x: '%s'/%d\n",
                (pointer_sized_int) mf, desc, mf->allocation_id);
        }
}
```

§**14.** We have seen how memory is allocated in large blocks, and that a linked list of memory frames will live inside those blocks; we have seen how the list is checked for integrity; but we not seen how it is built. Every memory frame is created by the following function:

```
void *allocate_mem(int mem_type, int extent) {
    unsigned char *cp;
    memory_frame *mf;
    int bytes_free_in_current_memblock, extent_without_overheads = extent;
    extent += sizeof(memory_frame);                    each allocation is preceded by a memory frame
    extent += SAFETY_MARGIN;                           each allocation is followed by SAFETY_MARGIN null bytes
    ⟨Ensure that the current memory block has room for this many bytes 15⟩;
    cp = ((unsigned char *) (current_memblock_header->the_memory)) + used_in_current_memblock;
    used_in_current_memblock += extent;
    mf = (memory_frame *) cp;                                                the new memory frame,
    cp = cp + sizeof(memory_frame);                                  following which is the actual allocated data
    mf->integrity_check = INTEGRITY_NUMBER;
    mf->allocation_id = alloc_status[mem_type].objects_allocated;
    mf->mem_type = mem_type;
```

```
    ⟨Add the new memory frame to the big linked list of all frames 16⟩;
    ⟨Update the allocation status for this type of object 17⟩;
    no_frames_allocated++;
    return (void *) cp;
}
```

§**15.** The granularity error below will be triggered the first time a particular object type is allocated: if the Inform test suite passes on a given platform, then the granularity error can never occur. So this is not a potential time-bomb just waiting for a user with a particularly long and involved source text to discover. (It has only exploded once in Inform's development: when Inform was ported to 64-bit processors in November 2007, which greatly increased `sizeof` for many structures. This is why the granularity is now defined with a factor allowing for larger word-size CPUs.)

⟨Ensure that the current memory block has room for this many bytes 15⟩ ≡

```
    if (current_memblock_header == NULL) allocate_another_block();
    bytes_free_in_current_memblock = MEMORY_GRANULARITY - (used_in_current_memblock + extent);
    if (bytes_free_in_current_memblock < BLANK_END_SIZE) {
        allocate_another_block();
        if (extent+BLANK_END_SIZE >= MEMORY_GRANULARITY)
            fatal_error("Memory manager failed because granularity too low");
    }
```

This code is used in §14.

§**16.** New memory frames are added to the tail of the list:

⟨Add the new memory frame to the big linked list of all frames 16⟩ ≡

```
    mf->next_frame = NULL;
    if (first_memory_frame == NULL) first_memory_frame = mf;
    else last_memory_frame->next_frame = mf;
    last_memory_frame = mf;
```

This code is used in §14.

§**17.** See the definition of `alloc_status` above.

⟨Update the allocation status for this type of object 17⟩ ≡

```
    if (alloc_status[mem_type].first_in_memory == NULL)
        alloc_status[mem_type].first_in_memory = (void *) cp;
    alloc_status[mem_type].last_in_memory = (void *) cp;
    alloc_status[mem_type].objects_allocated++;
    alloc_status[mem_type].bytes_allocated += extent_without_overheads;
```

This code is used in §14.

§**18. Level 3: managing linked lists of allocated objects.** We define macros which look as if they are functions, but for which one argument is the name of a type: expanding these macros provides suitable C functions to handle each possible type. These macros provide the interface through which all other sections of Inform allocate and leaf through memory.

Note that `inweb` allows multi-line macro definitions without backslashes to continue them, unlike ordinary C. Otherwise these are "standard" macros, though this was my first brush with the `##` concatenation operator: basically `CREATE(thing)` expands into `(allocate_thing())` because of the `##`. (See Kernighan and Ritchie, section 4.11.2.)

```
define CREATE(type_name) (allocate_##type_name())
define CREATE_BEFORE(existing, type_name) (allocate_##type_name##_before(existing))
define DESTROY(this, type_name) (deallocate_##type_name(this))
define FIRST_OBJECT(type_name) ((type_name *) alloc_status[type_name##_MT].first_in_memory)
define LAST_OBJECT(type_name) ((type_name *) alloc_status[type_name##_MT].last_in_memory)
define NEXT_OBJECT(this, type_name) ((type_name *) (this->next_structure))
define PREV_OBJECT(this, type_name) ((type_name *) (this->prev_structure))
define NUMBER_CREATED(type_name) (alloc_status[type_name##_MT].objects_count)
```

§**19.** The following macros are widely used (well, the first one is, anyway) for looking through the double linked list of existing objects of a given type.

```
define LOOP_OVER(var, type_name)
    for (var=FIRST_OBJECT(type_name); var != NULL; var = NEXT_OBJECT(var, type_name))
define LOOP_OVER_FROM(var, type_name, start)
    for (var=(start)?start:(FIRST_OBJECT(type_name)); var != NULL; var = NEXT_OBJECT(var, type_name))
define LOOP_BACKWARDS_OVER(var, type_name)
    for (var=LAST_OBJECT(type_name); var != NULL; var = PREV_OBJECT(var, type_name))
```

§**20. Allocator functions created by macros.** The following macros generate a family of systematically named functions. For instance, we shall shortly expand `ALLOCATE_INDIVIDUALLY(parse_node)`, which will expand to three functions: `allocate_parse_node`, `deallocate_parse_node` and `allocate_parse_node_before`.

Quaintly, `#type_name` expands into the value of `type_name` put within double-quotes.

```
define NEW_OBJECT(type_name) ((type_name *) allocate_mem(type_name##_MT, sizeof(type_name)))
define ALLOCATE_INDIVIDUALLY(type_name)
MAKE_REFERENCE_ROUTINES(type_name, type_name##_MT)
type_name *allocate_##type_name(void) {
    alloc_status[type_name##_MT].name_of_type = #type_name;
    type_name *prev_obj = LAST_OBJECT(type_name);
    type_name *new_obj = NEW_OBJECT(type_name);
    new_obj->allocation_id = alloc_status[type_name##_MT].objects_allocated-1;
    new_obj->next_structure = NULL;
    if (prev_obj != NULL)
        prev_obj->next_structure = (void *) new_obj;
    new_obj->prev_structure = prev_obj;
    alloc_status[type_name##_MT].objects_count++;
    return new_obj;
}
void deallocate_##type_name(type_name *kill_me) {
    type_name *prev_obj = PREV_OBJECT(kill_me, type_name);
    type_name *next_obj = NEXT_OBJECT(kill_me, type_name);
    if (prev_obj == NULL) {
```

```
        alloc_status[type_name##_MT].first_in_memory = next_obj;
    } else {
        prev_obj->next_structure = next_obj;
    }
    if (next_obj == NULL) {
        alloc_status[type_name##_MT].last_in_memory = prev_obj;
    } else {
        next_obj->prev_structure = prev_obj;
    }
    alloc_status[type_name##_MT].objects_count--;
}
type_name *allocate_##type_name##_before(type_name *existing) {
    type_name *new_obj = allocate_##type_name();
    deallocate_##type_name(new_obj);
    new_obj->prev_structure = existing->prev_structure;
    if (existing->prev_structure != NULL)
        ((type_name *) existing->prev_structure)->next_structure = new_obj;
    else alloc_status[type_name##_MT].first_in_memory = (void *) new_obj;
    new_obj->next_structure = existing;
    existing->prev_structure = new_obj;
    alloc_status[type_name##_MT].objects_count++;
    return new_obj;
}
```

§**21.** `ALLOCATE_IN_ARRAYS` is still more obfuscated. When we `ALLOCATE_IN_ARRAYS(X, 100)`, the result will be definitions of a new type `X_block` and functions `allocate_X`, `allocate_X_block`, `deallocate_X_block` and `allocate_X_block_before` (though the last is not destined ever to be used). Note that we are not provided with the means to deallocate individual objects this time: that's the trade-off for allocating in blocks.

```
define ALLOCATE_IN_ARRAYS(type_name, NO_TO_ALLOCATE_TOGETHER)
MAKE_REFERENCE_ROUTINES(type_name, type_name##_array_MT)
typedef struct type_name##_array {
    int used;
    struct type_name array[NO_TO_ALLOCATE_TOGETHER];
    MEMORY_MANAGEMENT
} type_name##_array;
ALLOCATE_INDIVIDUALLY(type_name##_array)
type_name##_array *next_##type_name##_array = NULL;
struct type_name *allocate_##type_name(void) {
    if ((next_##type_name##_array == NULL) ||
        (next_##type_name##_array->used >= NO_TO_ALLOCATE_TOGETHER)) {
        alloc_status[type_name##_array_MT].no_allocated_together = NO_TO_ALLOCATE_TOGETHER;
        next_##type_name##_array = allocate_##type_name##_array();
        next_##type_name##_array->used = 0;
    }
    return &(next_##type_name##_array->array[
        next_##type_name##_array->used++]);
}
```

The structure type_name##_array is private to this section.

§**22. Expanding many macros.** Each given structure must have a typedef name, say `marvel`, and can be used in one of two ways. Either way, we can obtain a new one with the macro `CREATE(marvel)`.

Either (a) it will be individually allocated. In this case `marvel_MT` should be defined with a new MT (memory type) number, and the macro `ALLOCATE_INDIVIDUALLY(marvel)` should be expanded. The first and last objects created will be `FIRST_OBJECT(marvel)` and `LAST_OBJECT(marvel)`, and we can proceed either way through a double linked list of them with `PREV_OBJECT(mv, marvel)` and `NEXT_OBJECT(mv, marvel)`. For convenience, we can loop through marvels, in creation order, using `LOOP_OVER(var, marvel)`, which expands to a `for` loop in which the variable `var` runs through each created marvel in turn; or equally we can run backwards through using `LOOP_BACKWARDS_OVER(var, marvel)`. In addition, there are corruption checks to protect the memory from overrunning accidents, and the structure can be used as a value in the symbols table.

Or (b) it will be allocated in arrays. Once again we can obtain new marvels with `CREATE(marvel)`. This is more efficient both in speed and memory usage, but we lose the ability to loop through the objects. For this arrangement, define `marvel_array_MT` with a new MT number and expand the macro `ALLOCATE_IN_ARRAYS(marvel, 100)`, where 100 (or what may you) is the number of objects allocated jointly as a block.

Deep breath, then: the following macros define several hundred functions.

```
ALLOCATE_INDIVIDUALLY(action_name)

```

§**24. Simple memory allocations.** Not all of our memory will be claimed in the form of structures: now and then we need to use the equivalent of traditional `malloc` and `calloc` routines.

```
define EXTENSION_DICTIONARY_MREASON 0
define INDEX_SORTING_MREASON 1
define INSTANCE_COUNTING_MREASON 2
define LEXER_TEXT_MREASON 3
define LEXER_WORDS_MREASON 4
define MAP_INDEX_MREASON 5
define PARTITION_MREASON 6
define STREAM_MREASON 7
define TYPE_TABLES_MREASON 8
define INV_LIST_MREASON 9
define NUMBER_OF_MREASONS 10

char *memory_needs[NUMBER_OF_MREASONS] = {
    "extension dictionary",
    "index sorting",
    "instance-of-kind counting",
    "source text",
    "source text details",
    "map in the World index",
    "initial state for relations in groups",
    "internal text-handling",
    "tables of details of the kinds of values",
    "lists for type-checking invocations"
};
```

§**25.** We keep some statistics on this. The value for "memory claimed" is the net amount of memory currently owned, which is increased when we allocate it and decreased when we free it. Whether the host OS is able to make efficient use of the memory we free, we can't know, but it probably is, and therefore the best estimate of how well we're doing is the "maximum memory claimed" – the highest recorded net usage count over Inform's run.

```
int max_memory_at_once_for_each_need[NUMBER_OF_MREASONS],
    memory_claimed_for_each_need[NUMBER_OF_MREASONS],
    number_of_claims_for_each_need[NUMBER_OF_MREASONS];
int total_claimed_simply = 0;
```

§**26.** Our allocation routines behave just like the standard C library's `malloc` and `calloc`, but where a third argument supplies a reason why the memory is needed, and where any failure to allocate memory is tidily dealt with. Inform exits on any such failure, so that the caller can be certain that the return values of these functions are always non-`NULL` pointers.

```
void *I7_calloc(int how_many, int size_in_bytes, int reason) {
    return I7_alloc(how_many, size_in_bytes, reason);
}
void *I7_malloc(int size_in_bytes, int reason) {
    return I7_alloc(-1, size_in_bytes, reason);
}
```

The function I7_calloc is called from 3/lex, 4/edict, 4/vm, 5/rel, 7/tids, 7/inv, 9/cot, 9/map, 9/tmap and 11/ina.
The function I7_malloc is called from 2/strm and 3/lex.

§**27.** And this, then, is the joint routine implementing both.

```
void *I7_alloc(int N, int S, int R) {
    void *pointer;
    int bytes_needed;
    if ((R < 0) || (R >= NUMBER_OF_MREASONS)) internal_error("no such memory reason");
    if (total_claimed_simply == 0) ⟨Zero out the statistics on simple memory allocations 29⟩;
    ⟨Claim the memory using malloc or calloc as appropriate 28⟩;
    ⟨Update the statistics on simple memory allocations 30⟩;
    simple_memory_claim *smc = CREATE(simple_memory_claim);
    smc->memory_claimed = pointer;
    smc->extent_of_claim = bytes_needed;
    return pointer;
}
```

§**28.** I am nervous about assuming that `calloc(0, X)` returns a non-`NULL` pointer in all implementations of the standard C library, so the case when `N` is zero allocates a tiny but positive amount of memory, just to be safe.

⟨Claim the memory using malloc or calloc as appropriate 28⟩ ≡

```
    if (N > 0) {
        pointer = calloc(N, S);
        bytes_needed = N*S;
    } else {
        pointer = malloc(S);
        bytes_needed = S;
    }
    if (pointer == NULL)
        memory_allocation_problem(_P_(BelievedImpossible),                    i.e., not reliably testable
            memory_needs[R]);
```

This code is used in §27.

§**29.** These statistics have no function except to improve the diagnostics in the debugging log, but they are very cheap to keep, since `I7_alloc` is called only rarely and to allocate large blocks of memory.

⟨Zero out the statistics on simple memory allocations 29⟩ ≡

```
    int i;
    for (i=0; i<NUMBER_OF_MREASONS; i++) {
        max_memory_at_once_for_each_need[i] = 0;
        memory_claimed_for_each_need[i] = 0;
        number_of_claims_for_each_need[i] = 0;
    }
```

This code is used in §27.

§**30.**

⟨Update the statistics on simple memory allocations 30⟩ ≡

```
memory_claimed_for_each_need[R] += bytes_needed;
total_claimed_simply += bytes_needed;
number_of_claims_for_each_need[R]++;
if (memory_claimed_for_each_need[R] > max_memory_at_once_for_each_need[R])
    max_memory_at_once_for_each_need[R] = memory_claimed_for_each_need[R];
```

This code is used in §27.

§**31.** We also provide our own wrapper for `free`. This looks as if it might be a little slow, since it has to loop through all of the SMC objects to find the right one. But note that SMC objects are removed from the SMC linked list using `DESTROY` when the memory in question is freed; that means there are typically fewer than 10 in the domain of `LOOP_OVER` at any one time.

```
void I7_free(void *pointer, int R) {
    if ((R < 0) || (R >= NUMBER_OF_MREASONS)) internal_error("no such memory reason");
    if (pointer == NULL) internal_error("can't free NULL memory");
    simple_memory_claim *smc;
    LOOP_OVER(smc, simple_memory_claim)
        if (smc->memory_claimed == pointer) {
            free(pointer);
            memory_claimed_for_each_need[R] -= smc->extent_of_claim;
            total_claimed_simply -= smc->extent_of_claim;
            DESTROY(smc, simple_memory_claim);
            return;
        }
    internal_error("can't free this memory, which is not now allocated");
}
```

The function I7_free is called from 2/strm, 3/lex, 4/edict, 4/vm, 7/tids, 9/tmap and 11/ina.

§**32.** Some parts of Inform have no convenient way to deallocate their own memory – notably the lexer, when it calls for extensions to its workspace. At the end of the run, then, we call the following, which frees whatever has not already been freed. We don't bother to `DESTROY` them, since the SMC object list will never be used again.

```
void I7_free_all_remaining(void) {
    simple_memory_claim *smc;
    LOOP_OVER(smc, simple_memory_claim) {
        free (smc->memory_claimed);
        total_claimed_simply -= smc->extent_of_claim;
    }
    if (total_claimed_simply != 0)
        internal_error("memory not freed exactly correctly");
}
```

§**33.** And the following provides statistics, and a mini-report, for the memory report in the debugging log (for which, see below).

```
int log_I7_alloc_usage(int total) {
    if (total_claimed_simply == 0) return 0;
    int i, t = 0;
    for (i=0; i<NUMBER_OF_MREASONS; i++) {
        t += max_memory_at_once_for_each_need[i];
        if (total > 0)
            LOG("0.%03d: %s - %d bytes in %d claim(s)\n",
                memory_proportion(max_memory_at_once_for_each_need[i], total),
                memory_needs[i],
                max_memory_at_once_for_each_need[i],
                number_of_claims_for_each_need[i]);
    }
    return t;
}
```

§**34. Memory usage report.** A small utility routine to help keep track of Inform's unquestioned profligacy.

```
void debug_memory_statistics(void) {
    int total_for_objects = MEMORY_GRANULARITY*no_blocks_allocated;                    usage in bytes
    int total_for_SMAs = log_I7_alloc_usage(0);                                        usage in bytes
    int sorted_usage[NO_MEMORY_TYPES];                                  memory type numbers, in usage order
    int total = (total_for_objects + total_for_SMAs)/1024;                          total memory usage in KB
    ⟨Sort the table of memory type usages into decreasing size order 36⟩;
    int total_for_objects_used = 0;                          out of the total_for_objects, the bytes used
    int total_objects = 0;
    ⟨Calculate the memory usage for objects 35⟩;
    int overhead_for_objects = total_for_objects - total_for_objects_used;                bytes wasted
    ⟨Print the report to the debugging log 37⟩;
}
```

The function debug_memory_statistics is invoked by a command in a `.i6t` template file.

§**35.**

⟨Calculate the memory usage for objects 35⟩ ≡

```
    int i, j;
    for (j=0; j<NO_MEMORY_TYPES; j++) {
        i = sorted_usage[j];
        if (alloc_status[i].objects_allocated != 0) {
            if (alloc_status[i].no_allocated_together == 1)
                total_objects += alloc_status[i].objects_allocated;
            else
                total_objects += alloc_status[i].objects_allocated*
                                 alloc_status[i].no_allocated_together;
            total_for_objects_used += alloc_status[i].bytes_allocated;
        }
    }
```

This code is used in §34.

§**36.** This is the criterion for sorting memory types in the report: descending order of total number of bytes allocated.

⟨Sort the table of memory type usages into decreasing size order 36⟩ ≡

```
int i;
for (i=0; i<NO_MEMORY_TYPES; i++) sorted_usage[i] = i;
qsort(sorted_usage, NO_MEMORY_TYPES, sizeof(int), compare_usage_entries);
```

This code is used in §34.

§**37.** And here is the actual report:

⟨Print the report to the debugging log 37⟩ ≡

```
LOG("\nReport by memory manager:\n\n");
LOG("Total consumption was %dK = %dMB, divided up in the following proportions:\n",
    total, (total+512)/1024);
LOG("0.%03d: %d objects in %d frames in %d memory blocks (of %dK each):\n",
    memory_proportion(total_for_objects, total),
    total_objects, no_frames_allocated, no_blocks_allocated, MEMORY_GRANULARITY/1024);
LOG("    0.%03d: memory manager overhead - %d bytes\n",
    memory_proportion(overhead_for_objects, total), overhead_for_objects);
int i, j;
for (j=0; j<NO_MEMORY_TYPES; j++) {
    i = sorted_usage[j];
    if (alloc_status[i].objects_allocated != 0) {
        LOG("    0.%03d: %s  -  ",
            memory_proportion(alloc_status[i].bytes_allocated, total),
            alloc_status[i].name_of_type);
        if (alloc_status[i].no_allocated_together == 1) {
            LOG("%d ", alloc_status[i].objects_count);
            if (alloc_status[i].objects_count != alloc_status[i].objects_allocated)
                LOG("(+%d deleted) ",
                    alloc_status[i].objects_allocated - alloc_status[i].objects_count);
        } else LOG("%d blocks of %d = %d ",
            alloc_status[i].objects_allocated, alloc_status[i].no_allocated_together,
            alloc_status[i].objects_allocated*alloc_status[i].no_allocated_together);
        LOG("objects, %d bytes\n", alloc_status[i].bytes_allocated);
    }
}
log_I7_alloc_usage(total);
LOG("\nNOTES:\nSpecifications: %d created, %d copies made\n",
    new_spec_count, copied_spec_count);
LOG("Permanent MLs: %d; Ephemeral MLs: %d; GAP movements: %d\n",
    no_permanent_MLs, no_ephemeral_MLs, GAP_movements);
LOG("Created %d kovas, %d kovkos, %d kovivs, %d kovcons\n",
    no_kovas_created, no_kovkos_created, no_kovivs_created, no_kovcons_created);
```

This code is used in §34.

§**38.**

```
int compare_usage_entries(const void *ent1, const void *ent2) {
    int ix1 = *((const int *) ent1);
    int ix2 = *((const int *) ent2);
    return alloc_status[ix2].bytes_allocated - alloc_status[ix1].bytes_allocated;
}
```

§**39.** Finally, a little routine to compute the proportions of memory for each usage. Recall that `bytes` is measured in bytes, but `total` in kilobytes.

```
int memory_proportion(int bytes, int total) {
    float B = (float) bytes, T = (float) total;
    float P = (1000*B)/(1024*T);
    return (int) P;
}
```

§**40. Run-time pointer type checking.** In several places Inform needs to store pointers of type `void *`, that is, pointers which have no indication of what type of data they point to. This is not type-safe and therefore offers plenty of opportunity for blunders. The following provides run-time type checking to ensure that each time we dereference a typeless pointer, it does indeed point to a structure of the type we think it should.

The structure `general_pointer` holds a `void *` pointer to any one of the following:

(a) `NULL`, to which we assign ID number -1;
(b) `char`, to which we assign ID number 1000;
(c) any individually allocated structure of the types listed above, to which we assign the ID numbers used above: for instance, `blorb_figure_MT` is the ID number for a `general_pointer` which points to a `blorb_figure` structure.

define `NULL_GENERAL_POINTER (STORE_POINTER_NULL())`

```
typedef struct general_pointer {
    void *pointer_to_data;
    int run_time_type_code;
} general_pointer;

general_pointer STORE_POINTER_NULL(void) {
    general_pointer gp;
    gp.pointer_to_data = NULL;
    gp.run_time_type_code = -1;                    guaranteed to differ from all _MT values
    return gp;
}
int GENERAL_POINTER_IS_NULL(general_pointer gp) {
    if (gp.run_time_type_code == -1) return TRUE;
    return FALSE;
}
```

The function GENERAL_POINTER_IS_NULL is called from 6/tcpr.
The structure general_pointer is private to this section.

§**41.** The symbols tables need to look at pointer values directly without knowing their types, but only to test equality, so we abstract that thus. And the debugging log also shows actual hexadecimal addresses to distinguish nameless objects and to help with interpreting output from GDB, so we abstract that too.

```
define COMPARE_GENERAL_POINTERS(gp1, gp2)
    (gp1.pointer_to_data == gp2.pointer_to_data)
define GENERAL_POINTER_AS_INT(gp)
    ((pointer_sized_int) gp.pointer_to_data)
```

§**42.** If we have a pointer to `circus` (say) then `g=STORE_POINTER_circus(p)` returns a `general_pointer` with `p` as the actual pointer, but will not compile unless `p` is indeed of type `circus *`. When we later `RETRIEVE_POINTER_circus(g)`, an internal error is thrown if `g` contains a pointer which is other than `void *`, or which has never been referenced.

```
define MAKE_REFERENCE_ROUTINES(type_name, id_code)
general_pointer STORE_POINTER_##type_name(type_name *data) {
    general_pointer gp;
    gp.pointer_to_data = (void *) data;
    gp.run_time_type_code = id_code;
    return gp;
}
type_name *RETRIEVE_POINTER_##type_name(general_pointer gp) {
    if (gp.run_time_type_code != id_code) {
        LOG("Wanted ID code %d, found %d\n", id_code, gp.run_time_type_code);
        internal_error("attempt to retrieve wrong pointer type as " #type_name);
    }
    return (type_name *) gp.pointer_to_data;
}
general_pointer PASS_POINTER_##type_name(general_pointer gp) {
    if (gp.run_time_type_code != id_code) {
        LOG("Wanted ID code %d, found %d\n", id_code, gp.run_time_type_code);
        internal_error("attempt to pass wrong pointer type as " #type_name);
    }
    return gp;
}
int VALID_POINTER_##type_name(general_pointer gp) {
    if (gp.run_time_type_code == id_code) return TRUE;
    return FALSE;
}
```

§**43.** Suitable `MAKE_REFERENCE_ROUTINES` were expanded for all of the memory allocated objects above; so that leaves only humble `char *` pointers:

```
MAKE_REFERENCE_ROUTINES(char, 1000)
```

§**44. The general pointer attached to a specification.** As we shall see in Chapter 7, the SP structure has a "structure" field which is a general pointer – SPs can represent a wide range of different Inform concepts, and the field usually points to the internal data structure in question. For instance, the text "Table of Gotham City Hideouts" might parse to a SP representing a constant value of kind "table" (i.e., `kova(TABLE_TY)`), and its structure field would be a pointer to the `table` structure created when Inform parsed the Table of Gotham City Hideouts elsewhere in the source text.

It greatly simplifies the code to provide convenient routines to convert pointers to structures to and from the specifications representing them. We'll call these "conversion routines".

```
define CONVERSION_ROUTINES(SPECNAME, STRUCTNAME)
STRUCTNAME *SPECNAME##_spec_to_##STRUCTNAME(specification *spec) {
    if (spec == NULL) internal_error("tried to find " #STRUCTNAME " within NULL type");
    if (!(spec_is_actual_CONSTANT_of_kova(spec, SPECNAME##_TY))) {
        LOG("Bad spec is: $S\n", spec);
        internal_error("tried to find " #STRUCTNAME " inside SP of wrong type");
    }
    STRUCTNAME *str = RETRIEVE_POINTER_##STRUCTNAME(spec_get_structure_field(spec));
    if (str == NULL) internal_error("found NULL " #STRUCTNAME " within " #SPECNAME " type");
    return str;
}
specification *STRUCTNAME##_to_##SPECNAME##_spec(STRUCTNAME *str) {
    if (str == NULL) internal_error("tried to make null " #STRUCTNAME " into " #SPECNAME " type");
    specification *spec = new_actual_CONSTANT_spec(kova(SPECNAME##_TY));
    spec_set_structure_field(spec, STORE_POINTER_##STRUCTNAME(str));
    return spec;
}
define RETRIEVE_FROM_SPEC(spec, structure)
    RETRIEVE_POINTER_##structure(spec_get_structure_field(spec))
define ATTACH_TO_SPEC(spec, structure, pointer)
    spec_set_structure_field(spec, STORE_POINTER_##structure(pointer))
```

§**45.** And here are the cases we actually need:

```
CONVERSION_ROUTINES(ACTION_NAME, action_name)
CONVERSION_ROUTINES(ACTIVITY, activity)
CONVERSION_ROUTINES(EQUATION, equation)
CONVERSION_ROUTINES(OBJECT, world_object)
CONVERSION_ROUTINES(PROPERTY, property_name)
CONVERSION_ROUTINES(RELATION, binary_predicate)
CONVERSION_ROUTINES(RULE, booked_rule)
CONVERSION_ROUTINES(RULEBOOK, rulebook)
CONVERSION_ROUTINES(RULEBOOK_OUTCOME, named_rulebook_outcome)
CONVERSION_ROUTINES(SCENE, scene)
CONVERSION_ROUTINES(TABLE, table)
CONVERSION_ROUTINES(TABLE_COLUMN, table_column)
CONVERSION_ROUTINES(UNDERSTANDING, grammar_verb)
CONVERSION_ROUTINES(USEOPTION, use_option)
```

Streams 2/strm

Purpose

Support for writing structured textual output, perhaps to the screen, to a file, or to a flexible-sized area of memory.

Definitions

¶1. Inform produces textual output in many formats (HTML, EPS, plain text, Inform 6 code, XML, and so on), writing to a variety of files, and often needs to juggle and rearrange partially written segments. These texts tend to be structured with running indentation, and may eventually need to be written to a disc file with either ISO Latin-1 or UTF-8 encodings. "Streams" are an abstraction to make it easy to handle all of this. The writer to a stream never needs to know where the text will come out, or how it should be indented or encoded.

¶2. The `STREAM` data type began as a generalisation of the standard C library's `FILE`, and it is used in mostly similar ways. The user – the whole program outside of this section – deals only with `STREAM *` pointers to represent streams in use.

All stream handling is defined via macros. While many operations could be handled by ordinary functions, others cannot. `STREAM` cannot have exactly the semantics of `FILE` since we cannot rely on the host operating system to allocate and deallocate the structures behind `STREAM *` pointers; and we cannot use our own memory system, either, since we need stream handling to work both before the memory allocator starts and after it has finished. Our macros allow us to hide all this from the rest of Inform. Besides that, a macro approach makes it easier to retrofit new implementations as necessary. (The present implementation is the second stab at it.)

¶3. The main purpose of many functions in Inform is to write textual material to some file. Such functions almost always have a special argument in their prototypes: `OUTPUT_STREAM`. This tells them where to pipe their output, which is always to a "current stream" called `OUT`. What this leads to, and who will see that it's properly opened and closed, are not their concern.

define `OUTPUT_STREAM STREAM *OUT` *used only as a function prototype argument*

¶4. `WRITE` is essentially `printf` but prints to the current stream instead of `stdout`, while `STREAM_WRITE` does the same but to any named stream. `INDEX` writes to the currently open index file; another commonly-used macro, `LOG`, does eventually write to a stream but has a more elaborate definition in "Debugging Log".

They are defined as what the C standard calls "variadic macros", meaning they have a variable-number-of-arguments token. They are written in the old-fashioned pre-C99 way, for compatibility with old copies of GCC, and avoid the need for comma deletion around empty tokens, as that is a point of incompatibility between implementations of the C preprocessor `cpp`. All the same, if you're porting this code, you may need to rewrite the macro with `...` in place of `args...` in the header, and then `__VA_ARGS__` in place of `args` in the definition: that being the modern way, apparently.

```
#define WRITE(args...) stream_printf(OUT, args)
#define INDEX(args...) stream_printf(ifl, args)
#define STREAM_WRITE(stream, args...) stream_printf(stream, args)
```

¶5. PUT and STREAM_PUT similarly print single characters, which are specified as unsigned integer values. In practice, STREAM_WRITE and STREAM_PUT are seldom needed because there is almost always only one stream of interest at a time – OUT, the current stream.

```
define PUT(c) stream_putc(c, OUT)
define STREAM_PUT(stream, c) stream_putc(c, stream)
```

¶6. Each stream has a current indentation level, initially 0. Lines of text will be indented by one tab stop for each level; it's an error for the level to become negative.

```
define INDENT stream_indent(OUT);
define STREAM_INDENT(x) stream_indent(x);
define OUTDENT stream_outdent(OUT);
define STREAM_OUTDENT(x) stream_outdent(x);
```

¶7. Three other output streams are always open. One is NULL, that is, its value as a STREAM * pointer is NULL, the generic C null pointer. This represents an oubliette: it is entirely valid to use it, but output sent to NULL will never be seen again.

The others are STDOUT and STDERR. As the names suggest these are wrappers for stdout and stderr, the standard console output and error messages "files" provided by the C library.

Inform always uses STREAM_WRITE(STDOUT, ...) instead of printf(...) for console output, so there are no uses of printf anywhere in the program.

```
define STDOUT stream_get_stdout()
define STDERR stream_get_stderr()
```

¶8. Other streams only exist when explicitly created, or "opened". A function is only allowed to open a new stream if it can be proved that this stream will always subsequently be "closed". (Except for the possibility of Inform halting with an internal error, and therefore an exit(1), while the stream is still open.) A stream can be opened and closed only once, and outside that time its state is undefined: it must not be used at all.

The simplest way is to make a temporary stream, which can be used as a sort of clipboard. For instance, suppose we have to compile X before Y, but have to ensure Y comes before X in the eventual output. We create a temporary stream, compile X into it, then compile Y to OUT, then copy the temporary stream into OUT and dispose of it.

Temporary streams are always created in memory, held in C's local stack frame rather than allocated and freed via malloc and free. It must always be possible to prove that execution passes from TEMPORARY_STREAM to CLOSE_TEMPORARY_STREAM. The stream exists only between those macros, only in that one function, and is called TEMP. We can legitimately create a temporary stream many times in one function (for instance inside a loop body) because each time TEMP is created as a new stream, overwriting the old one. TEMP is a different stream each time it is created, so it does not violate the rule that every stream is opened and closed once only.

```
define TEMPORARY_STREAM
    char dest[2048];
    STREAM TEMP_stream_structure = stream_new_buffer(2048, dest);
    STREAM *TEMP = &TEMP_stream_structure;
define CLOSE_TEMPORARY_STREAM
    STREAM_CLOSE(TEMP);
```

¶9. Otherwise we can create new globally existing streams, provided we take on the responsibility for seeing that they are properly closed. There are two choices: a stream in memory, allocated via `malloc` and freed by `free` when the stream is closed; or a file written to disc, opened via `fopen` and later closed by `fclose`. Files are always written in text mode, that is, `"w"` not `"wb"`, for those platforms where this makes a difference.

Inform uses streams to handle all of its text file output, so there are no calls to `fprintf` anywhere in the program except in the streams implementation below.

```
define STREAM_OPEN_TO_FILE(new, fn, enc) stream_open_to_file(new, fn, enc)
define STREAM_OPEN_TO_FILE_APPEND(new, fn, enc) stream_open_to_file_append(new, fn, enc)
define STREAM_OPEN_IN_MEMORY(new) stream_open_to_memory(new, 20480)
define STREAM_CLOSE(stream) stream_close(stream)
```

¶10. The following operation is equivalent to `fflush` and makes it more likely (I put it no higher) that the text written to a stream has all actually been copied onto the disc, rather than sitting in some operating system buffer. This helps ensure that the debugging log is up to the minute, in case of a crash, but its absence wouldn't hurt Inform's normal function. Flushing a memory stream is legal but does nothing.

```
define STREAM_FLUSH(stream) stream_flush(stream)
```

¶11. A piece of information we can read for any stream is the number of characters written to it: its "extent". In fact, UTF-8 multi-byte encoding schemes, together with differing platform interpretations of C's `'\n'`, mean that this extent is not necessarily either the final file size or bytes or the actual number of human-readable characters. We will only actually use it to detect whether text has, or has not, been written to a stream between two points in time, by seeing whether or not it has increased.

```
define STREAM_EXTENT(x) stream_get_position(x)
```

¶12. Any stream can have the following flag set or cleared. When this is set, the XML (and HTML) escapes of `&` for ampersand, and `<` and `>` for angle brackets, will be used automatically on writing. By default this flag is clear, that is, no conversion is made.

```
define STREAM_USE_XML_ESCAPES(x, state) if (x) x->use_xml_escapes = state;
```

¶13. A theological question: what is the text encoding for the null stream?

```
define STREAM_ENCODING(x) ((x)?(x->encoding_to_write_to_file):ISO_ENC)
```

¶14. The remaining operations are available only for streams in memory (well, and for `NULL`, but of course they do nothing when applied to that). While they could be provided for file streams, this would be so inefficient that we will pretend it is impossible. Any Inform function which might need to use one of these operations should open with the following sentinel macro:

```
define STREAM_MUST_BE_IN_MEMORY(x)
    if ((x != NULL) && (x->write_to_memory == NULL))
        internal_error("STREAM not in memory");
```

¶15. First, we can erase one or more recently written characters:

```
define STREAM_BACKSPACE(x) stream_set_position(x, stream_get_position(x) - 1)
define STREAM_ERASE_BACK_TO(start_position) stream_set_position(OUT, start_position)
```

¶16. Second, we can look at the text written. The minimal form is to look at just the most recent character, but we can also copy one entire memory stream into another stream (where the target can be either a memory or file stream).

We can also access a null-terminated C string containing the contents of a memory stream up as far as, at least, the first 255 characters. `STREAM_TEXT` is permitted to return a truncated string if a memory stream exceeds that.

```
define STREAM_MIN_ACCESSIBLE_LENGTH 255
define STREAM_MOST_RECENT_CHAR(x) stream_latest(x)
define STREAM_COPY(to, from) stream_copy(to, from)
define STREAM_TEXT(x) stream_get_text(x)
```

¶17. So much for the definition; now the implementation. Here is the `STREAM` structure. Open memory streams are represented by structures where `write_to_memory` is valid, open file streams by those where `write_to_file` is valid. That counts every open stream except `NULL`, which of course doesn't point to a `STREAM` structure at all.

```
typedef struct STREAM {
    FILE *write_to_file;                          for an open stream, exactly one of these is NULL
    char *write_to_memory;
    int encoding_to_write_to_file;                                relevant only for file streams
    int use_xml_escapes;                                                          see above
    int allocated_by_malloc;                      was the write_to_memory pointer claimed by malloc?
    int chars_written;                                    number of characters sent, counting \n as 1
    int chars_capacity;              maximum number the stream can accept without claiming more resources
    struct STREAM *stream_continues;                  if one memory stream is extended by another
    int indentation_level;                                    number of tab stops in from the left margin
    int indentation_pending;                    we have just ended a line, so further text should indent
} STREAM;
```

The structure STREAM is private to this section.

¶18. When text is stored at `write_to_memory`, it is kept as a zero-terminated C string and encoded as ISO Latin-1, with one byte per character. It turns out to be efficient to preserve a small margin of clear space at the end of the space, so out of the `chars_capacity` space, the following amount will be kept clear:

```
define SPACE_AT_END_OF_STREAM 100
```

¶19. A statistic we keep, since it costs little:

```
int total_file_writes = 0;                        number of text files opened for writing during the run
```

§**1. Initialising the stream structure.** Note that the following fills in sensible defaults for every field, but the result is not a valid open stream; it's a blank form ready to be filled in.

By default the upper limit on file size is 2 GB. It's very hard to see this ever being approached for text files whose size is proportionate to the result of human writing. The only output file with a sorceror's-apprentice-like ability to grow and grow is the debugging file, and if it should reach 2 GB then it *deserves* to be truncated and we will shed no tears.

```
void stream_initialise(STREAM *stream) {
    if (stream == NULL) internal_error("tried to initialise NULL stream");
    stream->write_to_file = NULL;
    stream->write_to_memory = NULL;
    stream->allocated_by_malloc = FALSE;
    stream->chars_written = 0;
    stream->chars_capacity = 2147483647;
    stream->stream_continues = NULL;
    stream->encoding_to_write_to_file = ISO_ENC;
    stream->use_xml_escapes = FALSE;
    stream->indentation_level = 0;
    stream->indentation_pending = FALSE;
}
```

§**2. Standard I/O wrappers.** The first call to `stream_get_stdout()` creates a suitable wrapper for `stdout` and returns a `STREAM *` pointer to it; subsequent calls just return this wrapper.

```
STREAM STDOUT_struct; int stdout_wrapper_initialised = FALSE;
STREAM *stream_get_stdout(void) {
    if (stdout_wrapper_initialised == FALSE) {
        stream_initialise(&STDOUT_struct); STDOUT_struct.write_to_file = stdout;
        stdout_wrapper_initialised = TRUE;
    }
    return &STDOUT_struct;
}
```

§**3.** And similarly for the standard error file.

```
STREAM STDERR_struct; int stderr_wrapper_initialised = FALSE;
STREAM *stream_get_stderr(void) {
    if (stderr_wrapper_initialised == FALSE) {
        stream_initialise(&STDERR_struct); STDERR_struct.write_to_file = stderr;
        stderr_wrapper_initialised = TRUE;
    }
    return &STDERR_struct;
}
```

§**4. Creating file streams.** Note that this can fail, if the host filing system refuses to open the file, so we return `TRUE` if and only if successful.

```
int stream_open_to_file(STREAM *stream, char *filename, int encoding) {
    if (stream == NULL) internal_error("tried to open NULL stream");
    if (filename == NULL) internal_error("stream_open_to_file on null filename");
    stream_initialise(stream);
    stream->write_to_file = iso_fopen(filename, "w");
    if (stream->write_to_file == NULL) return FALSE;
    stream->encoding_to_write_to_file = encoding;
    total_file_writes++;
    return TRUE;
}
```

§**5.** Similarly for appending:

```
int stream_open_to_file_append(STREAM *stream, char *filename, int encoding) {
    if (stream == NULL) internal_error("tried to open NULL stream");
    if (filename == NULL) internal_error("stream_open_to_file on null filename");
    stream_initialise(stream);
    stream->write_to_file = iso_fopen(filename, "a");
    if (stream->write_to_file == NULL) return FALSE;
    stream->encoding_to_write_to_file = encoding;
    total_file_writes++;
    return TRUE;
}
```

§**6. Creating memory streams.** Here we have a choice. One option is to use `malloc` to allocate memory to hold the text of the stream; this too can fail for host platform reasons, so again we return a success code.

```
int stream_open_to_memory(STREAM *stream, int capacity) {
    if (stream == NULL) internal_error("tried to open NULL stream");
    if (capacity < STREAM_MIN_ACCESSIBLE_LENGTH + SPACE_AT_END_OF_STREAM)
        internal_error("memory stream too small");
    stream_initialise(stream);
    stream->write_to_memory = I7_malloc(capacity, STREAM_MREASON);
    if (stream->write_to_memory == NULL) return FALSE;
    (stream->write_to_memory)[0] = 0;
    stream->allocated_by_malloc = TRUE;
    stream->chars_capacity = capacity;
    return TRUE;
}
```

§**7.** The other option avoids `malloc` by using specific storage already available. (That avoids gratuitously frequent use of `malloc` and `free`, since this incurs speed costs on some platforms.) If called validly, this cannot fail.

```
STREAM stream_new_buffer(int capacity, char *at) {
    if (at == NULL) internal_error("tried to make stream wrapper for NULL string");
    if (capacity < STREAM_MIN_ACCESSIBLE_LENGTH + SPACE_AT_END_OF_STREAM)
        internal_error("memory stream too small");
    STREAM stream;
    stream_initialise(&stream);
    stream.write_to_memory = at;
    (stream.write_to_memory)[0] = 0;
    stream.chars_capacity = capacity;
    return stream;
}
```

§**8. Flush and close.** Note that flush is an operation which can be performed on any stream, including `NULL`:

```
void stream_flush(STREAM *stream) {
    if (stream == NULL) return;
    if (stream->write_to_file) fflush(stream->write_to_file);
}
```

§**9.** But closing is not allowed for `NULL` or the standard I/O wrappers:

```
void stream_close(STREAM *stream) {
    if (stream == NULL) internal_error("tried to close NULL stream");
    if (stream == &STDOUT_struct) internal_error("tried to close STDOUT stream");
    if (stream == &STDERR_struct) internal_error("tried to close STDERR stream");
    if (stream->chars_capacity == -1) internal_error("stream closed twice");
    if (stream->stream_continues) {
        stream_close(stream->stream_continues);
        stream->stream_continues = NULL;
    }
    stream->chars_capacity = -1;                                    mark as closed
    if (stream->write_to_file) ⟨Take suitable action to close the file stream 10⟩;
    if (stream->write_to_memory) ⟨Take suitable action to close the memory stream 11⟩;
}
```

§**10.** Note that we need do nothing to close a memory stream when the storage was supplied by our client; it only needs freeing if we were the ones who allocated it.

Inscrutably, `fclose` returns `EOF` to report any failure.

⟨Take suitable action to close the file stream 10⟩ ≡

```
    if ((ferror(stream->write_to_file)) || (fclose(stream->write_to_file) == EOF))
        fatal_error("The host computer reported an error trying to write a text file");
    stream->write_to_file = NULL;
```

This code is used in §9.

§**11.** Note that we need do nothing to close a memory stream when the storage was supplied by our client; it only needs freeing if we were the ones who allocated it. `free` is a void function; in theory it cannot fail, if supplied a valid argument.

We have to be very careful once we have called `free`, because that memory may well contain the `STREAM` structure to which `stream` points – see how continuations are made, below.

⟨Take suitable action to close the memory stream 11⟩ ≡
```
if (stream->allocated_by_malloc) {
    I7_free(stream->write_to_memory, STREAM_MREASON); stream = NULL;
}
```
This code is used in §9.

§**12. Writing.** The following function is modelled on the "minimum `printf`" function used as an example in Kernighan and Ritchie, Chapter 7. All text in the formatting string is treated as raw except for `%` escapes, which are handled by ordinary `fprintf`, and new `$` escapes, which are signals to pretty-print NI data structures.

```
void stream_printf(STREAM *stream, char *fmt, ...) {
    va_list ap;                                          the variable argument list signified by the dots
    char *p;
    if (stream == NULL) return;
    STREAM_FLUSH(dl);
    va_start(ap, fmt);                                   macro to begin variable argument processing
    for (p = fmt; *p; p++) {
        while (stream->stream_continues) stream = stream->stream_continues;
        switch (*p) {
            case '%':
                ⟨Ensure there is room to expand the escape sequence into 17⟩;
                ⟨Insert indentation if this is pending 16⟩;
                ⟨Recognise traditional printf escape sequences 13⟩; break;
            default: stream_putc(*p, stream); break;
        }
    }
    va_end(ap);                                          macro to end variable argument processing
}
```

§**13.** We don't trouble to check that correct `printf` escapes have been used: instead, we pass anything in the form of a percentage sign, followed by up to four nonalphabetic modifying characters, followed by an alphabetic category character for numerical printing, straight through to `sprintf` or `fprintf`.

Thus an escape like `%04d` is handled by the standard C library, but not `%s`, which we handle directly. That's for two reasons: first, we want to be careful to prevent overruns of memory streams; second, we need to ensure that the correct encoding is used when writing to disc. The numerical escapes involve only characters whose representation is the same in all our file encodings, but expanding `%s` does not.

⟨Recognise traditional printf escape sequences 13⟩ ≡
```
int ival; double dval; char *sval;
char format_string[8], category = ' ';
int i = 1;
format_string[0] = '%';
p++;
while (*p) {
    format_string[i++] = *p;
```

```
        if ((islower(*p)) || (isupper(*p)) || (*p == '%')) category = *p;
        p++;
        if ((category != ' ') || (i==6)) break;
    }
    format_string[i] = 0; p--;
    switch (category) {
        case 'c': case 'd': case 'i': case 'x':            char is promoted to int in variable arguments
            ival = va_arg(ap, int);
            if (stream->write_to_file) fprintf(stream->write_to_file, format_string, ival);
            if (stream->write_to_memory) {
                sprintf(stream->write_to_memory + stream->chars_written, format_string, ival);
                stream->chars_written += strlen(stream->write_to_memory + stream->chars_written);
            }
            break;
        case 'f':
            dval = va_arg(ap, double);
            if (stream->write_to_file) fprintf(stream->write_to_file, format_string, dval);
            if (stream->write_to_memory) {
                sprintf(stream->write_to_memory + stream->chars_written, format_string, dval);
                stream->chars_written += strlen(stream->write_to_memory + stream->chars_written);
            }
            break;
        case 's':
            for (sval = va_arg(ap, char *); *sval; sval++)
                stream_putc(*sval, stream);
            break;
        case '%': stream_putc('%', stream); break;
        default:
            fprintf(stderr, "*** Bad escape: <%s> ***\n", format_string);
            internal_error("Unknown % string escape in stream_printf");
    }
```

This code is used in §12.

§**14.** Our equivalent of `fputc` reads:

```
void stream_putc(int c_int, STREAM *stream) {
    unsigned int c;
    if (c_int >= 0) c = c_int; else c = c_int + 256;
    if (stream == NULL) return;
    if (c != '\n') ⟨Insert indentation if this is pending 16⟩;
    if (stream->use_xml_escapes) {
        switch(c) {
            case NEWLINE_IN_STRING: stream_literal(stream, "<br>"); return;
            case '&': stream_literal(stream, "&amp;"); return;
            case '<': stream_literal(stream, "&lt;"); return;
            case '>': stream_literal(stream, "&gt;"); return;
        }
    }
    while (stream->stream_continues) stream = stream->stream_continues;
    ⟨Ensure there is room to expand the escape sequence into 17⟩;
    if (stream->write_to_file) {
        switch(stream->encoding_to_write_to_file) {
            case UTF8_ENC: ⟨Put a UTF8-encoded character into the underlying file 15⟩; break;
```

```
            case ISO_ENC: fputc(c, stream->write_to_file); break;
            default: internal_error("stream has unknown text encoding");
        }
    } else if (stream->write_to_memory) {
        (stream->write_to_memory)[stream->chars_written] = c;
        (stream->write_to_memory)[stream->chars_written+1] = 0;
    }
    if (c == '\n') stream->indentation_pending = TRUE;
    stream->chars_written++;
}
```

§**15.** Where we pack large character values as follows. The following works only if $0 \leq c < 2048$, but since Inform uses only ISO Latin-1 strings internally, it only needs to work for $0 \leq c < 256$.

⟨Put a UTF8-encoded character into the underlying file 15⟩ ≡

```
    if (c >= 128) {
        fputc(0xC0 + (c >> 6), stream->write_to_file);
        fputc(0x80 + (c & 0x3f), stream->write_to_file);
    } else fputc(c, stream->write_to_file);
```

This code is used in §14.

§**16.**

⟨Insert indentation if this is pending 16⟩ ≡

```
    if (stream->indentation_pending) {
        stream->indentation_pending = FALSE;
        int i;
        for (i=0; i<stream->indentation_level; i++) {
            stream_putc(' ', stream); stream_putc(' ', stream);
            stream_putc(' ', stream); stream_putc(' ', stream);
        }
    }
```

This code is used in §12,14,12,14,12,14.

§**17.** The following is checked before any numerical `printf`-style escape is expanded into the stream, or before any single character is written. Thus we cannot overrun our buffers unless the expansion of a numerical escape exceeds `SPACE_AT_END_OF_STREAM` plus 1 in size. Since no outside influence gets to choose what formatting escapes we use (so that `%3000d`, say, can't occur), we can be pretty confident.

The interesting case occurs when we run out of memory in a memory stream. We make a continuation to a fresh `STREAM` structure, which points to twice as much memory as the original, allocated via `malloc`. (We will actually need a little more memory than that because we also have to make room for the `STREAM` structure itself.) We then set `stream` to the `continuation`. Given that `malloc` was successful – and it must have been or we would have stopped with a fatal error – the continuation is guaranteed to be large enough, since it's twice the size of the original, which itself was large enough to hold any escape sequence when opened.

⟨Ensure there is room to expand the escape sequence into 17⟩ ≡

```
    if (stream->chars_written + SPACE_AT_END_OF_STREAM >= stream->chars_capacity) {
        if (stream->write_to_file) return;                    write nothing further
        if (stream->write_to_memory) {
            size_t offset = 32 + 2*stream->chars_capacity;
            size_t needed = offset + sizeof(STREAM) + 32;
            void *further_allocation = I7_malloc(needed, STREAM_MREASON);
```

```
            if (further_allocation == NULL) fatal_error("Out of memory");
            STREAM *continuation = (STREAM *) (further_allocation + offset);
            stream_initialise(continuation);
            continuation->write_to_memory = further_allocation;
            continuation->chars_capacity = 2*stream->chars_capacity;
            (continuation->write_to_memory)[0] = 0;
            stream->stream_continues = continuation;
            stream = continuation;
        }
    }
```

This code is used in §12,14,12,14,12,14.

§**18.** Literal printing is just printing with XML escapes switched off:

```
void stream_literal(STREAM *stream, char *p) {
    if (stream == NULL) return;
    int i, x = stream->use_xml_escapes;
    stream->use_xml_escapes = FALSE;
    for (i=0; p[i]; i++) stream_putc((unsigned int) (p[i]), stream);
    stream->use_xml_escapes = x;
}
```

§**19.** Shifting indentation. For every indent there must be an equal and opposite outdent, but error conditions can cause some compilation routines to issue problem messages and then leave what they're doing incomplete, so we will be a little cautious about assuming that a mismatch means an error in Inform's program.

```
void stream_indent(STREAM *stream) {
    if (stream == NULL) return;
    stream->indentation_level++;
}
void stream_outdent(STREAM *stream) {
    if (stream == NULL) return;
    stream->indentation_level--;
    if ((stream->indentation_level < 0) && (problem_count == 0))
        internal_error("stream indentation negative");
}
```

§**20.** We can read the position for any stream, including `NULL`, but no matter how much is written to `NULL` this position never budges.

Because of continuations, this is not as simple as returning the `chars_written` field.

```
int stream_get_position(STREAM *stream) {
    int t = 0;
    while (stream) {
        t += stream->chars_written;
        stream = stream->stream_continues;
    }
    return t;
}
```

§**21. Memory-stream-only functions.** While it would be easy enough to implement this for file streams too, there's no point, since it is used only in concert with backspacing.

```
int stream_latest(STREAM *stream) {
    if (stream == NULL) return 0;
    if (stream->write_to_file) internal_error("stream_latest on file stream");
    while ((stream->stream_continues) && (stream->stream_continues->chars_written > 0))
        stream = stream->stream_continues;
    if (stream->write_to_memory) {
        if (stream->chars_written > 0)
            return (stream->write_to_memory)[stream->chars_written - 1];
    }
    return 0;
}
```

§**22.** Now for what is the trickiest function, because the position may be moved back so that later continuations fall away. This will very rarely happen, so we won't worry about the inefficiency of freeing up the memory saved by closing such continuation blocks (which would be inefficient if we immediately had to open similar ones again).

```
void stream_set_position(STREAM *stream, int position) {
    if (stream == NULL) return;
    if (position < 0) position = 0;                          to simplify the implementation of backspacing
    if (stream->write_to_file) internal_error("stream_set_position on file stream");
    if (stream->write_to_memory) {
        while (position > stream->chars_written) {
            position = position - stream->chars_written;
            stream = stream->stream_continues;
            if (stream == NULL) internal_error("can't set position forwards");
        }
        stream->chars_written = position;
        (stream->write_to_memory)[stream->chars_written] = 0;
        if (stream->stream_continues) {
            stream_close(stream->stream_continues);
            stream->stream_continues = NULL;
        }
    }
}
```

§**23.** We must return a valid C string which contains at least the first `STREAM_MIN_ACCESSIBLE_LENGTH` characters in the stream. The complete text of the stream may be cut up into a number of C strings because of continuations, but we know that the first has at least the length we need, because we don't allow memory streams to be opened with capacities smaller than that.

```
char *stream_get_text(STREAM *stream) {
    if (stream == NULL) return NULL;
    if (stream->write_to_file) internal_error("stream_get_text on file stream");
    return stream->write_to_memory;
}
```

§**24.** Lastly, our copying function, where `from` has to be a memory stream (or `NULL`) but `to` can be anything (including `NULL`).

```
void stream_copy(STREAM *to, STREAM *from) {
    if ((from == NULL) || (to == NULL)) return;
    if (from->write_to_file) internal_error("stream_copy from file stream");
    if (from->write_to_memory) {
        int i;
        for (i=0; i<from->chars_written; i++) {
            int c = (from->write_to_memory)[i];
            stream_putc(c, to);
        }
        if (from->stream_continues) stream_copy(to, from->stream_continues);
    }
}
```

Filenames 2/files

Purpose

Given the different environments in which we might be running, and the large range of files we may need from within a project folder, it's useful to have a section of code simply to deduce filenames.

2/files. ¶2-0 Filing system assumptions; §1 Location of extensions; §2-8 Project bundles; §9-11 Directory handling utilities; §12 Reading a line from a text file

---

Definitions

¶1. We begin with the leafnames of the main output files, which are the same on all platforms. The following list excludes the HTML index files: those have leafnames following their main headings (thus the Kinds index page is stored as `Kinds.html`, and so on).

```
define I6_OUTPUT_LEAFNAME "auto.inf"
define DEBUG_LOG_LEAFNAME "Debug log.txt"
define PROBLEM_LOG_LEAFNAME "Problems.html"
define XML_HEADINGS_LEAFNAME "Headings.xml"
define METADATA_LEAFNAME "Metadata.iFiction"
define UUID_LEAFNAME "uuid.txt"
define BLURB_LEAFNAME "Release.blurb"
define MANIFEST_LEAFNAME "manifest.plist"
define EPSMAP_LEAFNAME "Map.eps"
```

¶2. Filing system assumptions. It is assumed that our host filing system can manage at least 30-character filenames, that space is legal as a character in a filename, and that trailing extensions can be longer than 3 characters (in particular, that `.html` is allowed).

```
define MAX_FILENAME_LENGTH 522
```
Assuming no leafname exceeds 255 characters

---

§**1. Location of extensions.** NI looks for extensions in two places: a primary source, the "built in" set which comes as part of the resources of the Inform 7 application, and a secondary source, intended as a place where the designer can store downloaded extensions, new extensions being written, etc. Under Mac OS X, the secondary location is inside the user's Library, and to get its pathname we need to evaluate an environment variable which holds the current user's username. This has comparable results under generic Unix and Windows, but we take precautions against a null result anyway.

NI cannot know where the Inform 7 application is living in the filing system, nor where it keeps its built-in extensions (since this will depend on the platform being used). NI therefore expects to be told this information with the `-rules` command-line switch. The applications always call NI with `-rules` supplied, but in case NI is being invoked directly from the command line we do provide a default if `-rules` is omitted: which is simply to use the same library folder as for user-supplied extensions. See also the `main` routine, where this overriding is done.

```
char filename_of_tracefile[MAX_FILENAME_LENGTH];
char filename_of_telemetry[MAX_FILENAME_LENGTH];
char filename_of_options[MAX_FILENAME_LENGTH];
char filename_of_epsfile[MAX_FILENAME_LENGTH];
char pathname_of_extensions[MAX_FILENAME_LENGTH];
char pathname_of_templates[MAX_FILENAME_LENGTH];
```

```
char pathname_of_extension_docs[MAX_FILENAME_LENGTH];
char pathname_of_built_in_extensions[MAX_FILENAME_LENGTH];
void make_pathname_of_extensions(void) {
    char *home = (char *) (getenv("HOME"));
    if (home == NULL) home = "";
    strcpy(pathname_of_extensions, home); strcat(pathname_of_extensions, HOME_LIBRARY);
    strcpy(pathname_of_extension_docs, home); strcat(pathname_of_extension_docs, HOME_DOCS);
    strcpy(pathname_of_built_in_extensions, pathname_of_extensions);
    strcpy(filename_of_tracefile, home); strcat(filename_of_tracefile, TRACEFILE);
    strcpy(pathname_of_templates, home); strcat(pathname_of_templates, HOME_TEMPLATES);
    strcpy(filename_of_options, home); strcat(filename_of_options, OPTIONSFILE);
    strcpy(filename_of_telemetry, home); strcat(filename_of_telemetry, TELEMETRYFILE);
    int this_month = the_present->tm_mon + 1;
    int this_day = the_present->tm_mday;
    int this_year = the_present->tm_year + 1900;
    sprintf(filename_of_telemetry + strlen(filename_of_telemetry),
        " %04d-%02d-%02d.txt", this_year, this_month, this_day);
    set_platform_specific_eps_filename(filename_of_epsfile);
}
```

The function make_pathname_of_extensions is called from 14/main.

§**2. Project bundles.** For any given project, NI has only one fresh input file (the source text), but it generates a swathe of output in different formats, together with some temporary files along the way. It is convenient therefore to bundle all this material together – and essential if NI is being used with a port of the Inform 7 application, which needs to know where to put things and where to get them back again. If we are using this standard organisation, we say NI is running in "bundle mode"; it can also run less tidily as a command-line tool in which most of what it produces heaps up in the current working directory, but when NI is being used in the Inform 7 application, it will always be running in bundle mode.

The command line arguments to NI must specify either a bundle name, in which case `source_text_file` stays null, or an explicit source text filename, in which case `bundle_name` stays null: but not both.

```
char *bundle_name = NULL;
char *source_text_file = NULL;
```

§**3.** The layout of a bundle is as follows. Let us suppose the bundle is called, for want of a better name, Voltaire. (This does not have to be the same as the name of the project it makes: like any file, an Inform project can be renamed without changing its contents.) Then we have:

- `Voltaire.inform`
  - `Build`
    - `auto.inf` (the I6 code compiled by NI)
    - `Debug log.txt`
    - `gameinfo.dbg` (subsequently created by I6)
    - `Map.eps` (the EPS file created by NI)
    - `output.z5` (subsequently created by I6)
    - `Problems.html` (the report generated by NI)
    - `temporary file.inf` (used temporarily by NI)
    - `temporary file 2.inf` (used temporarily by NI)
  - `Index`
    - `Actions.html`
    - `Contents.html`
    - `Headings.xml` (not visible to the user)
    - `Kinds.html`
    - `Phrasebook.html`
    - `Rules.html`
    - `Scenes.html`
    - `World.html`
    - `Details` (a subfolder created as needed by NI)
      - `13_A.html` (and so forth: about 90 pages about actions)
  - `manifest.plist` (list of images and sounds used, made by NI)
  - `Metadata.iFiction` (iFiction record made by NI)
  - `Release.blurb` (releasing instructions for `cblorb`)
  - `Settings.plist` (used by the Inform application, not NI)
  - `Skein.skein` (used by the Inform application and `cblorb` but not NI)
  - `Source`
    - `story.ni` (the source text)
  - `uuid.txt` (UUID created by application and read by NI)

The application is free to store other resources in the bundle. (For instance, Inform for OS X also includes a `notes.rtf` file of rough notes made by the author: but NI does not notice this.)

§**4.** NI is not capable of creating a new project bundle: that is the responsibility of the Inform application, or, in extremis, the user. The following minimal structure must exist for NI to be able to work:

- `StEvremond.inform`
  - `Build` (empty subfolder)
  - `Index` (empty subfolder)
  - `Skein.skein` (only needs to exist for `cblorb` to release along with source)
  - `Source`
    - `story.ni` (the source text)
  - `uuid.txt` (the UUID)

It is essential that the application create a fresh UUID for each new project: see the Interactive Fiction ID section in chapter 10 below.

§**5.** Now for some dull but worthy routines to turn leafnames into filenames, splicing them together into a temporary buffer. (Only one of these routines can be used at a time, since otherwise the buffer is overwritten by one filename before the other has been finished with.)

```
char local_filename_buffer[MAX_FILENAME_LENGTH];
char *top_level_filename(char *leafname) {
    if (bundle_name == NULL) return leafname;                    outside bundle mode, use current directory
    sprintf(local_filename_buffer, "%s%c%s",
        bundle_name, FOLDER_SEPARATOR, leafname);
    return local_filename_buffer;
}
```

The function top_level_filename is called from 10/ifid and 10/bib.

§**6.** Filenames within the `Build` subfolder. The opening part may be a surprise: In extension census mode, NI is running not to compile something but to extract details of all the extensions installed. But it still needs somewhere to write its temporary and debugging files, and there is no project bundle to write into. To get round this, we use the user's installed extensions folder as if it were a project bundle.

```
char *build_filename(char *leafname) {
    if (census_mode) {
        if (verify_installed_extensions_tree() == FALSE) return leafname;
        sprintf(local_filename_buffer, "%s%c%s",
            pathname_of_extension_docs, FOLDER_SEPARATOR, leafname);
        return local_filename_buffer;
    }
    if (bundle_name == NULL) return leafname;
    sprintf(local_filename_buffer, "%s%cBuild%c%s",
        bundle_name, FOLDER_SEPARATOR, FOLDER_SEPARATOR, leafname);
    return local_filename_buffer;
}
```

The function build_filename is called from 2/prob3, 2/dl, 9/map, 10/bib and 14/i6t.

§**7.** Filenames within the `Source` subfolder: two versions here, as it is sometimes convenient to have the pathname from the top of the bundle, rather than an absolute pathname.

```
char *source_filename(char *leafname) {
    if (bundle_name == NULL) return leafname;
    sprintf(local_filename_buffer, "%s%cSource%c%s",
        bundle_name, FOLDER_SEPARATOR, FOLDER_SEPARATOR, leafname);
    return local_filename_buffer;
}
char *source_filename_relative_to_bundle(char *leafname) {
    if (bundle_name == NULL) return leafname;
    sprintf(local_filename_buffer, "Source%c%s",
        FOLDER_SEPARATOR, leafname);
    return local_filename_buffer;
}
```

The function source_filename_relative_to_bundle is called from 3/read.

§**8.** And filenames within the `Index` subfolder, where the further `Details` subfolder will be created if necessary. Filenames in `Details` have the form `N_S` where `N` is the integer supplied and `S` the leafname; for instance, `21_A.html` provides details page number 21 about actions, derived from the leafname `A.html`.

```
int details_subfolder_made = FALSE;
char *index_filename(char *leafname, int sub) {
    if (bundle_name == NULL) return leafname;
    sprintf(local_filename_buffer, "%s%cIndex%c",
        bundle_name, FOLDER_SEPARATOR, FOLDER_SEPARATOR);
    if (sub >= 0) {
        strcat(local_filename_buffer, "Details");
        if (details_subfolder_made == FALSE) {
            platform_specific_mkdir(local_filename_buffer);
            details_subfolder_made = TRUE;
        }
        sprintf(local_filename_buffer + strlen(local_filename_buffer),
            "%c%d_", FOLDER_SEPARATOR, sub);
    }
    sprintf(local_filename_buffer + strlen(local_filename_buffer), "%s", leafname);
    return local_filename_buffer;
}
```

The function index_filename is called from 2/index and 4/head.

§**9. Directory handling utilities.** The following routines handle directories, using routines defined in Platform-Specific Definitions.

The first creates a folder `new` at the given path in the Inform external materials area (e.g. the user's Library folder for OS X). This routine is always called in the right order, e.g., if Inform wants to make

```
Inform/Extensions/Frederick Bloggs
```

then it makes the following calls:

```
verify_library_folder(NULL, NULL, NULL, "Inform");
verify_library_folder("Inform", NULL, NULL, "Extensions");
verify_library_folder("Inform", "Extensions", NULL, "Frederick Bloggs");
```

```
int verify_library_folder(char *p1, char *p2, char *p3, char *new) {
    char path[MAX_FILENAME_LENGTH];
    char transcoded_path[MAX_FILENAME_LENGTH];
    char *home = (char *) (getenv("HOME"));
    int rv;
    path[0] = 0;
    if (home) sprintf(path, "%s%c", home, FOLDER_SEPARATOR);
    sprintf(path + strlen(path), "%s", INFORM_FOLDER_RELATIVE_TO_HOME);
    if (p1) sprintf(path + strlen(path), "%s%c", p1, FOLDER_SEPARATOR);
    if (p2) sprintf(path + strlen(path), "%s%c", p2, FOLDER_SEPARATOR);
    if (p3) sprintf(path + strlen(path), "%s%c", p3, FOLDER_SEPARATOR);
    if (new) sprintf(path + strlen(path), "%s", new);
    transcode_ISO_string_to_locale(path, transcoded_path);
    rv = platform_specific_mkdir(transcoded_path);
    if (rv == FALSE) LOG("verify_library_folder failed on path %s\ntranscoded %s\n", path, transcoded_path);
    return rv;
}
```

The function verify_library_folder is called from 4/edict and 4/edoc.

§**10.** In particular, here we make sure that we can definitely access the minimal library structure of directories for the "external area" which holds the user's installed extensions:

```
Inform
    Documentation
        Extensions
    Extensions
        Reserved
```

```
int verify_installed_extensions_tree(void) {
    if (verify_library_folder(NULL, NULL, NULL, "Inform") == 0) return FALSE;
    if (verify_library_folder("Inform", NULL, NULL, "Documentation") == 0) return FALSE;
    if (verify_library_folder("Inform", "Documentation", NULL, "Extensions") == 0) return FALSE;
    if (verify_library_folder("Inform", NULL, NULL, "Extensions") == 0) return FALSE;
    if (verify_library_folder("Inform", "Extensions", NULL, "Reserved") == 0) return FALSE;
    return TRUE;
}
```

The function verify_installed_extensions_tree is called from 4/excen and 4/edict.

§**11.** This routine writes the contents of the given folder to a plain text file, one item per line: e.g.

```
Emily Short/
Fried eggs.txt
Fred Quimby/
```

They can be written in any order. Any item which is itself a folder, rather than a file, should be terminated / (even if that is not the folder separator character on the current platform). The encoding of this file will be whatever the locale encoding is for filenames, something which will oblige us to take care later on.

```
int write_folder_contents_to_file(char *pathname, char *writeto) {
    STREAM CONTS_struct; STREAM *CONTS = &CONTS_struct;
    void *FOLDER = platform_specific_opendir(pathname);
    char leafname[MAX_FILENAME_LENGTH+1];
    if (FOLDER == NULL) return FALSE;
    if (STREAM_OPEN_TO_FILE(CONTS, writeto, ISO_ENC) == FALSE) return FALSE;
    while (platform_specific_readdir(FOLDER, pathname, leafname)) {
        if (leafname[0] == '.') continue;
        STREAM_WRITE(CONTS, "%s\n", leafname);
    }
    STREAM_CLOSE(CONTS);
    platform_specific_closedir(FOLDER);
    return TRUE;
}
```

The function write_folder_contents_to_file is called from 4/excen.

§**12. Reading a line from a text file.** The following utility might as well be given here as anywhere else: it's simply a form of `fgets` for reading a single line from an ISO Latin-1 text file up to a limited number of characters, regarding the first instance of any of the termination sequences `0A`, `0D`, `0A0D` or `0D0A` as a line ending.

```
int truncated_iso_fgets(FILE *F, char *buffer, int limit) {
    int len=0, c;
    if (buffer == NULL) return -1;
    if (feof(F)) return -1;
    while ((c = fgetc(F)) != EOF) {
        if (len >= limit) break;
        if (c == '\x0a') break;
        if (c == '\x0d') break;
        buffer[len++] = c;
    }
    buffer[len++] = 0;
    return len;
}
```

The function truncated_iso_fgets is called from 1/plat, 2/dl, 4/ext, 4/excen, 4/edict and 4/edoc.

Case-Insensitive Filenames 2/cifn

Purpose

On some of the Unix-derived file systems on which Inform runs, filenames are case-sensitive, so that FISH and fish might be different files. This makes extension files, installed by the user, prone to being missed. The code in this section provides a routine to carry out file opening as if filenames are case-insensitive, and is used only for extensions.

Definitions

¶1. This section contains a single utility routine, contributed by Adam Thornton: a specialised, case-insensitive form of `fopen()` called `ci_fopen()`. It is specialised in that it is designed for opening extensions, where the file path will be case-correct up to the last two components of the path (the leafname and the immediately containing directory), but where the casing may be wrong in those last two components.

¶2. If the exact filename or extension directory (case-correct) exists, `ci_fopen()` will choose it to open. If it does not, `ci_fopen` will use `strcasecmp()` to find a file or directory with the same name but differing in case and use it instead. If it finds exactly one candidate file, it will then attempt to `fopen()` it and return the result.

If `ci_fopen()` succeeds, it returns a `FILE *` (passed back to it from the underlying `fopen()`). If `ci_fopen()` fails, it returns `NULL`, and `errno` is set accordingly:

(a) If no suitable file was found, `errno` is set to `ENOENT`.
(b) If more than one possibility was found, but none of them exactly match the supplied case, `errno` is set to `EBADF`.
(c) Note that if multiple directories which match case-insensitively are found, but none is an exact match, `EBADF` will be set regardless of the contents of the directories.
(d) If `ci_fopen()` fails during its allocation of space to hold its intermediate strings for comparison, or for its various data structures, `errno` is set to `ENOMEM`.
(e) If an unambiguous filename is found but the `fopen()` fails, `errno` is left at whatever value the underlying `fopen()` set it to.

---

§**1. Use of POSIX.** The routine is available only on platforms where `POSIX_DIRECTORY_HANDLING` is defined (see "Platform-Specific Definitions"). In practice this means everywhere except Windows, but all Windows file systems are case-preserving and case-insensitive in any case.

```
#ifdef POSIX_DIRECTORY_HANDLING
```

§**2. The routine.** Briefly, we try to get the extension directory name right first, by looking for the given casing, then if that fails, for a unique alternative with different casing; and then repeat within that directory for the extension file itself.

```
FILE *ci_fopen(const char *path, const char *mode) {
    char *topdirpath = NULL, *ciextdirpath = NULL, *cistring = NULL, *ciextname = NULL;
    char *workstring = NULL, *workstring2 = NULL;
    DIR *topdir = NULL, *extdir = NULL; FILE *handle;
    size_t length;
    LOGIF(CI_FOPEN, "ci_fopen called on '%s' with mode '%s'\n", path, mode);
    for efficiency's sake, though it's logically equivalent, we try...
    handle = fopen(path, mode); if (handle) ⟨Happy ending to ci-fopen 6⟩;
    ⟨Find the length of the path, giving an error if it is empty or NULL 9⟩;
    ⟨Allocate memory for strings large enough to hold any subpath of the path 5⟩;
    ⟨Parse the path to break it into topdir path, extension directory and leafname 10⟩;
    topdir = opendir(topdirpath);                    whose pathname is assumed case-correct...
    if (topdir == NULL) ⟨Sad ending to ci-fopen 7⟩;          ...so that failure is fatal; errno is set by opendir
    sprintf(workstring, "%s%c%s", topdirpath, FOLDER_SEPARATOR, ciextdirpath);
    LOGIF(CI_FOPEN, "supplied dir = %s\n", workstring);
    extdir = opendir(workstring);                    try with supplied extension directory name
    if (extdir == NULL) ⟨Try to find a unique insensitively matching directory name in topdir 3⟩
    else strcpy(cistring, workstring);
    sprintf(workstring, "%s%c%s", cistring, FOLDER_SEPARATOR, ciextname);
    LOGIF(CI_FOPEN, "supplied name = %s\n", workstring);
    handle = fopen(workstring, mode);                try with supplied name
    if (handle) ⟨Happy ending to ci-fopen 6⟩;
    ⟨Try to find a unique insensitively matching entry in extdir 4⟩;
}
```

The function ci_fopen is called from 1/plat.

§**3. Looking for case-insensitive matches instead.** We emerge from the following only in the happy case where a unique matching directory name can be found.

⟨Try to find a unique insensitively matching directory name in topdir 3⟩ ≡

```
int rc = count_matches_within_directory(topdir, ciextdirpath, workstring);
switch (rc) {
    case 0:
        errno = ENOENT; ⟨Sad ending to ci-fopen 7⟩;
    case 1:
        sprintf(cistring, "%s%c%s", topdirpath, FOLDER_SEPARATOR, workstring);
        LOGIF(CI_FOPEN, "real dirname = %s\n", cistring);
        extdir = opendir(cistring);
        if (extdir == NULL) {
            LOGIF(CI_FOPEN, "%s not found\n", cistring);
            errno = ENOENT; ⟨Sad ending to ci-fopen 7⟩;
        }
        break;
    default:
        errno = EBADF; ⟨Sad ending to ci-fopen 7⟩;
}
```

This code is used in §2.

§**4.** More or less the same, but we never emerge at all: all cases of the switch return from the function.

⟨Try to find a unique insensitively matching entry in extdir 4⟩ ≡
```
int rc = count_matches_within_directory(extdir, ciextname, workstring);
switch (rc) {
    case 0:
        errno = ENOENT; ⟨Sad ending to ci-fopen 7⟩;
    case 1:
        sprintf(workstring2, "%s%c%s", cistring, FOLDER_SEPARATOR, workstring);
        workstring2[length] = 0;
        LOGIF(CI_FOPEN, "real filename = %s\n", workstring2);
        handle = fopen(workstring2, mode);
        if (handle) ⟨Happy ending to ci-fopen 6⟩;
        LOGIF(CI_FOPEN, "Couldn't open %s\n", workstring2);
        errno = ENOENT; ⟨Sad ending to ci-fopen 7⟩;
    default:
        errno = EBADF; ⟨Sad ending to ci-fopen 7⟩;
}
```

This code is used in §2.

§**5. Allocation and deallocation.** We use six strings to hold full or partial pathnames.

⟨Allocate memory for strings large enough to hold any subpath of the path 5⟩ ≡
```
workstring = calloc(length+1, sizeof(char));
if (workstring == NULL) { errno = ENOMEM; ⟨Sad ending to ci-fopen 7⟩; }
workstring2 = calloc(length+1, sizeof(char));
if (workstring2 == NULL) { errno = ENOMEM; ⟨Sad ending to ci-fopen 7⟩; }
topdirpath = calloc(length+1, sizeof(char));
if (topdirpath == NULL) { errno = ENOMEM; ⟨Sad ending to ci-fopen 7⟩; }
ciextdirpath = calloc(length+1, sizeof(char));
if (ciextdirpath == NULL) { errno = ENOMEM; ⟨Sad ending to ci-fopen 7⟩; }
cistring = calloc(length+1, sizeof(char));
if (cistring == NULL) { errno = ENOMEM; ⟨Sad ending to ci-fopen 7⟩; }
ciextname = calloc(length+1, sizeof(char));
if (ciextname == NULL) { errno = ENOMEM; ⟨Sad ending to ci-fopen 7⟩; }
```

This code is used in §2.

§**6.** If we are successful, we return a valid file handle...

⟨Happy ending to ci-fopen 6⟩ ≡
```
LOGIF(CI_FOPEN, "ci-fopen: succeeded\n");
⟨Prepare to exit ci-fopen cleanly 8⟩;
return handle;
```

This code is used in §2,4,2,4,2,4.

§**7.** ...and otherwise `NULL`, having already set `errno` with the reason why.

⟨Sad ending to ci-fopen 7⟩ ≡
```
LOGIF(CI_FOPEN, "ci-fopen: failed with errno = %d\n", errno);
⟨Prepare to exit ci-fopen cleanly 8⟩;
return NULL;
```

This code is used in §2,3,4,5,2,3,4,5,2,3,4,5.

§**8.**

⟨Prepare to exit ci-fopen cleanly 8⟩ ≡

```
if (workstring) free(workstring);
if (workstring2) free(workstring2);
if (topdirpath) free(topdirpath);
if (ciextdirpath) free(ciextdirpath);
if (cistring) free(cistring);
if (ciextname) free(ciextname);
if (topdir) closedir(topdir);
if (extdir) closedir(extdir);
```

This code is used in §6,7,6,7,6,7.

§9. Pathname hacking.

⟨Find the length of the path, giving an error if it is empty or NULL 9⟩ ≡

```
length = 0;
if (path) length = strlen(path);
if (length < 1) { errno = ENOENT; return NULL; }
```

This code is used in §2.

§**10.** And here we break up a pathname like

`/Users/bobama/Library/Inform/Extensions/Hillary Clinton/Health Care.i7x`

into three components:

`topdirpath` is `/Users/bobama/Library/Inform/Extensions`, and its casing is correct
`ciextdirpath` is `Hillary Clinton`, but its casing may not be correct
`ciextname` is `Health Care.i7x`, but its casing may not be correct

The contents of `workstring` are not significant afterwards.

⟨Parse the path to break it into topdir path, extension directory and leafname 10⟩ ≡

```
char *p;
size_t extdirindex, extindex, namelen, dirlen;

p = strrchr(path, FOLDER_SEPARATOR);
extindex = (size_t) (p - path);
namelen = length - extindex - 1;
strncpy(ciextname, path + extindex + 1, namelen);
ciextname[namelen] = 0;

strncpy(workstring, path, (extindex-1));
workstring[extindex-1] = 0;
p = strrchr(workstring, FOLDER_SEPARATOR);
extdirindex = (size_t) (p - workstring);
strncpy(topdirpath, path, extdirindex);
topdirpath[extdirindex] = 0;

dirlen = extindex - extdirindex - 1;
strncpy(ciextdirpath, path + extdirindex + 1, dirlen);
ciextdirpath[dirlen] = 0;

LOGIF(CI_FOPEN, "topdirpath = %s\n", topdirpath);
LOGIF(CI_FOPEN, "ciextdirpath = %s\n", ciextdirpath);
LOGIF(CI_FOPEN, "ciextname = %s\n", ciextname);
```

This code is used in §2.

§**11. Counting matches.** We count the number of names within the directory which case-insensitively match against `name`, and copy the last which matches into `last_match`. This must be at least as long as `name`. (We ought to be just a little careful in case of improbable cases where the matched name contains a different number of characters from `name`, for instance because on a strict reading of Unicode "SS" is casing-equivalent to the eszet, but it's unlikely that many contemporary implementations of `strcasecmp` are aware of this, and in any case the code above contains much larger buffers than needed.)

```
int count_matches_within_directory(void *vd, char *name, char *last_match) {
    DIR *d = (DIR *) vd;
    struct dirent *dirp;
    int rc = 0;
    last_match[0] = 0;
    while ((dirp = readdir(d)) != NULL) {
        LOGIF(CI_FOPEN, "testing: name = %s; entry = %s\n", name, dirp->d_name);
        if (strcasecmp(name, dirp->d_name) == 0) {
            LOGIF(CI_FOPEN, "accepted as match %d\n", rc);
            rc++;
            strcpy(last_match, dirp->d_name);
        }
    }
    LOGIF(CI_FOPEN, "count_matches_within_directory rc = %d\n", rc);
    return rc;
}
```

§**12. Non-POSIX tail.** On platforms without POSIX directory handling, we revert to regular `fopen`.

```
#else
FILE *ci_fopen(const char *path, const char *mode) {
    return fopen(path, mode);
}
#endif
```

The function ci_fopen is called from 1/plat.

Image Dimensions 2/image

Purpose

These utility routines, contributed by Toby Nelson, look at the headers of JPEG and PNG files to find the pixel dimensions of any images supplied by the user for cover art and figures.

§**1.** Image and sound files are the only binary files read by NI: we begin with a set of utilities to read them. To begin with, integers of 8, 16, 32 and 64 bit widths respectively, arranged with most significant byte (MSB) first.

```
int read_int8(FILE *binary_file, unsigned int *result) {
    int c1 = getc(binary_file);
    if (c1 == EOF) return FALSE;
    *result = (unsigned int) c1;
    return TRUE;
}
int read_int16(FILE *binary_file, unsigned int *result) {
    int c1, c2;
    c1 = getc(binary_file);
    c2 = getc(binary_file);
    if (c1 == EOF || c2 == EOF) return FALSE;
    *result = (((unsigned int) c1) << 8) + ((unsigned int) c2);
    return TRUE;
}
int read_int32(FILE *binary_file, unsigned int *result) {
    int c1, c2, c3, c4;
    c1 = getc(binary_file);
    c2 = getc(binary_file);
    c3 = getc(binary_file);
    c4 = getc(binary_file);
    if (c1 == EOF || c2 == EOF || c3 == EOF || c4 == EOF) return FALSE;
    *result = (((unsigned int) c1) << 24) +
                (((unsigned int) c2) << 16) +
                (((unsigned int) c3) << 8) + ((unsigned int) c4);
    return TRUE;
}
int read_int64(FILE *binary_file, unsigned long long *result) {
    int c1, c2, c3, c4, c5, c6, c7, c8;
    c1 = getc(binary_file);
    c2 = getc(binary_file);
    c3 = getc(binary_file);
    c4 = getc(binary_file);
    c5 = getc(binary_file);
    c6 = getc(binary_file);
    c7 = getc(binary_file);
    c8 = getc(binary_file);
    if (c1 == EOF || c2 == EOF || c3 == EOF || c4 == EOF || c5 == EOF
```

```
        || c6 == EOF || c7 == EOF || c8 == EOF) return FALSE;
    *result = (((unsigned long long) c1) << 56) +
            (((unsigned long long) c2) << 48) +
            (((unsigned long long) c3) << 40) +
            (((unsigned long long) c4) << 32) +
            (((unsigned long long) c5) << 24) +
            (((unsigned long long) c6) << 16) +
            (((unsigned long long) c7) << 8) +
                ((unsigned long long) c8);
    return TRUE;
}
```

The function read_int8 is called from 2/sounds.
The function read_int16 is called from 2/sounds.
The function read_int32 is called from 2/sounds.
The function read_int64 is called from 2/sounds.

§**2.** We will sometimes need to toggle between MSB and LSB representation of integers 32 or 64 bits wide:

```
void swap_bytes32(unsigned int *value) {
    unsigned int result = (((*value & 0xff) << 24) +
                           ((*value & 0xff00) << 8) +
                           ((*value & 0xff0000) >> 8) +
                           ((*value & 0xff000000) >> 24 ) );
    *value = result;
}
void swap_bytes64(unsigned long long *value) {
    unsigned long long result = (((*value & 0xff) << 56) +
                                 ((*value & 0xff00) << 40) +
                                 ((*value & 0xff0000) << 24) +
                                 ((*value & 0xff000000) << 8) +
                                 ((*value >> 8)  & 0xff000000) +
                                 ((*value >> 24) & 0xff0000) +
                                 ((*value >> 40) & 0xff00) +
                                 ((*value >> 56) & 0xff) );
    *value = result;
}
```

The function swap_bytes32 is called from 2/sounds.
The function swap_bytes64 is called from 2/sounds.

§**3.** Some file formats also have variable-sized integers, as a sequence of bytes (most significant first) in which each byte consists of seven bits of data plus a most significant bit which marks that a continuation byte follows:

```
int read_variable_length_integer(FILE *binary_file, unsigned int *result) {
    int c;
    *result = 0;
    do {
        c = getc(binary_file);
        if (c == EOF) return FALSE;
        *result = (*result << 7) + (((unsigned char) c) & 0x7F);
    } while  (((unsigned char) c) & 0x80);
    return TRUE;
}
```

The function read_variable_length_integer is called from 2/sounds.

§**4.** Here we read just the mantissa of a particular representation of floating-point numbers:

```
int read_float80(FILE *binary_file, unsigned int *result) {
    int c1, c2, exp;
    unsigned int prev = 0, mantissa;
    c1 = getc(binary_file);
    c2 = getc(binary_file);
    if (c1 == EOF || c2 == EOF) return FALSE;
    if (!read_int32(binary_file, &mantissa)) return FALSE;
    exp = 30 - c2;
    while  (exp--) {
        prev = mantissa;
        mantissa >>= 1;
    }
    if (prev & 1) mantissa++;
    *result = (unsigned int) mantissa;
    return TRUE;
}
```

The function read_float80 is called from 2/sounds.

§**5.** And lastly we read a string of a supplied length from the file, and then null terminate it to make it valid C string. (`string` must therefore be at least `length` plus 1 bytes long.)

```
int read_string(FILE *binary_file, char *string, unsigned int length) {
    if (length > 0) {
        if (fread(string, 1, length, binary_file) != length) return FALSE;
    }
    string[length] = 0;
    return TRUE;
}
```

The function read_string is called from 2/sounds.

§**6. JPEG files.** The following either finds the pixel width and height of a given JPEG file and returns `TRUE` or, if it can't read the file or doesn't recognise the header as having JPEG format, returns `FALSE`.

JPEG is properly speaking not a file format but a compression technique: the routine below works with either JIF (JPEG Interchange Format) or its simpler cousin JFIF (JPEG File Interchange Format).

We scan the file looking for "markers", each of which begins with an `0xFF` byte and is followed by a marker-type byte which is neither `0x00` nor `0xFF`. The compulsory marker SOI must appear at the start of the file, providing one way to detect probable JPEGs by looking at the first two bytes. There must also eventually be a start of frame marker, for the actual image: this can have many forms, but in all cases tells us the height and width.

```
int get_jpg_dimensions(FILE *JPEG_file, unsigned int *width, unsigned int *height) {
    unsigned int sig, length;
    int marker;
    if (!read_int16(JPEG_file, &sig)) return FALSE;
    if (sig != 0xFFD8) return FALSE;                                    0xFF (marker) then 0xD8 (SOI)
    do {
        do {
            marker = getc(JPEG_file);
            if (marker == EOF) return FALSE;
        } while (marker != 0xff);                                       skip to next 0xFF byte
        do {
            marker = getc(JPEG_file);
        } while (marker == 0xff);                                       skip to next non FF byte
        if (!read_int16(JPEG_file, &length)) return FALSE;              length of marker
        switch(marker) {
            all variant forms of "start of frame": e.g., 0xC0 is a baseline DCT image
            case 0xc0:
            case 0xc1: case 0xc2: case 0xc3:
            case 0xc5: case 0xc6: case 0xc7:
            case 0xc9: case 0xca: case 0xcb:
            case 0xcd: case 0xce: case 0xcf: {
                fortunately these markers all then open with the same format
                if (getc(JPEG_file) == EOF) return FALSE;               skip 1 byte of data precision
                if (!read_int16(JPEG_file, height)) return FALSE;
                if (!read_int16(JPEG_file, width)) return FALSE;
                return TRUE;
            }
            default:
                if (fseek(JPEG_file, length - 2, SEEK_CUR) != 0) return FALSE;      skip rest of marker
        }
    }
    while (marker != EOF);
    return FALSE;
}
```

The function get_jpg_dimensions is called from 10/bib and 10/fig.

§**7. PNG files.** The PNG file must start with a signature which indicates that the remainder contains a single PNG image, consisting of a series of chunks beginning with an IHDR chunk and ending with an IEND chunk (*Portable Network Graphics (PNG) Specification*, 2nd edition, section 5.2). We only need to scan the IHDR chunk, of which the pixel width and height are the first two words (section 11.2.2).

```
int get_png_dimensions(FILE *PNG_file, unsigned int *width, unsigned int *height) {
    unsigned int sig1, sig2, length, type;
    Check PNG signature
    if (!read_int32(PNG_file, &sig1)) return FALSE;
    if (!read_int32(PNG_file, &sig2)) return FALSE;
    if ((sig1 != 0x89504e47) || (sig2 != 0x0d0a1a0a)) return FALSE;
    Read first chunk
    if (!read_int32(PNG_file, &length)) return FALSE;
    if (!read_int32(PNG_file, &type)) return FALSE;
    First chunk must be IHDR
    if (type != 0x49484452) return FALSE;
    Width and height follow
    if (!read_int32(PNG_file, width)) return FALSE;
    if (!read_int32(PNG_file, height)) return FALSE;
    return TRUE;
}
```

The function get_png_dimensions is called from 10/bib and 10/fig.

Sound Durations 2/sounds

Purpose

These utility routines, again by Toby Nelson, look at the headers of AIFF and OGG files to find the durations, and verify that they are what they purport to be.

§**1.** To explicate the following, see the specifications for AIFF and OGG headers. Durations are measured in centiseconds.

§2. AIFF files.

```
int get_aiff_duration(FILE *pFile, unsigned int *pDuration,
    unsigned int *pBitsPerSecond, unsigned int *pChannels, unsigned int *pSampleRate) {
    unsigned int sig;
    unsigned int chunkID;
    unsigned int chunkLength;
    unsigned int numSampleFrames;
    unsigned int sampleSize;
    if (!read_int32(pFile, &sig)) return FALSE;
    if (sig != 0x464F524D) return FALSE;                          "FORM" indicating an IFF file
    if (!read_int32(pFile, &sig)) return FALSE;
    if (!read_int32(pFile, &sig)) return FALSE;
    if (sig != 0x41494646) return FALSE;                          "AIFF" indicating an AIFF file
    Read chunks, skipping over those we are not interested in
    while (TRUE) {
        if (!read_int32(pFile, &chunkID)) return FALSE;
        if (!read_int32(pFile, &chunkLength)) return FALSE;
        if (chunkID == 0x434F4D4D) {                              "COMM" indicates common AIFF data
            if (chunkLength < 18) return FALSE;                     Check we have enough data to read
            if (!read_int16(pFile, pChannels))          return FALSE;
            if (!read_int32(pFile, &numSampleFrames))  return FALSE;
            if (!read_int16(pFile, &sampleSize))       return FALSE;
            if (!read_float80(pFile, pSampleRate))      return FALSE;
            if (*pSampleRate == 0) return FALSE;                  Sanity check to avoid a divide by zero
            Result is in centiseconds
            *pDuration = ((unsigned long long) numSampleFrames * 100) / *pSampleRate;
            *pBitsPerSecond = *pSampleRate * *pChannels * sampleSize;
            return TRUE;
        } else {
            Skip unwanted chunk
            if (fseek(pFile, chunkLength, SEEK_CUR) != 0) return FALSE;
        }
    }
    *pDuration = 0;
    return FALSE;
}
```

The function get_aiff_duration is called from 10/sfx.

§3. OGG Vorbis files.

```
int get_ogg_duration(FILE *pFile, unsigned int *pDuration,
    unsigned int *pBitsPerSecond, unsigned int *pChannels, unsigned int *pSampleRate) {
    unsigned int sig;
    unsigned int version;
    unsigned int numSegments;
    unsigned int packetType;
    unsigned int vorbisSig1;
    unsigned int vorbisSig2;
    unsigned int seekPos;
    unsigned int fileLength, bytesToRead, lastSig, index;
    unsigned long long granulePosition;
    unsigned char buffer[256];
    if (!read_int32(pFile, &sig)) return FALSE;
    if (sig != 0x4F676753) return FALSE;                          "OggS" indicating an OGG file
    Check OGG version is zero
    if (!read_int8(pFile, &version)) return FALSE;
    if (version != 0) return FALSE;
    Skip header type, granule position, serial number, page sequence and CRC
    if (fseek(pFile, 21, SEEK_CUR) != 0) return FALSE;
    Read number of page segments
    if (!read_int8(pFile, &numSegments)) return FALSE;
    Skip segment table
    if (fseek(pFile, numSegments, SEEK_CUR) != 0) return FALSE;
    Vorbis Identification header
    if (!read_int8(pFile, &packetType)) return FALSE;
    if (packetType != 1) return FALSE;
    if (!read_int32(pFile, &vorbisSig1)) return FALSE;
    if (vorbisSig1 != 0x766F7262) return FALSE;                                  "VORB"
    if (!read_int16(pFile, &vorbisSig2)) return FALSE;
    if (vorbisSig2 != 0x6973) return FALSE;                                       "IS"
    Check Vorbis version is zero
    if (!read_int32(pFile, &version)) return FALSE;
    if (version != 0) return FALSE;
    Read number of channels
    if (!read_int8(pFile, pChannels)) return FALSE;
    Read sample rate
    if (!read_int32(pFile, pSampleRate)) return FALSE;
    swap_bytes32(pSampleRate);                                    Ogg Vorbis uses LSB first
    Skip bitrate maximum
    if (fseek(pFile, 4, SEEK_CUR) != 0) return FALSE;
    Read Nominal Bitrate
    if (!read_int32(pFile, pBitsPerSecond)) return FALSE;
    swap_bytes32(pBitsPerSecond);                                 Ogg Vorbis uses LSB first
    Encoders can be unhelpful and give no bitrate in the header
    if (pBitsPerSecond == 0) return FALSE;
    Search for the final Ogg page (near the end of the file) to read duration,
    i.e., read the last 4K of the file and look for the final "OggS" sig
    if (fseek(pFile, 0, SEEK_END) != 0) return FALSE;
```

```
    fileLength = ftell(pFile);
    seekPos = fileLength - 4096;
    if (seekPos < 0) seekPos = 0;
    lastSig = -1;
    while (seekPos < fileLength) {
        if (fseek(pFile, seekPos, SEEK_SET) != 0) return FALSE;
        bytesToRead = fileLength - seekPos;
        if (bytesToRead > 256) bytesToRead = 256;
        if (fread(buffer, 1, bytesToRead, pFile) != bytesToRead) return FALSE;
        for(index = 0; index < bytesToRead; index++) {
            if ((buffer[index] == 0x4F) &&
                (buffer[index + 1] == 0x67) &&
                (buffer[index + 2] == 0x67) &&
                (buffer[index + 3] == 0x53)) {
                lastSig = seekPos + index;
            }
        }
        Next place to read from is 256 bytes further on, but to catch
        sigs that span between these blocks, read the last four bytes again
        seekPos += 256 - 4;
    }
    if (lastSig == -1) return FALSE;
    if (fseek(pFile, lastSig, SEEK_SET) != 0) return FALSE;
    if (!read_int32(pFile, &sig)) return FALSE;
    if (sig != 0x4F676753) return FALSE;                    "OggS" indicating an OGG file
    Check OGG version is zero
    if (!read_int8(pFile, &version)) return FALSE;
    if (version != 0) return FALSE;
    Skip header Type
    if (fseek(pFile, 1, SEEK_CUR) != 0) return FALSE;
    if (!read_int64(pFile, &granulePosition)) return FALSE;
    swap_bytes64(&granulePosition);
    *pDuration = (unsigned int) ((granulePosition * 100) /
                    (unsigned long long) *pSampleRate);
    return TRUE;
}
```

The function get_ogg_duration is called from 10/sfx.

§4. MIDI files. At one time it was proposed that Inform 7 should allow a third sound file format: MIDI. This provoked considerable debate in July 2007 and enough doubts were raised that the implementation below was never in fact officially used. It is preserved here in case we ever revive the issue.

Inform is not really able to decide this for itself, in any case, since it can only usefully provide sound files which the virtual machines it compiles for will allow. At present, the Glulx virtual machine does not officially support MIDI, which makes the question moot.

```
int get_midi_file_information(FILE *pFile, unsigned int *pType,
    unsigned int *pNumTracks) {
    unsigned int sig;
    unsigned int length;
    unsigned int pulses;
    unsigned int frames_per_second;
    unsigned int subframes_per_frame;
    unsigned int clocks_per_second;
    unsigned int start_of_chunk_data;
    unsigned int status;
    unsigned int clocks;
    unsigned int sysex_length;
    unsigned int non_midi_event_length;
    unsigned int start_of_non_midi_data;
    unsigned int non_midi_event;
    if (!read_int32(pFile, &sig)) return FALSE;
    "RIFF" indicating a RIFF file
    if (sig == 0x52494646) {
        Skip the filesize and typeID
        if (fseek(pFile, 8, SEEK_CUR) != 0) return FALSE;
        now read the real MIDI sig
        if (!read_int32(pFile, &sig)) return FALSE;
    }
    "MThd" indicating a MIDI file
    if (sig != 0x4D546864) return FALSE;
    Read length of chunk
    if (!read_int32(pFile, &length)) return FALSE;
    Make sure we have enough data to read
    if (length < 6) return FALSE;
    Read the MIDI type: 0,1 or 2
    0 means one track containing up to 16 channels to make a single tune
    1 means one or more tracks, commonly each with a single channel, making up a single tune
    2 means one or more tracks, where each is a separate tune in it's own right
    if (!read_int16(pFile, pType)) return FALSE;
    Read the number of tracks
    if (!read_int16(pFile, pNumTracks)) return FALSE;
    Read "Pulses Per Quarter Note" (PPQN)
    if (!read_int16(pFile, &pulses)) return FALSE;
    if top bit set, then number of subframes per second can be deduced
    if (pulses >= 0x8000) {
        First byte is a negative number for the frames per second
        Second byte is the number of subframes in each frame
        frames_per_second    = (256 - (pulses & 0xff));
        subframes_per_frame  = (pulses >> 8);
```

```
    clocks_per_second    = frames_per_second * subframes_per_frame;
    LOG("frames_per_second   = %d\n",   frames_per_second);
    LOG("subframes_per_frame = %d\n", subframes_per_frame);
    LOG("clocks_per_second   = %d\n",   clocks_per_second);
    Number of pulses per quarter note unknown
    pulses = 0;
} else {
    unknown values
    frames_per_second    = 0;
    subframes_per_frame  = 0;
    clocks_per_second    = 0;
    LOG("pulses per quarter note = %d\n",   pulses);
}
Skip any remaining bytes in the MThd chunk
if (fseek(pFile, length - 6, SEEK_CUR) != 0) return FALSE;
Keep reading chunks, looking for "MTrk"
do {
    Read chunk signature and length
    if (!read_int32(pFile, &sig)) {
        if (feof(pFile)) return TRUE;
        return FALSE;
    }
    if (!read_int32(pFile, &length)) return FALSE;
    start_of_chunk_data = ftell(pFile);
    if (sig == 0x4D54726B) {                                                    "MTrk"
        LOG("track starts\n");
        Read each event, looking for information before the real tune starts, e.g., tempo
        do {
            Read the number of clocks since the previous event
            if (!read_variable_length_integer(pFile, &clocks))
                return FALSE;
            We bail out when the track starts
            if (clocks > 0) break;
            Read the MIDI Status byte
            if (!read_int8(pFile, &status)) return FALSE;
            Start or continuation of system exclusive data
            if ((status == 0xF0) || (status == 0xF7)) {
                Read length of system exclusive event data
                if (!read_variable_length_integer(pFile, &sysex_length)) return FALSE;

        Reached end of file
        if (feof(pFile)) return TRUE;
        Did we try to seek beyond the end of the file?
        if (ftell(pFile) < (start_of_chunk_data + length)) return TRUE;
    }
    while (TRUE);
    return TRUE;
}
```

The function get_midi_file_information is called from 10/sfx.

Make Inform 6 Names 2/isn

Purpose

To construct valid Inform 6 identifiers, dictionary word constants and double-quoted string constants as needed.

2/isn.§1 Automatically composed identifiers; §2-5 Explicitly translated identifiers; §6 I6 dictionary words; §7-8 I6 quoted text

---

§**1. Automatically composed identifiers.** A legal I6 identifier is a sequence of 1 to 31 characters, which must be alphanumeric or else underscores, except that the leading character must not be a 0.

For the sake of legibility of the I6 generated by NI, we adapt natural language descriptions to this format as best we can, in a standardised pattern which uses an identifying letter (e.g., A for Action), a unique ID number (preventing I6 name-clashes) and then a truncated alphanumeric-safe form of the words used in the textual description, if any. For example, an object called "apple crumble" might have I6 identifier `O100_apple_crumble`. Any other object also called "apple crumble" would have a different identifier since the number parts would be different.

Beginning with the identifying letter ensures that we do not open with a 0 digit.

We truncate to 28 characters in length so that other routines can concatenate our identifier with up to 3 further characters, if they choose.

```
void isn_compose_identifier(char *ledger,
    char nature_character, int id_number, int w1, int w2) {
    int j;
    char identifier[64];
    sprintf(identifier, "%c%d", nature_character, id_number);
    if ((w1>=0) && (w2>=w1)) {
        for (j=w1; j<=w2; j++) {
            identifier is at this point 32 chars or fewer in length: add at most 30 more
            if (strlen(lw_array[j].lw_text) > 30) sprintf(identifier + strlen(identifier), " etc");
            else sprintf(identifier + strlen(identifier), " %s", lw_array[j].lw_text);
            if (strlen(identifier) > 32) break;
        }
    }
    identifier[28] = 0;                          it was at worst 62 chars in size, but is now truncated to 28
    for (j=0; identifier[j]; j++) {
        int x = identifier[j];
        if (!(((x >= '0') && (x <= '9')) ||
            ((x >= 'a') && (x <= 'z')) || ((x >= 'A') && (x <= 'Z')) || (x == '_')))
            identifier[j] = '_';
    }
    strcpy(ledger, identifier);
}
```

The function isn_compose_identifier is called from 7/data, 9/qty, 9/prop, 9/model, 10/tab, 10/eqns, 10/exf, 11/act, 11/av and 12/rb.

§**2. Explicitly translated identifiers.** I7 provides the ability for the user to specify exactly what identifier name to use as the I6 image of something, overriding the automatically composed name above, in some cases. The following routine parses, tidies up and acts on "... translates into I6 as ..." sentences; it gives their sentence nodes an annotation marking what sort of thing is being translated.

```
define INVALID_I6TR 0
define PROPERTY_I6TR 1                                  "The open property translates into I6 as "open"."
define WORLD_OBJECT_I6TR 2                              "The north object translates into I6 as "n_obj"."
define RULE_I6TR 3                                      "The baffling rule translates into I6 as "BAFFLING_R"."
define VARIABLE_I6TR 4                                  "The sludge count variable translates into I6 as "sldgc".
define ACTION_I6TR 5                                    "The taking action translates into I6 as "Take".
define GRAMMAR_TOKEN_I6TR 6          "The grammar token "[whatever]" translates into I6 as "WHATEVER".
```

```
sentence_handler TRANSLATES_SH_handler =
    { SENTENCE_NT, TRANSLATES_VB, 0, translates_into_I6_as };

void translates_into_I6_as(parse_node *pn) {
    parse_node *p1 = pn->down->next;
    parse_node *p2 = pn->down->next->next;
    int category = INVALID_I6TR, w1, w2;
    if (traverse == 1) {
        pn_annotate_int(pn, category_of_I6_translation_ANNOT, INVALID_I6TR);
        ⟨Ensure that we are translating to a quoted I6 identifier 4⟩;
        [[w1, w2 <-- p1]];
        [[w1, w2 == the ... --> w1, w2]]; p1->word_ref1 = w1;
        if [[w1, w2 == ... property]] { p1->word_ref2--; category = PROPERTY_I6TR; }
        else if [[w1, w2 == ... object/kind]] { p1->word_ref2--; category = WORLD_OBJECT_I6TR; }
        else if [[w1, w2 == ... rule]] { category = RULE_I6TR; }
        else if [[w1, w2 == ... variable]] { p1->word_ref2--; category = VARIABLE_I6TR; }
        else if [[w1, w2 == ... action]] { p1->word_ref2--; category = ACTION_I6TR; }
        else if [[w1, w2 == understand token ...]] { p1->word_ref1 += 2; category = GRAMMAR_TOKEN_I6TR;
}
        else {
            sentence_problem(_P_(C2TranslatedUnknownCategory),
                "that isn't one of the things which can be translated to I6",
                "and should be '... property', '... object', '... kind', '... rule', or "
                "'... action'. For instance, 'The yourself object translates into "
                "I6 as \"selfobj\".'");
            return;
        }
        pn_annotate_int(pn, category_of_I6_translation_ANNOT, category);
    } else category = pn_int_annotation(pn, category_of_I6_translation_ANNOT);
    ⟨Take immediate action on the translation where possible 3⟩;
}
```

§**3.** In some cases, we might as well act now; but in others we will act later, traversing the parse tree to look for translation sentences of the right sort.

⟨Take immediate action on the translation where possible 3⟩ ≡
```
switch(category) {
    case PROPERTY_I6TR:
        property_translates(pn);
        pn_annotate_int(pn, category_of_I6_translation_ANNOT, INVALID_I6TR); break;
    case WORLD_OBJECT_I6TR: break;
    case RULE_I6TR: if (traverse == 2) handle_library_rule(pn); break;
    case VARIABLE_I6TR: if (traverse == 2) qty_translates(pn); break;
    case ACTION_I6TR: if (traverse == 2) an_translates(pn); break;
    case GRAMMAR_TOKEN_I6TR: if (traverse == 2) gv_translates(pn); break;
}
```

This code is used in §2.

§**4.** The word "as" is still loose here because "translates into I6 as" was too much for the sentence-breaker to swallow, so it broke at "translates into I6" and we therefore have to detect the "as" here ourselves.

⟨Ensure that we are translating to a quoted I6 identifier 4⟩ ≡
```
int valid = TRUE, w1, w2;
[[w1, w2 <-- p2]];
if ((![[w1, w2 == as ###]]) || (vocab_test_flags(w2, TEXT_MC) == 0)) valid = FALSE;
if (valid) ⟨Dequote it and see if it's valid 5⟩;
if (valid == FALSE) {
    sentence_problem(_P_(C2TranslatedToNonIdentifier),
        "Inform 7 constructions can only translate into quoted I6 identifiers",
        "which must be strings of 1 to 31 characters drawn from 1, 2, ..., 9, "
        "a or A, b or B, ..., z or Z, or underscore '_', except that the "
        "first character is not allowed to be a digit.");
    return;
}
```

This code is used in §2.

§**5.** If it turns out not to be, we simply set `valid` to false.

⟨Dequote it and see if it's valid 5⟩ ≡
```
int i;
char *p;
p2->word_ref1 = w2;
dequote_word(w2);
p = lw_array[w2].lw_text;
if ((strlen(p) == 0) || (strlen(p) > 31)) valid = FALSE;
for (i=0; p[i]; i++)
    if ((isdigit(p[i]) == 0) && (isalpha(p[i]) == 0) && (p[i] != '_'))
        valid = FALSE;
if (isdigit(p[0])) valid = FALSE;
```

This code is used in §4.

§6. I6 dictionary words. We now take an ISO Latin-1 string and compile an I6 dictionary word constant to lodge the same text into the virtual machine's parsing dictionary.

A legal I6 dictionary word can take several forms: it can be in single quotes, `'thus'`, but only if it is more than one character long, since `'t'` would be the character value of lower-case T instead. (Or it can be double-quoted `"so"`, but only in grammar or properties; this usage is deprecated and we avoid it.) Within the dictionary word, `^` is an escape character meaning a literal single quote, and the notation `@{xx}` is an escape meaning the character with hexadecimal value `xx`.

Optionally, a dictionary word can end with a pair of slashes and then, optionally again, markers to indicate that the word is (for instance) a plural: thus `'newts//p'`. Using no markers, as in `'toads//'`, makes a word equivalent to that without a marker, but avoids the single-letter problem – so the preferred modern way to write a single-character I6 dictionary word is `'t//'`, and this is what the following routine does. (Note the exceptional case where the word consists only of a `'/'`: here we cannot write `'///'` because I6 reads this as `//` plus an invalid marker `/`, and throws an error. We escape the single `/` to avoid this. In all other cases there's no need to escape a `/`.)

Dictionary words with a literal `~` in are, as it happens, not parsable by the Z-machine, but the code below – employing the `@{7E}` escape – is in principle legal, and it does work on Glulx.

```
void isn_compile_dictionary_word(OUTPUT_STREAM, char *p, int pluralise) {
    int c;
    WRITE("'");
    for (c=0; p[c] != 0; c++) {
        switch(p[c]) {
            case '/': if (p[1] == 0) WRITE("@{2F}"); else WRITE("/"); break;
            case '\'': WRITE("^"); break;
            case '^': WRITE("@{5E}"); break;
            case '~': WRITE("@{7E}"); break;
            case '@': WRITE("@{40}"); break;
            default: WRITE("%c", p[c]);
        }
    }
    if (pluralise) WRITE("//p");
    else if (strlen(p) == 1) WRITE("//");
    WRITE("'");
}
```

The function isn_compile_dictionary_word is called from 5/litp, 9/cot, 13/gv, 13/gl, 13/gtok, 13/gprv and 13/gpr.

§7. I6 quoted text. We now take an ISO Latin-1 string and compile a double-quoted I6 string constant which will print out the same content, or initialise a string array.

A subtly different set of escape characters are used here. It's all trickier than it might be because of some unfortunate design choices in I6. For instance, an `@` character can't be escaped as `@{40}` because that would be expanded too early in the string-reading process, so that it would still be read as an escape-character `@`, not a literal one. We therefore have to use `@@64`. This unfortunately goes wrong, however, when the immediately following character is a decimal digit, because then we might construct, e.g., `@@647`, and I6 will throw an error: no valid character has ZSCII code 647. We therefore use the `@{...}` escape to represent any digit following an `@@` escape. Since no digit is itself an escape character with side-effects, a vicious circle is avoided.

Initialisation of I6 string arrays has different conventions again: these behave more like dictionary words and the `@@` escape is not allowed.

define `ISN_CAPITALISE 1` *capitalise first letter of text*
define `ISN_EXPAND_APOSTROPHES 2` *sometimes regard ' as "*
define `ISN_RECOGNISE_APOSTROPHE_SUBSTITUTION 4` *recognise ['] as a literal '*

define ISN_DEQUOTE 8 *ignore initial and terminal " pair, e.g., render* `"fish"` *as* `fish`
define ISN_FOR_ARRAY 16 *force use of* `@{xx}` *form not* `@@ddd`
define ISN_FLATTEN_NEWLINES 32 *convert any* `'\n'` *to a simple space*

```
void isn_compile_string(OUTPUT_STREAM, char *p, int options) {
    int i, from = 0, to = strlen(p), esc_digit = FALSE;
    if ((options & ISN_DEQUOTE) && (p[0] == '"') && (p[to-1] == '"')) {
        from++; to--;
    }
    for (i=from; i<to; i++) {
        switch(p[i]) {
            case '\n':
                if (options & ISN_FLATTEN_NEWLINES) WRITE(" "); else WRITE("\n");
                break;
            case NEWLINE_IN_STRING: WRITE("^"); break;
            case '"': WRITE("~"); break;
            case '@':
                if (options & ISN_FOR_ARRAY) WRITE("@{40}");
                else { WRITE("@@64"); esc_digit = TRUE; continue; }
                break;
            case '^':
                if (options & ISN_FOR_ARRAY) WRITE("@{5E}");
                else { WRITE("@@94"); esc_digit = TRUE; continue; }
                break;
            case '~':
                if (options & ISN_FOR_ARRAY) WRITE("@{7E}");
                else { WRITE("@@126"); esc_digit = TRUE; continue; }
                break;
            case '\\': WRITE("@{5C}"); break;
            case '\'':
                if (options & ISN_EXPAND_APOSTROPHES)
                    ⟨Apply Inform 7's convention on interpreting single quotation marks 8⟩
                else WRITE("'");
                break;
            case '[':
                if ((options & ISN_RECOGNISE_APOSTROPHE_SUBSTITUTION) &&
                    (p[i+1] == '\'') && (p[i+2] == ']')) { i += 2; WRITE("'"); }
                else WRITE("[");
                break;
            default:
                if ((i==0) && (options & ISN_CAPITALISE))
                    WRITE("%c", toupper(p[i]));
                else if ((esc_digit) && (isdigit(p[i])))
                    WRITE("@{%02x}", p[i]);
                else
                    WRITE("%c", p[i]);
                break;
        }
        esc_digit = FALSE;
    }
}
```

The function isn_compile_string is called from 5/litp, 9/rsdt, 9/cot, 10/str, 12/cph and 13/test.

§**8.** This is where Inform's convention on expanding single quotation marks to double, provided they appear to be quoting text rather than used as apostrophes in contractions such as "don't", is implemented. Note the exceptional case.

⟨Apply Inform 7's convention on interpreting single quotation marks 8⟩ ≡

```
if ((i==from) && (p[i+1] == 's') && ((to == 3) || (p[i+2] == ' ')))
    WRITE("'");                                  allow apostrophe if appending e.g. "'s nose" to "Jane"
else if ((i>0) && (p[i+1]) && (isalpha(p[i-1])) && (isalpha(p[i+1])))
    WRITE("'");                                  allow apostrophe sandwiched between two letters
else WRITE("~");                                 and otherwise convert to double-quote
```

This code is used in §7.

Purpose

I7 is has no Dijkstra-like conscience about compiling code which is full of I6 `jump` statements, and these require labels to jump to. This section provides those labels, and other related unique-ID-number counters.

Template interpreter commands

```
4   {-callv:compile_allocated_counter_storage}
```

Definitions

¶1. For clarity we give each label in the whole I6 program its own unique name (even though this is not strictly necessary since labels have only local scope to their routines), and this means allowing for sets of labels with a unique ID number providing guaranteed-previously-unused new labels in every set.

So: each set of labels is identified with a name, and the labels written take the form `L_NameNumber`. For instance, `L_Marble17` is the 18th label in namespace `Marble`. Every label namespace's name must differ from every other. It is legal for a namespace's name to be the empty string, which generates labels `L_0`, `L_1`, ...

```
define MAX_NAMESPACE_PREFIX_LENGTH 20          when L_ and a number are added, we are within 31 chars

typedef struct label_namespace {
    char label_prefix[MAX_NAMESPACE_PREFIX_LENGTH + 1];
    int label_counter;                                  next free ID number for this label namespace
    int allocate_storage;                          number of words of memory to reserve for each label
    MEMORY_MANAGEMENT
} label_namespace;
```

The structure label_namespace is private to this section.

---

§**1.** The creator for new label namespaces. Note that, by default, a label namespace reserves no memory.

```
label_namespace *lns_new(char *name) {
    label_namespace *lns;
    int i;
    if (strlen(name) > MAX_NAMESPACE_PREFIX_LENGTH)
        sentence_problem(_P_(C2LabelNamespaceTooLong),
            "a label namespace prefix is too long",
            "and should be shortened to a few alphabetic characters.");
    lns = CREATE(label_namespace);
    for (i=0; (name[i]) && (i<MAX_NAMESPACE_PREFIX_LENGTH); i++)
        lns->label_prefix[i] = name[i];
    lns->label_prefix[i] = 0;
    lns->label_counter = 0;
    lns->allocate_storage = 0;
    return lns;
}
```

§**2.** The rest of NI tends not to store pointers to namespaces: instead it must access them by searching on the name. This is inefficient, but there are few namespaces and it happens fairly seldom, so there is no point in optimising.

```
label_namespace *lns_by_prefix(char *name) {
    label_namespace *lns;
    LOOP_OVER(lns, label_namespace)
        if (strcmp(name, lns->label_prefix) == 0)
            return lns;
    return NULL;
}
label_namespace *lns_read_or_create(char *name) {
    label_namespace *lns = lns_by_prefix(name);
    if (lns == NULL) lns = lns_new(name);
    return lns;
}
```

§**3.** The rest of NI is allowed only to call for a label in a given namespace, advancing the counter or not as it pleases; or to call for the current counter value.

```
void lns_zero_counter(char *namespace) {
    label_namespace *lns = lns_read_or_create(namespace);
    lns->label_counter = 0;
}
int lns_read_counter(char *namespace, int advance_flag) {
    label_namespace *lns = lns_read_or_create(namespace);
    int c = lns->label_counter;
    if (advance_flag) lns->label_counter++;
    return c;
}
void lns_write(char *namespace, OUTPUT_STREAM, int advance_flag) {
    label_namespace *lns = lns_read_or_create(namespace);
    WRITE("L_%s%d", lns->label_prefix, lns->label_counter);
    if (advance_flag) lns->label_counter++;
}
```

The function lns_zero_counter is called from 12/cinv.

The function lns_read_counter is called from 12/cinv and 14/i6t.

The function lns_write is called from 12/cinv.

§**4.** It is possible to mark a namespace as requiring 1 or more words of storage. If so, the namespace `Whatsit` makes a word array called `I7_ST_Whatsit` which contains enough words for each label actually allocated to have that many words of storage. (And we add 2 words, to provide a safety margin, and because in the event of a namespace for which no labels are created, I6 would otherwise throw an error at being asked to make an array with the specification `--> 0`.)

```
void lns_allocate_storage(char *namespace, int multiplier) {
    label_namespace *lns = lns_read_or_create(namespace);
    lns->allocate_storage = multiplier;
}
void compile_allocated_counter_storage(OUTPUT_STREAM) {
    label_namespace *lns;
    LOOP_OVER(lns, label_namespace)
        if (lns->allocate_storage > 0)
            WRITE("Array I7_ST_%s --> %d;\n",
                lns->label_prefix, (lns->allocate_storage)*(lns->label_counter)+2);
}
```

The function lns_allocate_storage is called from 12/cinv.

The function compile_allocated_counter_storage is invoked by a command in a `.i6t` template file.

HTML Files 2/html

Purpose

To provide utilities for writing HTML files such as the problems report, the extension documentation, the index files and so forth.

---

§**1.** Inform documentation – its HTML text and the images, etc., used within it – is stored in two areas: "built-in" and "external". The built-in area is expected to be within the Inform 7 application itself. For instance, on OS X, this is at:

`...wherever.../Inform.app/Contents/Resources/` and/or

`...wherever.../Inform.app/Contents/Resources/English.lproj/`

(The duplication is a complication to do with localisation which we can ignore here.) The material stored in this built-in area is fixed: the Inform application needs to work even if stored on a read-only disc, or where the user has insufficient permissions to alter it. NI itself neither reads from, nor writes to, any file in the built-in documentation area.

Documentation for the installed extensions does, however, change: it is written by NI as and when necessary. This is the material making up the "external" area, and it needs to be somewhere which the user certainly has the necessary permissions to write to. For instance:

`~/Library/Inform/Documentation/` (OS X)

`My Documents\Inform\Documentation\` (Windows)

Pages in these two areas, built-in and external, need to link to each other by `<a href=...>` links: in addition, pages in the external area need access to images stored in the built-in area.

The other HTML files written by NI are stored within the relevant project's bundle: these are the report of Problems (if any) and the Index. They, too, need access to images stored in the built-in area.

The problem we face is that these three mini-websites – the built-in documentation, the external documentation, and the project-specific pages – are written by tools which cannot know the correct file URLs. (For instance, it would not even help for the application to tell NI where the built-in area is: because the HTML written by NI would then cease to work if the user moved the application elsewhere in the filing system after NI had run.)

§**2. The "inform:" URL scheme.** We solve this by requiring that the Inform 7 application must support a new URL scheme.

(a) `<inform://...>` is interpreted as a file in the built-in documentation area, except that

(b) `<inform://Extensions/...whatever...>` should be fetched by first checking for "...whatever..." in the external area, and then – if that fails – also checking for "...whatever..." in the `ExtnDocs` subfolder of the built-in area.

For instance, Inform 7 for OS X would look for `inform://Extensions/magic.png` at the following locations:

(i) `~/Library/Inform/Documentation/magic.png`

(ii) `.../Inform.app/Contents/Resources/ExtnDocs/magic.png`

If no file was found in either place, the link should simply do nothing: the application is required not to produce a 404 error page, or to blank out the page currently showing.

§3. The "source:" URL scheme. The other non-standard Inform URL scheme is "source:", which is used for a link which, when clicked, opens the Source panel with the given line made visible.

For instance, line 21 of file `Bits and Pieces/marbles.txt` has URL

`source:Bits and Pieces/marbles.txt#line14`

Filenames are given relative to the current project bundle. However, if only a leafname is supplied, then this is read as a file within the `Source` subfolder of the project bundle. (Thus it is not possible to have a source link to a source file at the root of the project bundle: but this is no loss, since source is not allowed to be kept there.) For instance, line 14 of file `Source/story.ni` has URL

`source:story.ni#line14`

The following routine writes the clickable source-reference icon, and is the only place in NI where "source:" is used.

Source which is generated internally to NI cannot be opened in the Source panel, for obvious reasons, so we produce nothing if the location is internal.

```
void html_source_link(OUTPUT_STREAM, source_location sl) {
    if (sl.file_of_origin) {
        char *filename = sf_get_filename(sl.file_of_origin);
        if (bundle_name && (strncmp(filename, bundle_name, strlen(bundle_name)) == 0))
            filename += strlen(bundle_name) + 1;
        if ((strncmp(filename, "Source", 6)==0) && (filename[6]==FOLDER_SEPARATOR))
            filename += 7;
        WRITE(" <a href=\"source:%s#line%d\"><img border=0 src=inform:/Reveal.%s></a>",
            filename, sl.line_number, ICON_EXT);
    }
}
```

The function html_source_link is called from 2/index.

§4. Icons with and without tooltips. Tooltips are the evanescent pop-up windows which appear, a little behind the mouse arrow, when it is poised waiting over the icon. (We make heavy use of these in the World index, for instance, to clarify what abbreviations mean.)

```
void html_icon_with_tooltip(OUTPUT_STREAM, char *icon_name, char *tip, char *tip2) {
    WRITE("<img border=0 src=inform:/doc_images/%s ", icon_name);
    if (tip) {
        WRITE("title=\"%s", tip); if (tip2) WRITE(" %s", tip2); WRITE("\"");
    }
    WRITE(">");
}
```

The function html_icon_with_tooltip is called from 12/br.

§**5. Outcome images.** These are the two images used on the Problems page to visually indicate success or failure. We also use special images on special occasions.

The date of Easter depends on who and where you are. Inform's notional home is England. Following League of Nations advice in 1926, Easter is legally celebrated in England on the Sunday after the second Saturday in April, but a let-out clause allowed the churches to continue the old methods as an interim measure. The interim shows no sign of ending, so we have to turn to the church, and this is where it becomes complicated. There are five main algorithms ordained by major Christian churches: Catholic, continental European Protestant, Church of England, Eastern and Russian Orthodox. The first three always agree on the date, but usually disagree with the last two. The two eastern algorithms only disagree with each other once or twice a century, but the usual result has been riots with significant loss of life.

We will ignore the clumsy *Book of Common Prayer* method adopted by the Church of England as a political manoeuvre during the reign of George II and instead use the algorithm of J.-M. Oudin (*Étude sur la date de Pâques*, Bulletin astronomique, 1940), in a form now published by the US Naval Observatory: Oudin corrected a small mistake in the calculation by Gauss (1800) of the *Allgemeiner Reichskalender* (1776) which reconciled Lutheran Easter with Gregorian, which in turn followed the calendrical reforms of Clavius et al. (1582), which in turn... and so on. For a bewilderingly involved account of the classical history, see Leofranc Holford-Strevens, *The History of Time* (Oxford, 2005).

In principle we calculate the first Sunday after the first ecclesiastical moon that occurs on or after March 21. An "ecclesiastical moon" is one as seen from a longitude near Rome, but the ratios used to adjust lunar and solar calendars are not quite right. The result is also tampered with to stop Easter from coinciding with the pagan anniversary of the founding of Rome (for the convenience of people living in the Vatican) and also to stop it from coinciding with the Jewish Passover (a change motivated purely by anti-Semitism, playing down that the event commemorated the arrest of a Jew at the time of Passover). They botched this tampering, too.

Knuth remarks that calculating Easter was almost the only algorithmic research in the West for many centuries. Nevertheless the result is practically a random-number generator. The one thing to be said in its favour is that it can be computed accurately with integer arithmetic using fairly low numbers, and this we now do.

```
void html_outcome_image(OUTPUT_STREAM, char *image) {
    char *vn = "";
    int c, y, k, i, n, j, l, m, d;
    int this_month = the_present->tm_mon + 1;
    int this_day = the_present->tm_mday;
    int this_year = the_present->tm_year + 1900;

    y = this_year;

    c = y/100;
    n = y-19*(y/19);
    k = (c-17)/25;
    i = c-c/4-(c-k)/3+19*n+15;
    i = i-30*(i/30);
    i = i-(i/28)*(1-(i/28)*(29/(i+1))*((21-n)/11));
    j = y+y/4+i+2-c+c/4;
    j = j-7*(j/7);
    l = i-j;
    m = 3+(l+40)/44;
    d = l+28-31*(m/4);

    if ((this_month == m) && (this_day >= d-2) && (this_day <= d+1))
        vn = "_3";                                   that is, Good Friday to Easter Monday
    if ((this_year == 2018) && (this_month == 3) && (this_day >= 30))
        vn = "_3";                                   Easter Sunday falls on 1 April in 2018
```

```
    if ((this_month == 12) && (this_day >= 25))
        vn = "_2";                                    that is, Christmas Day to New Year's Eve
    WRITE("<p><center><img src=inform:/%s%s.png border=0></center><p>", image, vn);
}
```

The function html_outcome_image is called from 2/prob2.

§**6. Header and footer.** Cascading style sheets provide indentation levels of 0, 1, 2, 3 or 4 tabs deep, the tab stops being 25 pixels apart, and hanging indents. Rather than providing a `.css` file, we define this small amount of CSS in the HTML header.

The default font varies from platform to platform: for instance, on OS X we use the Lucida font.

```
void html_header(OUTPUT_STREAM, char *title, char *thumbnail, char *caption) {
    WRITE("<html><head><meta http-equiv=\"content-type\" ");
    WRITE("content=\"text/html; charset=UTF-8\">\n"); INDENT;
    WRITE("<style type=\"text/css\">\n");
    WRITE("<!--\n"); INDENT;
    WRITE("p.hang {\n"); INDENT;
    WRITE("padding-left: 25px;\n");
    WRITE("text-indent: -25px;\n");
    WRITE("margin-top: 0px;\n");
    WRITE("margin-bottom: 0px;\n");
    OUTDENT; WRITE("}\n");
    int margin;
    for (margin = 1; margin<=9; margin++) {
        WRITE("p.in%d {\n", margin); INDENT;
        WRITE("padding-left: %dpx;\n", (margin-1)*25);
        OUTDENT; WRITE("}\n");
        WRITE("p.tightin%d {\n", margin); INDENT;
        WRITE("padding-left: %dpx;\n", (margin-1)*25);
        WRITE("margin-top: 2px;\n");
        WRITE("margin-bottom: 2px;\n");
        OUTDENT; WRITE("}\n");
        WRITE("p.hangingin%d {\n", margin); INDENT;
        WRITE("padding-left: %dpx;\n", (margin+1)*25);
        WRITE("text-indent: -50px;\n");
        WRITE("margin-top: 0px;\n");
        WRITE("margin-bottom: 1px;\n");
        OUTDENT; WRITE("}\n");
    }
    WRITE("div.hr {\n"); INDENT;
    WRITE("border: 0;\n");
    WRITE("width: 100%%;\n");
    WRITE("color: #707070;\n");
    WRITE("background-color: #707070;\n");
    WRITE("height: 5px;\n");
    OUTDENT; WRITE("}\n");
    OUTDENT; WRITE("-->\n");
    OUTDENT; WRITE("</style>\n");
    WRITE("</head>\n");
    WRITE("<body>");
    if (JAVASCRIPT_MODEL == 1) {
        WRITE("<script language=\"JavaScript\">");
```

```
        WRITE("function pasteCode(code) { ");
        WRITE("var myProject = window.Project; ");
        WRITE("myProject.selectView('source'); ");
        WRITE("myProject.pasteCode(code); ");
        WRITE("}");
        WRITE("</script>\n");
    }
    WRITE("<font %s>", DEFAULT_HTML_FONT);
    if (thumbnail) {
        open_coloured_box(OUT, "e0e0e0");
        begin_html_table(OUT, NULL, TRUE, 0, 0, 0, 0, 0);
        first_html_column(OUT, 72);
        WRITE("<img border=1 src=inform:/doc_images/%s title=\"%s\"> ", thumbnail, caption);
        next_html_column(OUT, 0);
    }
    if (title[0]=='<') {                                    used for a details page beneath the page titled thus
        WRITE("<h3><b>%s</b>: Detail view  "
            "<a href=../%s.html><font color=\"#002060\"><i>Back to full view</i></font></a></h3><p>",
            title+1, title+1);
    } else WRITE("<h3><b>%s</b></h3>", title);
}
void html_header_complete(OUTPUT_STREAM, char *title, char *thumbnail) {
    if (thumbnail) {
        end_html_row(OUT); end_html_table(OUT);
        close_coloured_box(OUT, "e0e0e0");
        WRITE("</p><p>");
    }
}
void html_footer(OUTPUT_STREAM) {
    WRITE("</font></body></html>");
}
```

The function html_header is called from 2/index and 2/prob3.
The function html_header_complete is called from 2/index.
The function html_footer is called from 2/index and 2/dl.

§7. HTML paragraphs with indentation.

```
void open_html_paragraph(OUTPUT_STREAM, int depth, char *class) {
    int margin = depth;
    if (margin < 1) internal_error("minimal HTML indentation is 1");
    if (margin > 9) margin = 9;
    WRITE("<p class=\"%sin%d\">", class, margin);
    while (depth > 9) { depth--; WRITE("    "); }
}
```

The function open_html_paragraph is called from 2/index, 2/prob3, 4/head, 9/inpw, 9/tmap, 11/ina, 11/av, 12/br, 12/rb and 13/gl.

§**8.** A little testing routine, not otherwise used.

```
void test_html_paragraphs(void) {
    int k;
    char *text = "Jackdaws love my big sphinx of quartz, "
        "jinxed wizards pluck ivy from my quilt.";
    for (k=1; k<4; k++) {
        open_html_paragraph(ifl, k, ""); INDEX(text); INDEX("</p>");
    }
    for (k=1; k<4; k++) {
        open_html_paragraph(ifl, k, "tight"); INDEX(text); INDEX("</p>");
    }
    for (k=1; k<4; k++) {
        open_html_paragraph(ifl, k, "hanging"); INDEX(text); INDEX("</p>");
    }
}
```

§**9. Writing HTML characters.** The following routine is a low-level filter which takes ISO Latin-1 characters one at a time, feeding them out to the given stream with any unsafe characters converted to suitable HTML elements. (The stream writer will transcode to UTF-8 encoding, since all HTML file streams written by Inform are declared as having the UTF-8 character encoding.)

A special escape sequence, marked by starting and finishing with a character which otherwise can never occur, is expanded to a source code link. If we used an asterisk to denote this, then a source reference is fed into `html_char_out` as the following stream of characters:

```
*source text*Source/story.ni*14*
```

When we notice the trigger character, we cease to output HTML and instead buffer up the reference until we reach the terminating trigger character: we then parse a little, tidy up and send it to `html_source_link` to be turned into a `source:` link.

But of course we don't use an asterisk as trigger – we use character `F0`. Arguably this is dodgy, since the character is legal in ISO Latin-1. But it is a lower-case Icelandic eth, which is not allowed in unquoted Inform 7 source text (because of being absent from the ZSCII character set).

```
define SOURCE_REF_CHAR '\xf0'
define FORCE_NEW_PARA_CHAR '\xd0'
define MAX_SOURCE_REF_LENGTH (MAX_FILENAME_LENGTH + 20)

char source_ref_paraphrase[MAX_SOURCE_REF_LENGTH];                    field 1
char source_ref_filename[MAX_SOURCE_REF_LENGTH];                      field 2
char source_ref_line[MAX_SOURCE_REF_LENGTH];                          field 3
int source_ref_field = 0;                                  which field we are buffering
int source_ref_marker = -1;                    write position in buffer, or -1 if not buffering

void html_char_out(OUTPUT_STREAM, char c) {
    int charcode = (int) ((unsigned char) c);
    if (source_ref_field >= 1) {
        char *buffer = NULL;
        switch (source_ref_field) {
            case 1: buffer = source_ref_paraphrase; break;
            case 2: buffer = source_ref_filename; break;
            case 3: buffer = source_ref_line; break;
        }
        if (source_ref_marker >= MAX_SOURCE_REF_LENGTH)
            internal_error("filenames too long in paths to source text");
```

```
        if (c == SOURCE_REF_CHAR) {
            buffer[source_ref_marker] = 0;
            source_ref_marker = -1;
        } else {
            buffer[source_ref_marker++] = c;
            return;
        }
    }
    switch(c) {
        case '"': WRITE("&quot;"); return;
        case '<': WRITE("&lt;"); return;
        case '>': WRITE("&gt;"); return;
        case '&': WRITE("&amp;"); break;
        case NEWLINE_IN_STRING: WRITE("<br>"); return;
        case FORCE_NEW_PARA_CHAR: WRITE("</p><p class=\"in2\">");
            html_icon_with_tooltip(OUT, "ornament_flower.png", NULL, NULL);
            WRITE(" "); return;
        case SOURCE_REF_CHAR:
            source_ref_field++; source_ref_marker = 0;
            if (source_ref_field == 4) {
                source_ref_field = 0; source_ref_marker = -1;
                source_location sl;
                sl.file_of_origin = filename_to_source_file(source_ref_filename);
                sl.line_number = atoi(source_ref_line);
                html_source_link(OUT, sl);
            }
            return;
        default:
            PUT(charcode);
            return;
    }
}
```

The function html_char_out is called from 2/hdoc, 2/prob1, 5/litp and 9/map.

§**10. Writing HTML tables.** Opening a generic bland table with reasonable column spacing:

```
void begin_plain_html_table(OUTPUT_STREAM) {
    begin_html_table(OUT, NULL, FALSE, 0, 0, 0, 0, 0);
}
```

The function begin_plain_html_table is called from 2/hdoc, 4/vm, 5/rel, 7/dim, 7/kix, 9/map and 10/tab.

§**11.** And now the general table-writing code used throughout Inform, with only a couple of exceptions where fiddly spacing effects are being used (such as on the World index map).

```
void begin_html_table(OUTPUT_STREAM, char *colour, int full_width,
    int border, int cellspacing, int cellpadding, int height, int width) {
    WRITE("<table border=\"%d\" cellspacing=\"%d\" cellpadding=\"%d\"",
        border, cellspacing, cellpadding);
    if (colour) WRITE(" bgcolor=\"%s\"", colour);
    if (full_width) WRITE(" width=100%%");
    if (width > 0) WRITE(" width=\"%d\"", width);
    if (height > 0) WRITE(" height=\"%d\"", height);
    WRITE(">");
}
void first_html_column(OUTPUT_STREAM, int width) {
    WRITE("<tr><td align=\"left\" valign=\"top\"");
    if (width > 0) WRITE(" width=\"%d\"", width);
    WRITE("><font %s>", DEFAULT_HTML_FONT);
}
void next_html_column(OUTPUT_STREAM, int width) {
    WRITE("    </font></td>"
        "<td align=\"left\" valign=\"top\"");
    if (width > 0) WRITE(" width=\"%d\"", width);
    WRITE("><font %s>", DEFAULT_HTML_FONT);
}
void next_html_column_right_justified(OUTPUT_STREAM, int width) {
    WRITE("</font></td><td align=\"right\" valign=\"top\"");
    if (width > 0) WRITE(" width=\"%d\"", width);
    WRITE("><font %s>", DEFAULT_HTML_FONT);
}
void end_html_row(OUTPUT_STREAM) {
    WRITE("</font></td></tr>");
}
void end_html_table(OUTPUT_STREAM) {
    WRITE("</table>");
}
```

The function begin_html_table is called from 2/hdoc, 2/lexi, 9/map, 10/bib, 10/fig, 10/sfx, 10/exf, 11/ina and 12/rb.

The function first_html_column is called from 2/hdoc, 2/lexi, 4/vm, 5/rel, 7/dim, 7/kix, 9/map, 10/tab, 10/bib, 10/fig, 10/sfx, 10/exf, 11/ina and 12/rb.

The function next_html_column is called from 2/hdoc, 2/lexi, 4/vm, 5/rel, 7/dim, 7/kix, 9/map, 10/tab, 10/bib, 10/fig, 10/sfx, 10/exf and 11/ina.

The function next_html_column_right_justified is called from 12/rb.

The function end_html_row is called from 2/hdoc, 2/lexi, 4/vm, 5/rel, 7/dim, 7/kix, 9/map, 10/tab, 10/bib, 10/fig, 10/sfx, 10/exf, 11/ina and 12/rb.

The function end_html_table is called from 2/hdoc, 2/lexi, 4/vm, 5/rel, 7/dim, 7/kix, 9/map, 10/tab, 10/bib, 10/fig, 10/sfx, 10/exf, 11/ina and 12/rb.

§**12.** For boxes with rounded corners:

define CORNER_SIZE 8 *measured in pixels*

```
void open_coloured_box(OUTPUT_STREAM, char *html_colour) {
    WRITE("<table width=\"100%%\" cellpadding=\"0\" cellspacing=\"0\" border=\"0\" ");
    WRITE("style=\"background-color: #%s\">", html_colour);
    WRITE("<tr><td width=\"%d\">", CORNER_SIZE);
    box_corner(OUT, html_colour, "tl");
    WRITE("</td><td></td>");
    WRITE("<td width=\"%d\">", CORNER_SIZE);
    box_corner(OUT, html_colour, "tr");
    WRITE("</td></tr>", html_colour);
    WRITE("<tr><td width=\"%d\"></td><td>", CORNER_SIZE);
    WRITE("<font %s>", DEFAULT_HTML_FONT);
}
void close_coloured_box(OUTPUT_STREAM, char *html_colour) {
    WRITE("</font></td><td width=\"%d\"></td></tr>", CORNER_SIZE);
    WRITE("<tr><td width=\"%d\">", CORNER_SIZE);
    box_corner(OUT, html_colour, "bl");
    WRITE("</td><td></td>");
    WRITE("<td width=\"%d\">", CORNER_SIZE);
    box_corner(OUT, html_colour, "br");
    WRITE("</td></tr>", html_colour);
    WRITE("</table>");
}
void box_corner(OUTPUT_STREAM, char *html_colour, char *corner) {
    WRITE("<img src=\"inform:/%s_corner_%s.gif\" ", corner, html_colour);
    WRITE("width=\"%d\" height=\"%d\" border=\"0\" alt=\"...\" />",
        CORNER_SIZE, CORNER_SIZE);
}
```

The function open_coloured_box is called from 12/rb.
The function close_coloured_box is called from 12/rb.

§**13. Writing ISO Latin-1 strings as XML-escaped text.** We do occasionally use this on arbitrary Unicode text, so must not assume that we aren't touching Icelandic archaisms.

```
void write_xml_safe_text(OUTPUT_STREAM, char *txt) {
    int i, charcode;
    for (i=0; txt[i]; i++) {
        switch(txt[i]) {
            case '&': WRITE("&amp;"); break;
            case '<': WRITE("&lt;"); break;
            case '>': WRITE("&gt;"); break;
            default:
                charcode = (int) ((unsigned char) txt[i]);
                PUT(charcode);
                break;
        }
    }
}
```

The function write_xml_safe_text is called from 10/bib.

§14. Bibliographic text. "Bibliographic text" is text used in bibliographic data about the work of IF compiled: for instance, in the iFiction record, or in the Library Card section of the HTML index. Note that the exact output format depends on global variables, which allow the bibliographic text writing code to configure NI for its current purposes. On non-empty strings this routine therefore splits into one of three independent methods.

```
void compile_bibliographic_text(OUTPUT_STREAM, char *p) {
    STREAM_MUST_BE_IN_MEMORY(OUT);
    if (p == NULL) return;
    if (TEST_COMPILATION_MODE(COMPILE_TEXT_TO_XML_CMODE))
        ⟨Compile bibliographic text as XML respecting Treaty of Babel rules 15⟩;
    if (TEST_COMPILATION_MODE(TRUNCATE_TEXT_CMODE))
        ⟨Compile bibliographic text as a truncated filename 17⟩;
    ⟨Compile bibliographic text as HTML 16⟩;
}
```

The function compile_bibliographic_text is called from 10/str.

§15. This looks like a standard routine for converting ISO Latin-1 to UTF-8 with XML escapes, but there are a few conventions on whitespace, too, in order to comply with a strict reading of the Treaty of Babel. (This is intended for fields in iFiction records.)

⟨Compile bibliographic text as XML respecting Treaty of Babel rules 15⟩ ≡

```
    int i = 0, i2 = strlen(p)-1, snl, wsc, charcode;
    if ((p[0] == '"') && (p[i2] == '"')) { i++; i2--; }                omit surrounding double-quotes
    while (is_babel_whitespace(p[i])) i++;                             omit leading whitespace
    while ((i2>=0) && (is_babel_whitespace(p[i2]))) i2--;              omit trailing whitespace
    for (snl = FALSE, wsc = 0; i<=i2; i++) {
        switch(p[i]) {
            case ' ': case '\x0a': case '\x0d': case '\t':
                snl = FALSE;
                wsc++;
                if (wsc == 1) WRITE(" ");
                break;
            case NEWLINE_IN_STRING:
                if (snl) break;
                if (STREAM_MOST_RECENT_CHAR(OUT) == ' ') STREAM_BACKSPACE(OUT);
                WRITE("<br/>");
                snl = TRUE; wsc = 1; break;
            case '[':
                if ((p[i+1] == '\'') && (p[i+2] == ']')) {
                    i += 2;
                    WRITE("'"); break;
                }                                                      and otherwise fall through to the default case
            default:
                snl = FALSE;
                wsc = 0;
                switch(p[i]) {
                    case '&': WRITE("&amp;"); break;
                    case '<': WRITE("&lt;"); break;
                    case '>': WRITE("&gt;"); break;
                    default:
                        charcode = (int) (((unsigned char *)p)[i]);
                        PUT(charcode);
```

```
                    break;
                }
                break;
        }
    }
    return;
```

This code is used in §14.

§**16.** In the HTML version, we want to respect the forcing of newlines, and also the `[']` escape to obtain a literal single quotation mark.

⟨Compile bibliographic text as HTML 16⟩ ≡

```
    int i, whitespace_count=0, charcode;
    if (p[0] == '"') p++;
    for (i=0; p[i]; i++) {
        if ((p[i] == '"') && (p[i+1] == 0)) break;
        switch(p[i]) {
            case ' ': case '\x0a': case '\x0d': case '\t':
                whitespace_count++;
                if (whitespace_count == 1) PUT(' ');
                break;
            case NEWLINE_IN_STRING:
                while (p[i+1] == NEWLINE_IN_STRING) i++;
                PUT('<');
                PUT('p');
                PUT('>');
                whitespace_count = 1;
                break;
            case '[':
                if ((p[i+1] == '\'') && (p[i+2] == ']')) {
                    i += 2;
                    PUT('\''); break;
                }                                    and otherwise fall through to the default case
            default:
                charcode = (int) (((unsigned char *)p)[i]);
                whitespace_count = 0;
                PUT(charcode);
                break;
        }
    }
    return;
```

This code is used in §14.

§**17.** This code is used to work out a good filename for something given a name inside NI. For instance, if a project is called

"St. Bartholemew's Fair: Étude for a Push-Me/Pull-You Machine"

then what would be a good filename for its released story file?

In the filename version we must forcibly truncate the text to ensure that it does not exceed a certain length, and must also make it filename-safe, omitting characters used as folder separators on various platforms and (for good measure) removing accents from accented letters, so that we can arrive at a sequence of ASCII characters. Each run of whitespace is also converted to a single space. If this would result in an empty text or only a single space, we return the text "story" instead.

Our example (if not truncated) then emerges as:

```
St- Bartholemew's Fair- Etude for a Push-Me-Pull-You Machine
```

Note that we do not write any filename extension (e.g., `.z5`) here.

⟨Compile bibliographic text as a truncated filename 17⟩ ≡

```
int i, pos = STREAM_EXTENT(OUT), whitespace_count=0, black_chars_written = 0, charcode;
if (p[0] == '"') p++;
for (i=0; p[i]; i++) {
    if (STREAM_EXTENT(OUT) - pos >= BIBLIOGRAPHIC_TEXT_TRUNCATION) break;
    if ((p[i] == '"') && (p[i+1] == 0)) break;
    switch(p[i]) {
        case ' ': case '\x0a': case '\x0d': case '\t': case NEWLINE_IN_STRING:
            whitespace_count++;
            if (whitespace_count == 1) PUT(' ');
            break;
        default:
            charcode = (int) (((unsigned char *)p)[i]);
            ⟨Render the character code filename-safe if possible 18⟩;
            whitespace_count = 0;
            if (charcode < 128) {
                PUT(charcode); black_chars_written++;
            }
            break;
    }
}
if (black_chars_written == 0) WRITE("story");
return;
```

This code is used in §14.

§**18.** We change possible filename separators or extension indicators to hyphens, and remove accents from each possible ISO Latin-1 accented letter. This does still mean that the OE and AE digraphs will simply be omitted, while the German eszet will be barbarously shortened to a single "s", but life is just too short to care overmuch about this.

⟨Render the character code filename-safe if possible 18⟩ ≡

```
charcode = iso_remove_accents(charcode);
```

This code is used in §17.

§**19.** This is isolated as a routine since it is also convenient for cleaning the output to `stdout`.

```
int iso_remove_accents(int charcode) {
    if (charcode<0) charcode += 256;                                    in case char is signed
    switch (charcode) {
        case '/': case '\\': case ':': case '.': charcode = '-'; break;
        case 0xC0: case 0xC1: case 0xC2: case 0xC3:
        case 0xC4: case 0xC5: charcode = 'A'; break;
        case 0xE0: case 0xE1: case 0xE2: case 0xE3:
        case 0xE4: case 0xE5: charcode = 'a'; break;
        case 0xC8: case 0xC9: case 0xCA: case 0xCB: charcode = 'E'; break;
        case 0xE8: case 0xE9: case 0xEA: case 0xEB: charcode = 'e'; break;
        case 0xCC: case 0xCD: case 0xCE: case 0xCF: charcode = 'I'; break;
        case 0xEC: case 0xED: case 0xEE: case 0xEF: charcode = 'i'; break;
        case 0xD2: case 0xD3: case 0xD4: case 0xD5:
        case 0xD6: case 0xD8: charcode = 'O'; break;
        case 0xF2: case 0xF3: case 0xF4: case 0xF5:
        case 0xF6: case 0xF8: charcode = 'o'; break;
        case 0xD9: case 0xDA: case 0xDB: case 0xDC: charcode = 'U'; break;
        case 0xF9: case 0xFA: case 0xFB: case 0xFC: charcode = 'u'; break;
        case 0xDD: charcode = 'Y'; break;
        case 0xFD: charcode = 'y'; break;
        case 0xD1: charcode = 'N'; break;
        case 0xF1: charcode = 'n'; break;
        case 0xC7: charcode = 'C'; break;
        case 0xE7: charcode = 'c'; break;
        case 0xDF: charcode = 's'; break;
    }
    if (charcode >= 128) charcode = '-';
    return charcode;
}
```

The function iso_remove_accents is called from 4/iext.

§**20.** An irksome companion piece to this: a routine which converts the Unicode combining accents with letters, sufficient correctly to handle all characters in the above collection.

```
int combining_accent(int accent, int letter) {
    switch(accent) {
        case 0x0300:                                                    Unicode combining grave
            switch(letter) {
                case 'a': return 0xE0; case 'e': return 0xE8; case 'i': return 0xEC;
                case 'o': return 0xF2; case 'u': return 0xF9;
                case 'A': return 0xC0; case 'E': return 0xC8; case 'I': return 0xCC;
                case 'O': return 0xD2; case 'U': return 0xD9;
            }
            break;
        case 0x0301:                                                    Unicode combining acute
            switch(letter) {
                case 'a': return 0xE1; case 'e': return 0xE9; case 'i': return 0xED;
                case 'o': return 0xF3; case 'u': return 0xFA; case 'y': return 0xFF;
                case 'A': return 0xC1; case 'E': return 0xC9; case 'I': return 0xCD;
                case 'O': return 0xD3; case 'U': return 0xDA;
            }
```

```
            break;
        case 0x0302:                                        Unicode combining circumflex
            switch(letter) {
                case 'a': return 0xE2; case 'e': return 0xEA; case 'i': return 0xEE;
                case 'o': return 0xF4; case 'u': return 0xFB;
                case 'A': return 0xC2; case 'E': return 0xCA; case 'I': return 0xCE;
                case 'O': return 0xD4; case 'U': return 0xDB;
            }
            break;
        case 0x0303:                                        Unicode combining tilde
            switch(letter) {
                case 'a': return 0xE3; case 'n': return 0xF1; case 'o': return 0xF5;
                case 'A': return 0xC3; case 'N': return 0xD1; case 'O': return 0xD5;
            }
            break;
        case 0x0308:                                        Unicode combining diaeresis
            switch(letter) {
                case 'a': return 0xE4; case 'e': return 0xEB; case 'u': return 0xFC;
                case 'A': return 0xC4; case 'E': return 0xCB; case 'U': return 0xDC;
            }
            break;
        case 0x0327:                                        Unicode combining cedilla
            switch(letter) {
                case 'c': return 0xE7; case 'C': return 0xC7;
            }
            break;
    }
    return '?';
}
```

The function combining_accent is called from 1/plat.

§**21.** These are all the characters which would come out as whitespace in the sense of the Treaty of Babel rules on leading and trailing spaces in iFiction records.

```
int is_babel_whitespace(char c) {
    if ((c == ' ') || (c == '\t') || (c == '\x0a')
        || (c == '\x0d') || (c == NEWLINE_IN_STRING)) return TRUE;
    return FALSE;
}
```

Javascript Pastes 2/java

Purpose

To write valid HTML for a paste icon which, when clicked, calls a Javascript function which will paste Inform source text into the Source panel of the application.

2/java.§7 Individual characters

Definitions

¶1. The application is required to provide a Javascript function to copy text into the source window. Broadly speaking, the application needs to support Javascript in the following form:

```
var myProject = external.Project;
myProject.selectView('source');
myProject.pasteCode('Trying Taking Manhattan');
```

This for Windows: for OS X, the same code but `window.Project` rather than `external.Project`.

As this implies, the details unfortunately differ on different platforms. The constant `JAVASCRIPT_MODEL`, defined in Platform-Specific Definitions, can be any of:

(a) Model 0 - no Javascript pastes are available (so no icon will be set).
(b) Model 1 - paste in OS X style, directly within the HREF of a link.
(c) Model 2 - paste in Windows style, defining a function and calling that.

In model 2 we define a Javascript function for each individual paste because this protects against long paste texts overflowing what Windows considers the maximum permitted length of a link: the WebKit rendering engine in OS X has no such limit, apparently. This means that for Windows we define numerous copies of the Javascript code above. In model 1, we never need to compile fresh Javascript functions because the template file `ExtensionFileModel.html` for OS X contains a definition of the single Javascript function:

```
<script language="JavaScript">
function pasteCode(code) {
 var myProject = window.Project;
 myProject.selectView('source');
 myProject.pasteCode(code);
}
</script>
```

and we can simply call `href="javascript:pasteCode(...)"` from any link.

The text pasted may in some cases be quite long (say, 5K or more) and the code below should work whatever its length. It will of course be UTF-8 encoded, since all HTML produced by NI is.

¶2. We have found that different Javascript implementations handle escape characters in quoted text differently. (For instance, some allow a double-quote " to appear as a literal in single-quoted text, others require `&quot;` to be used, others still do not recognise HTML entities like `&quot;` and treat them as literal text.) To avoid these tiresome platform dependencies a single new escape-character syntax was added in November 2007. This puts obligations both on NI (and `indoc`, which also generates HTML with Javascript pastes), to make use of the escape syntax, and also on the application, to understand and act on it.

The application must implement `myProject.pasteCode(code)` such that every instance of `[=0xHHHH=]` is replaced with the Unicode character whose hexadecimal code is `HHHH`. There will always be four digits, with leading zeros as needed, and `A` to `F` will be written in upper case. The only Unicode characters with codes below `0x0020` which must be handled are newline, `0x000A`, and tab, `0x0009`.

The generator (NI or `indoc`) must always escape every instance of the following characters:

(a) every tab is escaped to `[=0x0009=]`;
(b) every newline is escaped to `[=0x000A=]`;
(c) every double quotation mark is escaped to `[=0x0022=]`;
(d) every ampersand is escaped to `[=0x0026=]`;
(e) every single quotation mark is escaped to `[=0x0027=]`;
(f) every less than sign is escaped to `[=0x003C=]`;
(g) every greater than sign is escaped to `[=0x003E=]`;
(h) every backslash is escaped to `[=0x005C=]`.

It may also choose to escape other character codes, as it prefers. Other characters are generated as literal UTF-8. In no case will any character with code below `0x0020` be passed as a literal.

---

§**1.** At the top level, the form of link used depends on the `JAVASCRIPT_MODEL`. Note that model 0 results in no material at all being output. The actual text to be passed is all set via `javascript_string_out` below, and which does not depend on the model.

```
int javascript_fn_counter = 1000;
void write_javascript_paste(OUTPUT_STREAM, int from, int to, char *alt_text) {
    switch(JAVASCRIPT_MODEL) {
        case 1:                                   OS X style, with long function arguments allowed in links
            WRITE("<a href=\"javascript:pasteCode(");
            javascript_string_out(OUT, from, to, alt_text);
            WRITE(")\"><img border=0 src=inform:/doc_images/paste.png></a>");
            break;
        case 2:                                   Windows style, with long function arguments in links unreliable
            WRITE("<script language=\"JavaScript\">\n");
            WRITE("function pasteCode%d(code) {\n", javascript_fn_counter); INDENT;
            WRITE("var myProject = external.Project;\n\n");
            WRITE("myProject.selectView('source');\n");
            WRITE("myProject.pasteCode(");
            OUTDENT; javascript_string_out(OUT, from, to, alt_text);
            WRITE(");\n");
            WRITE("}\n");
            WRITE("</script>\n");
            WRITE("<a href=\"javascript:pasteCode%d()\">"
                "<img border=0 src=inform:/doc_images/paste.png></a>",
                javascript_fn_counter++);
            break;
    }
}
```

The function write_javascript_paste is called from 2/hdoc, 4/edoc, 12/br and 12/rb.

§**2.** In the following, the source of the text can be either a range of words from the lexer (as for instance when a portion of an extension is being typeset as documentation, with an example that can be pasted), or can be a C string: if the latter, then its encoding must be ISO Latin-1. The conversion to UTF-8 is performed in `javascript_char_out` below.

```
void javascript_string_out(OUTPUT_STREAM, int from, int to, char *C_string) {
    WRITE("'");
    if (C_string) ⟨Write C string as Javascript string 3⟩;
    if (from >= 0) ⟨Write word range as Javascript string 4⟩;
    WRITE("'");
}
```

§**3.** The art of leadership is delegation.

⟨Write C string as Javascript string 3⟩ ≡

```
    int i;
    for (i=0; C_string[i]; i++)
        javascript_char_out(OUT, C_string[i]);
```

This code is used in §2.

§**4.** Writing a word range is much harder. In effect, we have to provide an inverse function for the lexer, which converted raw source text to nicely packaged up words.

See Lexer for details of how words are stored, and in particular for the `lw_break` character, which is `'\t'` when the word followed a tab, but is `'1'` to `'9'` when it followed a newline plus that many tabs. We need this because lexing has otherwise removed whitespace from the source, and we need it back again if we're to paste a faithful Javascript representation: otherwise the tabs used as column-dividers in tables will not come through, for instance. Moreover, indentation from the left margin is used to make prettier pastes (which respect the layout of the original examples from which the paste has been made), and for that we need the `'1'` to `'9'` possibilities.

Note that we expect the material pasted to be indented at 1 tab stop from the margin already, because it will almost always be a source text within an example, where any matter unindented will be commentary rather than source text. Thus a single tab after a newline is not significant, and we only need to supply extra Javascript tabs when the indentation is 2 tab stops or more.

⟨Write word range as Javascript string 4⟩ ≡

```
    int i, suppress_space = FALSE, follows_paragraph_break = FALSE;
    for (i=from; i<=to; i++) {
        int indentation = 0, j;
        char *p = lw_array[i].lw_rawtext;
        if [[word i == STROKE]] {                                   marker for a paragraph break
            javascript_char_out(OUT, '\n');
            javascript_char_out(OUT, '\n');
            suppress_space = TRUE;
            follows_paragraph_break = TRUE;
            while [[word i == STROKE]] i++; i--;                    elide multiple breaks
            continue;
        }
        if (isdigit(lw_array[i].lw_break)) indentation = lw_array[i].lw_break - '0';
        if (indentation > 0) {                          number of tab stops of indentation on this para
            javascript_char_out(OUT, '\n');
            for (j=0; j<indentation-1; j++) javascript_char_out(OUT, '\t');
            suppress_space = TRUE;
```

```
        }
        if ((lw_array[i].lw_break == '\t') && (follows_paragraph_break == FALSE)) {
            javascript_char_out(OUT, '\t');
            suppress_space = TRUE;
        }
        follows_paragraph_break = FALSE;
        if (suppress_space==FALSE)
            ⟨Restore inter-word spaces unless this would be unnatural 5⟩;
        suppress_space = FALSE;
        for (j=0; p[j]; j++) javascript_char_out(OUT, p[j]);
        ⟨Insert a close-literal-I6 escape sequence if necessary 6⟩;
    }
    javascript_char_out(OUT, '\n');
    javascript_char_out(OUT, '\n');
```

This code is used in §2.

§**5.** The lexer also broke words around punctuation marks, so that, for instance, "fish, finger" would have been lexed as `fish , finger` – three words. But we want to restore the more natural spacing.

⟨Restore inter-word spaces unless this would be unnatural 5⟩ ≡

```
    if ((i>from)
        && ((p[1] != 0) || (is_punctuation(p[0]) == FALSE) ||
            (p[0] == '(') || (p[0] == '{') || (p[0] == '}'))
        && (compare_word(i-1, OPENBRACKET_V)==FALSE))
        javascript_char_out(OUT, ' ');
```

This code is used in §4.

§**6.** Finally, the lexer rendered a literal I6 inclusion in the form

(- deadflag=2; -)

as a sequence of two lexical words: `(-` and then `deadflag=2;`. In order to paste back safely, we must supplement this with the closure "-)" once again:

⟨Insert a close-literal-I6 escape sequence if necessary 6⟩ ≡

```
    if (vocab_test_flags(i, I6_MC)) {
        javascript_char_out(OUT, '-');
        javascript_char_out(OUT, ')');
        javascript_char_out(OUT, ' ');
    }
```

This code is used in §4.

§**7. Individual characters.** Note that every character within the single quotes of a Javascript string is produced through the following routine. It combines the steps of escaping awkward characters and converting from ISO Latin-1 to UTF-8.

```
void javascript_char_out(OUTPUT_STREAM, char c) {
    switch(c) {
        case '\t': WRITE("[=0x0009=]"); return;
        case '\n': WRITE("[=0x000A=]"); return;
        case '"': WRITE("[=0x0022=]"); return;
        case '&': WRITE("[=0x0026=]"); return;
        case '\'': WRITE("[=0x0027=]"); return;
        case '<': WRITE("[=0x003C=]"); return;
        case '>': WRITE("[=0x003E=]"); return;
        case '\\': WRITE("[=0x005C=]"); return;
        default: {
            int charcode = (int) ((unsigned char) c);
            if (charcode < 32) {
                LOG("Illegal character %d found\n", charcode);
                internal_error("illegal character in Javascript paste");
            }
            if (charcode >= 128) {
                PUT(0xC0 + (charcode >> 6));
                PUT(0x80 + (charcode & 0x3f));
            } else PUT(charcode);
            return;
        }
    }
}
```

HTML Documentation 2/hdoc

Purpose

To translate a passage of source text into HTML-format documentation, for use in the automatically generated documentation pages on each installed extension.

---

§**1.** This is a port of a simplified version of the Inform documentation tool `indoc`, and like all Perl scripts ported to C, it bears a few scars.

Documentation is extracted from extensions by lexing them (ignoring all of the actual source text and picking up only after the divider line) and then running the code below on the word range for the lexed documentation. Our task is therefore to print out this documentation in an HTML format which matches the look and feel of pages produced by `indoc` for the manuals.

§**2. Links and leafnames.** Matters are complicated because an extension typically has not only a run of source text, but also up to 26 examples: suppose there are X of these. The extension then needs to produce $X+1$ pages of HTML: the primary one, which just has the body text, and then X variants which duplicate the primary one except that one of the examples is opened up to reveal its content. Each of these pages will have X anchor points named `#eg1` up to `#egX`, for the positions of the examples.

The pages will typically be filenamed with the extension title, followed by `-eg1`, `-eg2`, ..., in the case of the example variants, and then `.html`.

The following routine prints the leafname part of an HTML reference to the extension documentation, at anchor point `to_example_anchor` (or if 0 then at the top) of the version with example `to_example_variant` opened (or if 0 then the original with all examples closed). What complicates it is that the base leafname might be any of the above variant filenames, so we may need to strip off an existing ending. For instance, if we are in example 2 and want to link to anchor 5 on example 4, the base leafname might be `Gusher-eg2` and we need to remove the `-eg2` and replace with `-eg4` before we can add the `#eg5`.

This will fail if anyone's extension has a title ending in `-eg` followed by a number. I believe I can live with the guilt.

```
void href_of_example(OUTPUT_STREAM, char *base_leafname,
    int to_example_variant, int to_example_anchor) {
    int i;
    for (i=0; base_leafname[i]; i++) {
        if ((base_leafname[i] == '-') && (base_leafname[i+1] == 'e')
            && (base_leafname[i+2] == 'g') && (isdigit(base_leafname[i+3]))) break;
        WRITE("%c", base_leafname[i]);
    }
    if (to_example_variant > 0) WRITE("-eg%d", to_example_variant);
    WRITE(".html");
    if (to_example_anchor > 0) WRITE("#eg%d", to_example_anchor);
}
```

§**3. Structural blocks of extension documentation.** The extension documentation text can optionally include section and chapter headings, and also examples. Here we parse the opening of a paragraph to see if it might be a heading. For instance, a paragraph consisting of

Section: Black Gold

matches successfully and sets the level to 2 and the name to the word range "Black Gold".

```
int extension_documentation_heading(int w1, int w2,
    int *level, int *hn1, int *hn2) {
    int lev, end;
    if (w1+10 >= w2) return FALSE;                    not enough space: this runs into the end-of-file padding
    if [[w1, w2 == chapter COLON ...]] lev = 1;
    else if [[w1, w2 == section COLON ...]] lev = 2;
    else return FALSE;
    *level = lev;
    w1 += 2;
    end = w1; while ((end<=w2) && ([[word end == STROKE]] == FALSE)) end++; end--;
    *hn1 = w1; *hn2 = end;
    return TRUE;
}
```

§**4.** And here we do the same to identify an example, which has to satisfy a more exacting specification: a paragraph in the shape

Example: *** Gelignite Anderson - A Tale of the Texas Oilmen

which would result in the name being set to the range "Gelignite Anderson", an asterisk count of 3, and the rubric being "A Tale of the Texas Oilmen".

```
int extension_documentation_example(int w1, int w2,
    int *ast, int *egn1, int *egn2, int *egr1, int *egr2) {
    if (w1+10 >= w2) return FALSE;                    not enough space: this runs into the end-of-file padding
    if [[w1, w2 == example COLON ...]] {
        int aw = w1+2, n1, n2, r1, r2, asterisks = 0;
        after the colon, an optional row of unspaced asterisks:
        if [[word aw == ASTERISK]] asterisks = 1;
        if [[word aw == TWOASTERISKS]] asterisks = 2;
        if [[word aw == THREEASTERISKS]] asterisks = 3;
        if [[word aw == FOURASTERISKS]] asterisks = 4;
        n1 = aw; if (asterisks > 0) n1 = aw + 1;
        the example name now extends up as far as the next freestanding hyphen:
        n2 = n1;
        while ((n2 <= w2) && ([[word n2 == HYPHEN]] == FALSE)) n2++;
        if (n2 >= w2) return FALSE; n2--;
        on the other side of the hyphen, the rubric extends to the next paragraph break
        r1 = n2 + 2; r2 = r1;
        while ((r2 <= w2) && ([[word r2 == STROKE]] == FALSE)) r2++;
        if (r2 >= w2) return FALSE; r2--;
        a successful match has now been made
        *ast = asterisks; *egn1 = n1; *egn2 = n2; *egr1 = r1; *egr2 = r2;
        return TRUE;
    }
    return FALSE;
}
```

§5. The table of contents. The user sees chapters as A subheadings, numbered upwards from 1, and sees sections as B subheadings, numbered from 1 within each chapter. It is legal to have only A subheadings; only B subheadings; or a mixture of the two.

If a scan can find any headings at all then we will wish to typeset a table of contents up front. The following routine looks for what material might go into a TOC, and sets one if it finds anything: otherwise, it sets nothing and has no effect. Because of the compulsory paragraph break following the divider line in the extension, we can safely assume that every headng will follow a paragraph break word, even one right at the top of the extension's documentation.

(Examples are included in the table of contents only if they occur after the first heading, which I think is reasonable enough: there can be at most 26 per extension, enabling them to be lettered as Example A to Example Z.)

```
void edoc_set_table_of_contents(int w1, int w2, OUTPUT_STREAM, char *base_leafname) {
    int i;
    int heading_count = 0, chapter_count = 0, section_count = 0, example_count = 0;
    for (i=w1; i<=w2; i++) {
        int edhl, name_w1, name_w2, eg_rubric_w1, eg_rubric_w2, asterisks;
        if [[word i == STROKE]] {                          the lexer records this to mean a paragraph break
            while [[word i == STROKE]] i++; if (i>w2) break;
            if (extension_documentation_heading(i, w2, &edhl, &name_w1, &name_w2)) {
                heading_count++;
                if (heading_count == 1) WRITE("<p><hr><p>");                ruled line at top of TOC
                if (edhl == 1) {
                    chapter_count++; section_count = 0;
                    if (chapter_count > 1) WRITE("<br>");          skip a line between chapters in TOC
                }
                if (edhl == 2) section_count++;
                ⟨Typeset the table of contents entry for this heading 6⟩;
                i = name_w2; continue;
            }
            if ((heading_count > 0) && (example_count < 26) &&
                (extension_documentation_example(i, w2,
                    &asterisks, &name_w1, &name_w2, &eg_rubric_w1, &eg_rubric_w2))) {
                if (++example_count == 1) WRITE("<br><b>Examples</b><br>");
                ⟨Typeset the table of contents entry for this example 7⟩;
                i = eg_rubric_w2; continue;
            }
        }
    }
    if (heading_count > 0)
        WRITE("<p><hr><p>");                          ruled line at foot of TOC, if there is one
}
```

The function edoc_set_table_of_contents is called from 4/edoc.

§**6.** Internally, we are numbering all headings independently upwards from 1, and we set anchor points in the documentation called `#docsec1`, `#docsec2`, and so on: some of these will be chapter headings, some section headings. These are the destinations of links from heading lines in the TOC.

```
define EDOC_TOC_LINK_STYLE "STYLE=\"text-decoration: none\""
define EDOC_TOC_LINK_FONT "<font color=\"#000000\">"                    this must open a <font> tag
```

⟨Typeset the table of contents entry for this heading 6⟩ ≡

```
    char *html_to_close = NULL;
    switch (edhl) {
        case 1:
            WRITE("<b><a %s href=#docsec%d>%sChapter %d: ",
                EDOC_TOC_LINK_STYLE, heading_count, EDOC_TOC_LINK_FONT, chapter_count);
            html_to_close = "</font></a></b>";
            break;
        case 2:
            if (chapter_count > 0)                                  if there are chapters as well as sections...
                WRITE("   ");                          ...then set an indentation before entry
            WRITE("<a %s href=#docsec%d>%sSection ",
                EDOC_TOC_LINK_STYLE, heading_count, EDOC_TOC_LINK_FONT);
            if (chapter_count > 0)                                  if there are chapters as well as sections...
                WRITE("%d.%d: ", chapter_count, section_count);                    quote in form S.C
            else
                WRITE("%d: ", section_count);                         otherwise quote section number only
            html_to_close = "</font></a>";
            break;
        default: internal_error("unable to set this heading level in extension TOC");
    }
    edoc_set_body_text(name_w1, name_w2, OUT, EDOC_FRAGMENT_ONLY, NULL);
    WRITE("%s<br>\n", html_to_close);
```

This code is used in §5.

§**7.** The TOC entries for examples are similar. Here the link is to the variant page in the current family which has the given example open, and moreover, to the anchor in that page corresponding to the top of the example: thus as far as the user is concerned it opens the example and goes there.

⟨Typeset the table of contents entry for this example 7⟩ ≡

```
    WRITE("   ");                                always indent TOC entries for examples
    WRITE("<a %s href=\"", EDOC_TOC_LINK_STYLE);
    href_of_example(OUT, base_leafname, example_count, example_count);
    WRITE("\">%s%c: ", EDOC_TOC_LINK_FONT, 'A'+example_count-1);                    the letter A to Z
    edoc_set_body_text(name_w1, name_w2, OUT, EDOC_FRAGMENT_ONLY, NULL);
    WRITE("</font></a><br>");
```

This code is used in §5.

§8. Setting the body text.

define EDOC_ALL_EXAMPLES_CLOSED -1 *do not change this without also changing Extensions*
define EDOC_FRAGMENT_ONLY -2 *must differ from this and from all example variant numbers*

```
int edoc_set_body_text(int w1, int w2, OUTPUT_STREAM,
    int example_which_is_open, char *base_leafname) {
    int heading_count = 0, chapter_count = 0, section_count = 0, example_count = 0;
    int mid_example = FALSE, skipping_text_of_an_example = FALSE,
        start_table_next_line = FALSE, mid_I7_table = FALSE, row_of_table_is_empty = FALSE,
        mid_displayed_source_text = FALSE, indentation = 0;
    int i;
    for (i=w1; i<=w2; i++) {
        int edhl, name_w1, name_w2, eg_rubric_w1, eg_rubric_w2, asterisks;
        if [[word i == STROKE]] {                    the lexer records this to mean a paragraph break
            ⟨Handle a paragraph break 9⟩;
            while [[word i == STROKE]] i++; if (i>w2) break;    treat multiple paragraph breaks as one
            ⟨Determine indentation of new paragraph 10⟩;
            if (extension_documentation_heading(i, w2, &edhl, &name_w1, &name_w2)) {
                heading_count++;
                if (edhl == 1) {
                    chapter_count++; section_count = 0;
                    if (chapter_count > 1) WRITE("<p><hr>");          rule a line between chapters
                }
                if (edhl == 2) section_count++;
                ⟨Typeset the heading of this chapter or section 15⟩;
                i = name_w2; continue;
            }
            if ((example_count < 26) && (extension_documentation_example(i, w2,
                    &asterisks, &name_w1, &name_w2, &eg_rubric_w1, &eg_rubric_w2))) {
                skipping_text_of_an_example = FALSE;
                if (mid_example) ⟨Close the previous example's text 25⟩;
                mid_example = FALSE;
                example_count++;
                ⟨Typeset the heading of this example 16⟩;
                if (example_count == example_which_is_open) {
                    ⟨Open the new example's text 24⟩;
                    mid_example = TRUE;
                } else skipping_text_of_an_example = TRUE;
                i = eg_rubric_w2; continue;
            }
        }
        if (skipping_text_of_an_example) continue;
        ⟨Handle a line or column break, if there is one 11⟩;
        ⟨Transcribe an ordinary word of the documentation 12⟩;
    }
    if (mid_example) ⟨Close the previous example's text 25⟩;
    if (example_which_is_open != EDOC_FRAGMENT_ONLY) ⟨Handle a paragraph break 9⟩;
    return example_count;
}
```

The function edoc_set_body_text is called from 4/edoc.

§**9. Typesetting the standard matter.** A paragraph break might mean the end of displayed matter (and if so, then also the end of any table being displayed). Otherwise, it just means a paragraph break, and a chance to restore our tired variables.

⟨Handle a paragraph break 9⟩ ≡
```
if (mid_displayed_source_text)  {
    WRITE("</font>");
    if (mid_I7_table) ⟨End I7 table in extension documentation 23⟩;
    WRITE("</blockquote>");
}
WRITE("\n<p>\n");
mid_displayed_source_text = FALSE; mid_I7_table = FALSE;
```

This code is used in §8.

§**10.** The indentation setting is made here because a tab anywhere else does not mean a paragraph has been indented. Here `i` is at the number of the first word after the paragraph break; the break character corresponding to it is the one before that word, so describes the kind of whitespace between the paragraph break and the first nonwhitespace of the new paragraph.

⟨Determine indentation of new paragraph 10⟩ ≡
```
indentation = 0; if (lw_array[i].lw_break == '\t') indentation = 1;
```

This code is used in §8.

§**11.** Two lower-level sorts of breaks can also occur in the middle of a paragraph: line breaks, indicated by newlines plus some tabs, and column breaks inside I7 source tables, indicated by tabs. We have to deal with those before we can move on to the subsequent word.

⟨Handle a line or column break, if there is one 11⟩ ≡
```
if (isdigit(lw_array[i].lw_break)) indentation = lw_array[i].lw_break - '0';
if (indentation > 0) ⟨Handle the start of a line which is indented 14⟩;
if [[i, w2 == ASTERISK COLON ...]] {
    ⟨Incorporate an icon linking to a Javascript function to paste the text which follows 13⟩;
    i++; continue;
}
indentation = 0;
if ((mid_I7_table) && ((lw_array[i].lw_break == '\t') || (lw_array[i].lw_break == '1'))) {
    if (row_of_table_is_empty == FALSE)
        ⟨End table cell for I7 table in extension documentation 20⟩;
    ⟨Begin table cell for I7 table in extension documentation 21⟩;
    row_of_table_is_empty = FALSE;
}
```

This code is used in §8.

§**12.** See Javascript Pastes for further explanation of the general method here.

⟨Transcribe an ordinary word of the documentation 12⟩ ≡

```
char *p = lw_array[i].lw_rawtext; int j;
if ((i>w1)
    && ((p[1] != 0) || (is_punctuation(p[0]) == FALSE)
        || (p[0] == '(') || (p[0] == '{') || (p[0] == '}'))
    && (compare_word(i-1, OPENBRACKET_V)==FALSE))
    WRITE(" ");                                    restore normal spacing around punctuation
for (j=0; p[j]; j++) html_char_out(OUT, p[j]);                          set the actual word
if ((![[word i == OPENI6]]) &&
    (vocab_test_flags(i, I6_MC))) WRITE("-) ");                  ensure I6 literals are closed
```

This code is used in §8.

§**13.** A paste causes the same material to be set twice: once in the argument to the Javascript paste function (which is passed to the application when the user clicks on the paste icon, and thus ends up in the Source panel), and once also in the HTML documentation. That's why the code here ranges forward to see how far it should go (to the next paragraph break which is not followed by further tabbed matter, or in other words, to the end of the display), but does not advance `i` commensurately.

⟨Incorporate an icon linking to a Javascript function to paste the text which follows 13⟩ ≡

```
int from = i+2, to = w2, j;
for (j=from; j<=to; j++)                                  first find the end of the quoted passage
    if [[word j == STROKE]] {
        int possible_end = j-1;
        while [[word j == STROKE]] j++;
        if ((j<to) && ((lw_array[j].lw_break == '\t') || (isdigit(lw_array[j].lw_break)))) continue;
        to = possible_end; break;
    }
write_javascript_paste(OUT, from, to, NULL);
```

This code is used in §11.

§**14.** The first step of indentation is handled using the `<blockquote>` tag; within that, further tab stops are simulated by printing a row of four non-breaking spaces for each indentation level above 1. A paragraph of indented (i.e., display matter) beginning with the word "Table" is taken to be an I7 table, and we remember that the next line break will take us past the titling line and into the table entries, which we will need to achieve with an HTML `<table>`.

⟨Handle the start of a line which is indented 14⟩ ≡

```
int j;
if (mid_displayed_source_text) {
    if (start_table_next_line) {
        start_table_next_line = FALSE;
        mid_I7_table = TRUE;
        ⟨Begin I7 table in extension documentation 19⟩;
    } else {
        if (mid_I7_table) ⟨Begin new row of I7 table in extension documentation 22⟩
        else WRITE("<br>");
    }
    if (mid_I7_table) row_of_table_is_empty = TRUE;
} else {
    WRITE("<blockquote><font color=\"#000080\">");
    mid_displayed_source_text = TRUE;
```

```
        if [[word i == table]] start_table_next_line = TRUE;
    }
    indentation--;
    for (j=0; j<indentation; j++) WRITE("    ");
```

This code is used in §11.

§**15. Typesetting the headings.** That is thankfully all for the tormented logic of all those changes of state: from here to the rest of the section, all we do is to generate pretty HTML, and without altering any variables or causing any side-effects at all. First, the headings. Recall that heading number `N` is required to be at anchor `#docsecN`.

```
define EDOC_TOC_C_HEAD_FONT "<font color=\"#800000\">"          this must open a <font> tag
define EDOC_TOC_S_HEAD_FONT "<font color=\"#000000\">"          this must open a <font> tag
```

⟨Typeset the heading of this chapter or section 15⟩ ≡

```
    switch (edhl) {
        case 1:
            WRITE("<p><a name=docsec%d><b>%sChapter %d: ",
                heading_count, EDOC_TOC_C_HEAD_FONT, chapter_count);
            break;
        case 2:
            WRITE("<p><a name=docsec%d><b>%sSection ",
                heading_count, EDOC_TOC_S_HEAD_FONT);
            if (chapter_count > 0) WRITE("%d.", chapter_count);
            WRITE("%d: ", section_count);
            break;
    }
    edoc_set_body_text(name_w1, name_w2, OUT, EDOC_FRAGMENT_ONLY, NULL);
    WRITE("</b>");
```

This code is used in §8.

§**16.** An example is set with a two-table header, and followed optionally by a table of its inset copy, shaded to distinguish it from the rest of the page. The heading is constructed with a main table of one row of two cells, in the following section. The left-hand cell then contains a further table, in the next section.

⟨Typeset the heading of this example 16⟩ ≡

```
    WRITE("<hr><p>");                                   rule a line before the example heading
    WRITE("<a name=eg%d>", example_count);              provide the anchor point
    begin_plain_html_table(OUT);
    WRITE("<tr>");
    Left hand cell: the oval icon
    WRITE("<td halign=\"left\" valign=\"top\" cellpadding=0 cellspacing=0 width=38px>");
    ⟨Typeset the lettered oval example icon 17⟩;
    WRITE("</td>");
    Right hand cell: the asterisks and title, with rubric underneath
    WRITE("<td cellpadding=0 cellspacing=0 halign=\"left\" valign=\"top\"><font %s>",
        DEFAULT_HTML_FONT);
    ⟨Incorporate link to the example opened up 18⟩;
    while (asterisks-- > 0)
        WRITE("<img border=\"0\" src='inform:/doc_images/asterisk.png'>");
    WRITE("<b><font color=\"#505050\"> Example </font> <font color=\"#000000\">");
    edoc_set_body_text(name_w1, name_w2, OUT, EDOC_FRAGMENT_ONLY, base_leafname);
    WRITE("</font></b></a>");                                                  end the textual link
```

```
    WRITE("<br>");
    edoc_set_body_text(eg_rubric_w1, eg_rubric_w2, OUT, EDOC_FRAGMENT_ONLY, base_leafname);
    WRITE("<p>");
    WRITE("</td></tr>");
    end_html_table(OUT);
    WRITE("<p>");
```

This code is used in §8.

§**17.** The little oval icon with its superimposed boldface letter is much harder to get right on all browsers than it looks, and the following is the result of some pretty grim experimentation. Basically, we make a tight, borderless, one-cell-in-one-row table, use CSS to make a transparent PNG image of an oval the background image for the table, then put a boldface letter in the centre of its one and only cell. (Things were even worse when IE6 for Windows still had its infamous PNG transparency bug.)

⟨Typeset the lettered oval example icon 17⟩ ≡

```
    begin_plain_html_table(OUT);
    WRITE("<tr class=\"oval\"><td width=38px height=30px align=\"left\" valign=\"center\">");
    ⟨Incorporate link to the example opened up 18⟩;
    WRITE("<div class=\"paragraph Body\" style=\"line-height: 1px; margin-bottom: 0px; "
        "margin-top: 4px; padding-bottom: 0pt; padding-top: 4px; text-align: center; "
        "color: #202020; font-size: 14px; line-height: 1px;\"><b>%c</b></div>",
        'A' + example_count - 1);
    WRITE("</a></td></tr>");
    end_html_table(OUT);
```

This code is used in §16.

§**18.** Clicking on the example banner opens it up, if it's currently closed, or closes it up, if it's currently open.

⟨Incorporate link to the example opened up 18⟩ ≡

```
    WRITE("<a href=\"");
    if (example_count == example_which_is_open)                    this example currently open
        href_of_example(OUT, base_leafname, EDOC_ALL_EXAMPLES_CLOSED, example_count);
    else                                                           this example not yet open
        href_of_example(OUT, base_leafname, example_count, example_count);
    WRITE("\" STYLE=\"text-decoration: none\">");
```

This code is used in §16,17,16,17,16,17.

§**19. Typesetting I7 tables in displayed source text.** Unsurprisingly, I7 tables are set (after their titling lines) as HTML tables, and this is fiddly but elementary in the usual way of HTML tables:

⟨Begin I7 table in extension documentation 19⟩ ≡

```
    WRITE("</font><br>");
    begin_plain_html_table(OUT);
    first_html_column(OUT, 0);
```

This code is used in §14.

§**20.** Drinka.

⟨End table cell for I7 table in extension documentation 20⟩ ≡
```
WRITE("</font>");
next_html_column(OUT, 0);
```
This code is used in §11.

§**21.** Pinta.

⟨Begin table cell for I7 table in extension documentation 21⟩ ≡
```
WRITE("<font color=\"#000080\">");
```
This code is used in §11.

§**22.** Milka.

⟨Begin new row of I7 table in extension documentation 22⟩ ≡
```
end_html_row(OUT);
first_html_column(OUT, 0);
```
This code is used in §14.

§**23.** Day.

⟨End I7 table in extension documentation 23⟩ ≡
```
end_html_row(OUT);
end_html_table(OUT);
```
This code is used in §9.

§**24. Typesetting the body of an example.** This is done just the way all other extension documentation material is handled, except that it is inside an inset box: which is provided by a shaded HTML table, containing just one row, which contains just one cell. Here the inset table begins:

⟨Open the new example's text 24⟩ ≡
```
begin_html_table(OUT, "#f0f0f0", TRUE, 0, 0, 0, 0, 0);
first_html_column(OUT, 0);
WRITE("<p>");
```
This code is used in §8.

§**25.** And here the inset table ends:

⟨Close the previous example's text 25⟩ ≡
```
end_html_row(OUT);
end_html_table(OUT);
WRITE("<p>");
```
This code is used in §8.

Index File Services 2/index

Purpose

To provide routines to help build the various HTML index files, none of which are actually created in this section.

2/index.§3-5 Links to source and extension footnotes; §6 Links to detail pages; §7-11 Links to documentation; §12 "See below" links; §13-15 Miscellaneous utilities

---

Template interpreter commands

```
2   {-callv:complete_index}
```

Definitions

¶1. If only we had an index file, we could look it up under "index file"...

The Index of a project is a set of HTML files describing its milieu: the definitions it makes, the world model resulting, and the rules in force, which arise as a combination of the source text and the extensions (in particular, the Standard Rules).

¶2. Documentation is arranged in a series of HTML pages identified by section number 0, 1, 2, ..., and the index contains little blue help icons which link into this. In order to give these links the correct destinations, NI needs to know which section number contains what: but section numbering moves around a lot as the documentation is written.

To avoid needlessly recompiling NI when documentation changes, we give certain sections aliases called "symbols" which are rather more lasting than the section numbering. For instance, the sentence

> Document KINDSVALUE at doc64.

(in the Standard Rules, the only source file allowed to define symbols) creates the symbol `KINDSVALUE` and says that it currently corresponds to `doc64.html` in the documentation. Such sentences are automatically amended by `indoc` to keep the Standard Rules in line with the Inform documentation.

```
typedef struct documentation_ref {
    int symbol;                          Word number in source where the symbol is
    int section;                         HTML page number
    int used_already;                    Has this been used in a problem message already?
    char *chapter_reference;             Or NULL if no chapter name supplied
    char *section_reference;             Or NULL if no section name supplied
    MEMORY_MANAGEMENT
} documentation_ref;
```

The structure documentation_ref is private to this section.

---

§**1.** The index is written at the end of each successful compilation. During indexing, only one index file is ever open for output at a time: this always has the file handle `ifl`. The following routine is called to open a new index file for output.

```
char current_thumbnail_image[MAX_FILENAME_LENGTH];
char current_thumbnail_caption[MAX_FILENAME_LENGTH];
int cti_set = FALSE;
void set_thumbnail_image(char *image, char *caption) {
    cti_set = TRUE;
    strcpy(current_thumbnail_image, image);
    strcpy(current_thumbnail_caption, caption);
}
void open_index_file(char *index_leaf, char *title, int sub,
    char *explanation) {
    char *fn = index_filename(index_leaf, sub);
    if (ifl) close_index_file();
    if (STREAM_OPEN_TO_FILE(&index_file_struct, fn, UTF8_ENC) == FALSE)
        fatal_error2("Can't open index file", fn);
    ifl = &index_file_struct;
    html_header(ifl, title, (cti_set)?current_thumbnail_image:NULL, (cti_set)?current_thumbnail_caption:NULL);
    if (explanation) {
        char temp[MAX_FILENAME_LENGTH];
        strcpy(temp, explanation);
        int i, len = strlen(temp), italics_open = FALSE;
        open_html_paragraph(ifl, 1, "tight");
        for (i=0; i<len; i++) {
            switch (temp[i]) {
                case '|': INDEX("<br><i>"); italics_open = TRUE; break;
                case '<': {
                    int j = i+1;
                    INDEX(" ");
                    while ((j<len) && (temp[j] != '>')) j++;
                    temp[j] = 0;
                    index_doc_link(temp+i+1);
                    i = j;
                    break;
                }
                case '[': {
                    int j = i+1;
                    while ((j<len) && (temp[j] != ']')) j++;
                    temp[j] = 0;
                    index_below_link(temp+i+1);
                    INDEX(" ");
                    i = j;
                    break;
                }
                default: INDEX("%c", temp[i]); break;
            }
        }
        if (italics_open) INDEX("</i>");
        INDEX("</p>\n");
    }
    html_header_complete(ifl, title, (cti_set)?current_thumbnail_image:NULL);
```

```
    ⟨Start keeping track of references to source text in extensions 3⟩;
    indexing_stage = TRUE;
}
```

The function set_thumbnail_image is called from 14/i6t.
The function open_index_file is called from 11/ina, 12/rb and 14/i6t.

§**2.** Written index files are closed either when the next one is opened (see above), or when the `.i6t` interpreter signals the end of indexing by calling `complete_index` below.

```
void complete_index(void) {
    if (ifl) close_index_file();
}
void close_index_file(void) {
    if (ifl == NULL) return;
    ⟨Add footnotes for references to source text in extensions 4⟩;
    html_footer(ifl);
    STREAM_CLOSE(ifl); ifl = NULL;
}
```

The function complete_index is invoked by a command in a `.i6t` template file.

§**3. Links to source and extension footnotes.** When index files need to reference source text material, they normally do so by means of orange back-arrow icons which are linked to positions in the source as typed by the user. But source text also comes from extensions. We don't want to provide source links to those, because they can't easily be opened in the Inform application (on some platforms, anyway), and in any case, can't easily be modified (or should not be, anyway). Instead, we produce footnotes. Each time we start an index file, we wipe the slate clean:

⟨Start keeping track of references to source text in extensions 3⟩ ≡

```
    ef_clear_extension_footnotes();
```

This code is used in §1.

§**4.** And at the foot of each index file, we provide anchors `#fn_1`, `#fn_2`, ..., to footnotes explaining which extension was being referred to:

⟨Add footnotes for references to source text in extensions 4⟩ ≡

```
    extension_file *ef;
    int fnc = 0, n;
    INDEX("<p>");
    for (n=1; n<=ef_no_of_footnoted_extensions(); n++) {
        ef = ef_by_footnote(n);
        if (ef) {
            if (++fnc == 1) INDEX("<hr><p>");
            INDEX("<a name=fn_%d><img border=0 src=inform:/Revealext.png>. Defined in ",
                n, n);
            /* INDEX("<a name=fn_%d><font color=\"#800000\">[E%d]</font>. Defined in ",
                n, n); */
            ef_write_full_title_to_file(ef, ifl);
            INDEX("<br>");
        }
    }
```

This code is used in §2.

§**5.** So, then, source links are omitted if the reference is to a location in the Standard Rules; if it is to an extension other than that, the link is replaced by a square-bracketed footnote about this; and otherwise we make a link to the source text in the application.

```
void index_link(source_location sl) {
    extension_file *ef = sf_get_extension_corresponding(sl.file_of_origin);
    if (ef) {
        if (ef != standard_rules_extension) {
            /* int fn = ef_get_footnote(ef);
            INDEX(" <small><a href=#fn_%d><font color=\"#800000\">", fn);
            INDEX("[E%d]</font></a></small>", fn); */
            INDEX(" ");
            begin_extension_link(ifl, ef_get_eid(ef), NULL);
            INDEX("<img border=0 src=inform:/Revealext.png>");
            end_extension_link(ifl, ef_get_eid(ef));
        }
        return;
    }
    html_source_link(ifl, sl);
}
```

The function index_link is called from 2/lexi, 4/ext, 4/vm, 4/head, 5/rel, 5/aph, 7/dim, 7/kix, 9/qty, 9/inpw, 9/tmap, 10/tab, 10/eqns, 10/fig, 10/sfx, 10/exf, 11/act, 11/nap, 11/av, 12/phin, 12/tiph, 12/br, 12/rb and 13/gl.

§**6. Links to detail pages.** The "Beneath" icon is used for links to details pages seen as beneath the current index page: for instance, for the link from the Actions page to the page about the taking action.

```
void index_detail_link(char *stub, int sub, int down) {
    INDEX(" <a href=%s%d_%s.html><img border=0 src=inform:/Beneath.png></a>",
        (down)?"Details/":"", sub, stub);
}
```

The function index_detail_link is called from 11/act, 11/ina, 12/rb and 13/gl.

§**7. Links to documentation.** The blue query icons link to pages in the documentation, as described above. Documentation references are used to match the documentation text against the NI compiler so that each can be changed independently of the other. First, we handle the Standard-Rules-only sentences which specify documentation references:

```
sentence_handler DOC_SH_handler =
    { SENTENCE_NT, DOC_VB, 1, dref_new };
void dref_new(parse_node *p) {
    int sym1, sym2, ref1, ref2;
    [[sym1, sym2 <-- p->down->next]];
    [[ref1, ref2 <-- p->down->next->next]];
    documentation_ref *dr = CREATE(documentation_ref);
    dr->symbol = sym1+1;
    dr->section = ref1;
    dr->used_already = FALSE;
    dr->chapter_reference = NULL;
    dr->section_reference = NULL;
    if ((ref2 >= ref1+1) && (vocab_test_flags(ref1+1, TEXT_MC))) {
        dequote_word(ref1+1);
        dr->chapter_reference = lw_array[ref1+1].lw_text;
```

```
    }
    if ((ref2 >= ref1+2) && (vocab_test_flags(ref1+2, TEXT_MC))) {
        dequote_word(ref1+2);
        dr->section_reference = lw_array[ref1+2].lw_text;
    }
}
```

§**8.** The following routine is used to verify that a given text is, or is not, a valid documentation reference symbol. (For instance, we might look up `kind_vehicle` to see if any section of documentation has been flagged as giving information on vehicles.) If our speculative link symbol exists, we return the leafname for this documentation page, without filename extension (say `doc24`); if it does not exist, we return NULL.

```
char *dref_validate_if_possible(char *temp) {
    documentation_ref *dr;
    LOOP_OVER(dr, documentation_ref)
        if (compare_word_by_strcmp(dr->symbol, temp))
            return lw_array[dr->symbol].lw_text;
    return NULL;
}
```

The function dref_validate_if_possible is called from 9/inpw.

§**9.** And similarly, though case-sensitively this time, returning the page we link to:

```
char *dref_link_if_possible_once(char *temp, char **chap, char **sec) {
    documentation_ref *dr;
    LOOP_OVER(dr, documentation_ref)
        if (compare_raw_word_by_strcmp(dr->symbol, temp))
            if (dr->used_already == FALSE) {
                char *leaf = lw_array[dr->section].lw_text;
                *chap = dr->chapter_reference;
                *sec = dr->section_reference;
                LOOP_OVER(dr, documentation_ref)
                    if (strcmp(leaf, lw_array[dr->section].lw_text) == 0)
                        dr->used_already = TRUE;
                return leaf;
            }
    return NULL;
}
```

The function dref_link_if_possible_once is called from 2/prob3.

§**10.** In the Standard Rules, a number of phrases (and other constructs) are defined along with markers to sections in the documentation: here we parse these markers, returning either the word number of the documentation symbol in question, or −1 if there is none.

```
int dref_position_of_symbol(int *w1, int *w2, int front) {
    int x1 = *w1, x2 = *w2;
    if (x2 < x1+4) return -1;
    if (front == FALSE) x1 = x2-4;
    if [[x1, x2 == OPENBRACKET documented at ### CLOSEBRACKET]] {
        if (front) *w1 += 5; else *w2 -= 5;
        return x1+3;
    }
    if [[x1, x2 == DASHDASH documented at ### DASHDASH]] {
        if (front) *w1 += 5; else *w2 -= 5;
        return x1+3;
    }
    return -1;
}
```

The function dref_position_of_symbol is called from 8/creat, 9/qty, 11/av and 12/ph.

§**11.** Finally, the blue "see relevant help page" icon links are placed by the following routine. The internal error will, of course, never occur, but the reader will draw his own conclusion from the way it is so very communicative if it does.

```
void index_doc_link(char *fn) {
    documentation_ref *dr;
    int c = 0;
    LOOP_OVER(dr, documentation_ref) {
        c++;
        if (compare_raw_word_by_strcmp(dr->symbol, fn)) {
            INDEX(" <a href=inform:/%s.html><img border=0 src=inform:/help.png></a>",
                lw_array[dr->section].lw_rawtext);
            return;
        }
    }
    LOG("Bad ref was <%s>. %d known references are:\n", fn, c);
    LOOP_OVER(dr, documentation_ref) {
        LOG("<%s> = %s\n", lw_array[dr->symbol].lw_rawtext, lw_array[dr->section].lw_rawtext);
    }
    internal_error("Bad index documentation reference");
}
```

The function index_doc_link is called from 2/lexi, 4/ext, 7/kix, 9/qty, 9/inpw, 10/tab, 10/eqns, 10/bib, 10/fig, 10/sfx, 10/exf, 11/nap, 12/phin and 12/rb.

§**12. "See below" links.** These are the grey magnifying glass icons. The links are done by internal href links to anchors lower down the same HTML page. These can be identified either by number, or by name: whichever is more convenient for the indexing code.

```
void index_below_link(char *p) {
    INDEX(" <a href=#%s><img border=0 src=inform:/Below.%s></a>",
        p, ICON_EXT);
}
void index_anchor(char *p) {
    INDEX("<a name=%s></a>", p);
}
void index_below_link_numbered(int n) {
    INDEX(" <a href=#A%d><img border=0 src=inform:/Below.%s></a>", n,
        ICON_EXT);
}
void index_anchor_numbered(int n) {
    INDEX("<a name=A%d></a>", n);
}
```

The function index_below_link is called from 9/inpw, 12/phin and 13/gv.

The function index_anchor is called from 2/lexi, 4/ext, 4/vm, 9/qty, 9/inpw, 9/tmap, 10/bib, 11/act, 11/nap, 11/ina, 12/phin and 13/gl.

The function index_below_link_numbered is called from 2/lexi, 7/kix, 9/tmap and 12/phin.

The function index_anchor_numbered is called from 2/lexi, 7/kix, 9/tmap and 12/phin.

§**13. Miscellaneous utilities.** First: to print a double-quoted word into the index, without its surrounding quotes.

```
void index_dequote(char *p) {
    int i = 1;
    if ((p[0] == 0) || (p[1] == 0)) return;
    for (i=1; p[i+1]; i++) {
        char c = p[i];
        switch(c) {
            case '"': INDEX("&quot;"); break;
            default: INDEX("%c", c); break;
        }
    }
}
```

The function index_dequote is called from 9/inpw.

§**14.** Next: indexing the name of a world object, supplementing it with a link to the sentence in the source text which created it.

```
void index_name_object(world_object *wo, char *before, char *after) {
    INDEX("%s", before);
    if (wo->word_ref1 < 0) INDEX("(nameless)");
    else print_raw_text_to_file(wo->word_ref1, wo->word_ref2, ifl);
    INDEX("%s", after);
    if (wo->creating_sentence != NULL)
        index_link(lw_array[wo->creating_sentence->word_ref1].lw_source);
}
```

The function index_name_object is called from 7/kix and 9/inpw.

§**15.** Finally: three routines for indexing kinds of value and data types.

```
void index_kov(kind_of_value *kov) {
    int w1, w2;
    world_object *wo = kovko_get_kind(kov);
    if (wo) {
        print_raw_text_to_file(wo->word_ref1, wo->word_ref2, ifl);
        return;
    }
    kov_get_name(kov, &w1, &w2, FALSE);
    if (w1 >= 0) print_raw_text_to_file(w1, w2, ifl);
    else INDEX("%s", kov_get_description(kov));
}
void index_lowercase_dtid(int vs) {
    int w1, w2;
    type_ID_copy_name(vs, &w1, &w2);
    if (w1 >= 0) print_text_to_file(w1, w2, ifl);
    else INDEX("%s", type_ID_get_description(vs));
}
void log_lowercase_dtid(int vs) {
    int w1, w2;
    type_ID_copy_name(vs, &w1, &w2);
    if (w1 >= 0) print_text_to_file(w1, w2, dl);
    else INDEX("%s", type_ID_get_description(vs));
}
void index_lowercase_kov(kind_of_value *kov) {
    int w1, w2;
    world_object *wo = kovko_get_kind(kov);
    if (wo) {
        print_text_to_file(wo->word_ref1, wo->word_ref2, ifl);
        return;
    }
    kov_get_name(kov, &w1, &w2, FALSE);
    if (w1 >= 0) print_text_to_file(w1, w2, ifl);
    else INDEX("%s", kov_get_description(kov));
}
```

The function index_kov is called from 9/inpw.

The function index_lowercase_dtid is called from 7/kix and 12/phin.

The function log_lowercase_dtid is called from 7/tids.

The function index_lowercase_kov is called from 9/qty and 12/phtd.

Lexicon Index 2/lexi

Purpose

To construct the Lexicon portion of the Phrasebook page of the Index, which gives brief definitions and references for nouns, adjectives and verbs used in source text for the current project.

2/lexi.§4-5 Producing the lexicon; §6-9 Stocking the lexicon; §10-11 Processing the lexicon; §12-19 Printing the lexicon out in HTML format; §20-21 The table of verbs

---

Definitions

¶1. The lexicon is the part of the Index which gives an alphabetised list of adjectives, nouns, verbs and other words which can be used in descriptions of things: it's the nearest thing to an index of the meanings inside NI. This is in one sense quite an elaborate indexing mechanism, since it brings together meanings relating to various different NI structures under a single umbrella, the "lexicon entry" structure:

```
define NOUN_LEXE 1                          a kind
define PROPER_NOUN_LEXE 2                   a world object which is not a kind
define ADJECTIVAL_PHRASE_LEXE 3             the subject of a "Definition:"
define ENUMERATED_QUANTITY_LEXE 4           e.g., "green" if colour is a kind of value and green a colour
define VERB_LEXE 5                          and ordinary verb
define ABLE_VERB_LEXE 6                     a "to be able to..." verb
define MISCELLANEOUS_LEXE 7                 a connective, article or determiner
```

¶2. We can set entries either to excerpts of words from the source, or to any collation of up to 5 vocabulary entries.

```
typedef struct lexicon_entry {
    int w1, w2;                             either the text of the entry, or -1,-1, in which case...
    struct vocabulary_entry *ve1;           ...the first word is here
    struct vocabulary_entry *ve2;           second word, or NULL
    struct vocabulary_entry *ve3;           third word, or NULL
    struct vocabulary_entry *ve4;           fourth word, or NULL
    struct vocabulary_entry *ve5;           fifth word, or NULL
    int part_of_speech;                     one of those above
    char *category;                         textual description of said, e.g., "adjective"
    struct general_pointer entry_refers_to; depending on which part of speech
    struct parse_node *verb_defined_at;     sentence where defined (verbs only)
    char *gloss_note;                       gloss on the definition, or NULL if none is provided
    char reduced_to_lower_case[32];         text converted to lower case for sorting
    struct lexicon_entry *sorted_next;      next in lexicographic order
    MEMORY_MANAGEMENT
} lexicon_entry;

lexicon_entry *sorted_lexicon = NULL;       head of list in lexicographic order
lexicon_entry *current_main_verb = NULL;    when parsing verb declarations
```

The structure lexicon_entry is private to this section.

---

§**1.** Lexicon entries are created by the following routine:

```
lexicon_entry *lexicon_new_entry(int w1, int w2) {
    lexicon_entry *lex = CREATE(lexicon_entry);
    lex->w1 = w1; lex->w2 = w2;
    lex->ve1 = NULL; lex->ve2 = NULL; lex->ve3 = NULL; lex->ve4 = NULL; lex->ve5 = NULL;
    lex->part_of_speech = MISCELLANEOUS_LEXE;
    lex->entry_refers_to = NULL_GENERAL_POINTER;
    lex->category = NULL; lex->gloss_note = NULL; lex->verb_defined_at = NULL;
    return lex;
}
```

§**2.** The next two routines provide higher-level creators for lexicon entries. The `current_main_verb` setting is used to ensure that inflected forms of the same verb are grouped together in the verbs table.

```
lexicon_entry *lexicon_new_entry_with_details(int w1, int w2, int pos,
    vocabulary_entry *ve1, vocabulary_entry *ve2, char *category, char *gloss) {
    lexicon_entry *lex = lexicon_new_entry(w1, w2);
    lex->part_of_speech = pos;
    lex->ve1 = ve1; lex->ve2 = ve2;
    lex->category = category; lex->gloss_note = gloss;
    return lex;
}
lexicon_entry *lexicon_new_main_verb(vocabulary_entry *infinitive, int part) {
    lexicon_entry *lex = lexicon_new_entry(-1, -1);
    lex->ve1 = infinitive;
    lex->part_of_speech = part;
    lex->category = "verb";
    lex->verb_defined_at = current_sentence;
    current_main_verb = lex;
    return lex;
}
```

The function lexicon_new_entry_with_details is called from 5/det.
The function lexicon_new_main_verb is called from 5/conj.

§**3.** As we've seen, a lexicon entry's text can be either a word range or a collection of vocabulary words, and it's therefore convenient to have a utility routine which extracts the name in plain text from either source.

define `MAX_TEXT_FOR_LEXICON_ENTRY (5*MAX_WORD_LENGTH+5)` *the theoretical worst-case length, plus 1*

```
void lexicon_copy_to_string(lexicon_entry *lex, char *str) {
    if (lex->w1 >= 0) print_raw_text_to_string(lex->w1, lex->w2, str);
    else {
        str[0] = 0;
        if (lex->ve1) sprintf(str+strlen(str), "%s", vocab_get_exemplar(lex->ve1, FALSE));
        if (lex->ve2) sprintf(str+strlen(str), " %s", vocab_get_exemplar(lex->ve2, FALSE));
        if (lex->ve3) sprintf(str+strlen(str), " %s", vocab_get_exemplar(lex->ve3, FALSE));
        if (lex->ve4) sprintf(str+strlen(str), " %s", vocab_get_exemplar(lex->ve4, FALSE));
        if (lex->ve5) sprintf(str+strlen(str), " %s", vocab_get_exemplar(lex->ve5, FALSE));
    }
}
```

§4. **Producing the lexicon.** The lexicon is by no means empty when the following routine is called: lexicon entries have already been created for verbs and determiners. But it doesn't yet contain nouns or adjectives.

```
void index_lexicon(void) {
    ⟨Stock the lexicon with nouns from names of kinds of object 6⟩;
    ⟨Stock the lexicon with adjectives from names of adjectival phrases 7⟩;
    ⟨Stock the lexicon with nouns from names of quantities 8⟩;
    ⟨Stock the lexicon with miscellaneous bits and pieces 9⟩;
    ⟨Create lower-case forms of all lexicon entries 10⟩;
    ⟨Sort the lexicon into alphabetical order 11⟩;
    int common_nouns_only = FALSE;
    index_anchor("LEXICON");
    INDEX("<b>Lexicon of words used in descriptions</b><p>\n");
    ⟨Explanatory head-note at the top of the lexicon 12⟩;
    ⟨Main body of the lexicon 13⟩;
    INDEX("<p><hr><p>");
    index_anchor("RELTABLE");
    INDEX("<b>Relations</b><p>\n");
    index_table_of_relations();
    INDEX("<p><hr><p>");
    index_anchor("VERBTABLE");
    INDEX("<b>Verbs used in descriptions</b><p>\n");
    ⟨Table of parts of verbs at the foot of the lexicon 20⟩;
}
```

The function index_lexicon is called from 12/phin.

§5. And here is a cut-down version which prints a lexicon of common nouns only, for the foot of the World index.

```
void index_common_nouns(void) {
    int common_nouns_only = TRUE;
    index_anchor("LEXICON");
    INDEX("<p><hr><p><b>A to Z</b><p>\n");
    ⟨Main body of the lexicon 13⟩;
}
```

The function index_common_nouns is called from 9/inpw.

§**6. Stocking the lexicon.** Despite the implication of the over-cautious code below, kinds do always have creation nodes – i.e., their names always derive from the source text.

⟨Stock the lexicon with nouns from names of kinds of object 6⟩ ≡

```
lexicon_entry *lex;
world_object *wo;
LOOP_OVER(wo, world_object)
    if (wo->word_ref1 >= 0) {
        lex = lexicon_new_entry(wo->word_ref1, wo->word_ref2);
        if (wo->kind_flag) lex->part_of_speech = NOUN_LEXE;
        else lex->part_of_speech = PROPER_NOUN_LEXE;
        lex->category = "noun";
        lex->entry_refers_to = STORE_POINTER_world_object(wo);
    }
```

This code is used in §4.

§**7.** These are adjectives set up by "Definition:".

⟨Stock the lexicon with adjectives from names of adjectival phrases 7⟩ ≡

```
lexicon_entry *lex;
adjectival_phrase *adj;
LOOP_OVER(adj, adjectival_phrase) {
    lex = lexicon_new_entry(adj->word_ref1, adj->word_ref2);
    lex->part_of_speech = ADJECTIVAL_PHRASE_LEXE;
    lex->category = "adjective";
    lex->entry_refers_to = STORE_POINTER_adjectival_phrase(adj);
}
```

This code is used in §4.

§**8.** The idea here is that if a new kind of value such as "colour" is created, then its values should be indexed as nouns – "red", "blue" and so on. (Sometimes these will also be listed separately with an adjectival sense.)

⟨Stock the lexicon with nouns from names of quantities 8⟩ ≡

```
lexicon_entry *lex;
quantity *qn;
LOOP_OVER(qn, quantity)
    if ((qty_is_a_variable(qn) == FALSE) &&
        (kov_is_an_enumeration(qty_kind_of_value(qn)))) {
        property_name *prn = kov_get_coinciding_property(qty_kind_of_value(qn));
        if ((prn) && (prn_condition_of_which_object(prn))) continue;
        lex = lexicon_new_entry(qn->word_ref1, qn->word_ref2);
        lex->part_of_speech = ENUMERATED_QUANTITY_LEXE;
        lex->category = "noun";
        lex->entry_refers_to = STORE_POINTER_quantity(qn);
    }
```

This code is used in §4.

§**9.** It seems unfitting for a dictionary to omit “a”, “an”, “the”, “some”, “which” or “who”.

⟨Stock the lexicon with miscellaneous bits and pieces 9⟩ ≡

```
lexicon_entry *lex;
lex = lexicon_new_entry(-1, -1);
lex->ve1 = which_V;
lex->part_of_speech = MISCELLANEOUS_LEXE; lex->category = "connective";
lex->gloss_note = "used to place a further condition on a description: "
    "'A which is B', or 'A which carries B', for instance.";
lex = lexicon_new_entry(-1, -1);
lex->ve1 = who_V;
lex->part_of_speech = MISCELLANEOUS_LEXE; lex->category = "connective";
lex->gloss_note = "- see </i>which<i>.";
lex = lexicon_new_entry(-1, -1);
lex->ve1 = a_V;
lex->part_of_speech = MISCELLANEOUS_LEXE; lex->category = "indefinite article";
lex = lexicon_new_entry(-1, -1);
lex->ve1 = an_V;
lex->part_of_speech = MISCELLANEOUS_LEXE; lex->category = "indefinite article";
lex->gloss_note = "- see </i>a<i>";
lex = lexicon_new_entry(-1, -1);
lex->ve1 = some_V;
lex->part_of_speech = MISCELLANEOUS_LEXE; lex->category = "indefinite article";
lex = lexicon_new_entry(-1, -1);
lex->ve1 = the_V;
lex->part_of_speech = MISCELLANEOUS_LEXE; lex->category = "definite article";
```

This code is used in §4.

§**10. Processing the lexicon.** Before we can sort the lexicon, we need to turn its disparate forms of name into a single, canonical, lower-case representation. We truncate this to at most 31 characters to keep the storage requirements reasonable: so in fact sorting of the lexicon will fail correctly to sequence name variations after the 31st character, but this seems an acceptable trade-off.

⟨Create lower-case forms of all lexicon entries 10⟩ ≡

```
lexicon_entry *lex;
LOOP_OVER(lex, lexicon_entry) {
    int i;
    char entry_text[MAX_TEXT_FOR_LEXICON_ENTRY];
    lexicon_copy_to_string(lex, entry_text); entry_text[31] = 0;
    for (i=0; entry_text[i]; i++) entry_text[i] = tolower(entry_text[i]);
    strcpy(lex->reduced_to_lower_case, entry_text);
}
```

This code is used in §4.

§**11.** The lexicon is sorted by insertion sort, which is not ideally fast, but which is convenient when dealing with linked lists: there are unlikely to be more than 1000 or so entries, so the speed penalty for insertion rather than (say) quicksort is not great.

⟨Sort the lexicon into alphabetical order 11⟩ ≡

```
lexicon_entry *lex;
LOOP_OVER(lex, lexicon_entry) {
    lexicon_entry *lex2, *last_lex;
    if (sorted_lexicon == NULL) {
        sorted_lexicon = lex; lex->sorted_next = NULL; continue;
    }
    for (last_lex = NULL, lex2 = sorted_lexicon; lex2;
        last_lex = lex2, lex2 = lex2->sorted_next)
        if (strcmp(lex->reduced_to_lower_case, lex2->reduced_to_lower_case) < 0) {
            if (last_lex == NULL) sorted_lexicon = lex;
            else last_lex->sorted_next = lex;
            lex->sorted_next = lex2; goto Inserted;
        }
    last_lex->sorted_next = lex; lex->sorted_next = NULL;
    Inserted: ;
}
```

This code is used in §4.

§12. Printing the lexicon out in HTML format.

⟨Explanatory head-note at the top of the lexicon 12⟩ ≡

```
INDEX("<small>For instance, the description 'an unlocked door' is made "
    "up from the adjective 'unlocked' and the noun 'door', both of which "
    "can be found below. Property adjectives, like 'open', can be used "
    "when creating things - 'In the Ballroom is an open container' is "
    "allowed because 'open' is a property - but those with complicated "
    "definitions, like 'empty', can only be tested during play, e.g. "
    "with rules like 'Instead of taking an empty container, ...'.</small><p>");
```

This code is used in §4.

§**13.** Now for the bulk of the work. Entries appear in CSS paragraphs with hanging indentation and no interparagraph spacing, so we need to insert regular `<p>` paragraphs between the As and the Bs, then between the Bs and the Cs, and so on. Each entry consists of the wording, then maybe some icons, then an explanation of what it is: for instance,

player's holdall [icon] *noun, a kind of* container

In a few cases, there is a further textual gloss to add.

⟨Main body of the lexicon 13⟩ ≡

```
lexicon_entry *lex;
char current_initial_letter = '?';
int verb_count = 0, entry_count = 0, c;
for (lex = sorted_lexicon; lex; lex = lex->sorted_next)
    if (lex->part_of_speech == PROPER_NOUN_LEXE)
        entry_count++;
if (common_nouns_only) {
    begin_html_table(ifl, NULL, TRUE, 0, 0, 0, 0, 0);
    first_html_column(ifl, 0);
```

```
}
for (c = 0, lex = sorted_lexicon; lex; lex = lex->sorted_next) {
    if (common_nouns_only) { if (lex->part_of_speech != PROPER_NOUN_LEXE) continue; }
    else { if (lex->part_of_speech == PROPER_NOUN_LEXE) continue; }
    if ((common_nouns_only) && (c++ == entry_count/2)) next_html_column(ifl, 0);
    if (current_initial_letter != lex->reduced_to_lower_case[0]) {
        INDEX("<p>");
        current_initial_letter = lex->reduced_to_lower_case[0];
    }
    INDEX("<p class=\"hang\">");
    ⟨Text of the actual lexicon entry 14⟩;
    ⟨Icon with link to documentation, source or verb table, if any 15⟩;
    INDEX("  <i>");
    if ((common_nouns_only == FALSE) && (lex->category))
        INDEX("%s", lex->category);
    switch(lex->part_of_speech) {
        case ADJECTIVAL_PHRASE_LEXE:
            ⟨Description of adjectival phrase entry 18⟩; break;
        case ENUMERATED_QUANTITY_LEXE:
            ⟨Description of enumerated quantity entry 19⟩; break;
        case PROPER_NOUN_LEXE:
            ⟨Description of proper noun entry 17⟩; break;
        case NOUN_LEXE:
            ⟨Description of noun entry 16⟩; break;
        default: INDEX("</i>"); break;
    }
    if (lex->gloss_note) INDEX(" <i>%s</i>", lex->gloss_note);
    INDEX("</p>");
}
if (common_nouns_only) { end_html_row(ifl); end_html_table(ifl); }
```

This code is used in §4,5,4,5,4,5.

§**14.** In traditional dictionary fashion, we present the text in what may not be the most normal ordering, in order to place the alphabetically important part first: thus "see, to be able to" rather than "to be able to see". (Compare "Gallifreyan High Council, continual incidences of madness and treachery amongst the" in *Doctor Who: The Completely Useless Encyclopaedia*, eds. Howarth and Lyons (1996).)

⟨Text of the actual lexicon entry 14⟩ ≡

```
char entry_text[MAX_TEXT_FOR_LEXICON_ENTRY];
lexicon_copy_to_string(lex, entry_text);
print_literal_string_to_file(ifl, entry_text);
if (lex->part_of_speech == ABLE_VERB_LEXE) INDEX(", to be able to");
```

This code is used in §13.

§**15.** Main lexicon entries to do with verbs link further down the index page to the corresponding entries in the verb table. We want to use numbered anchors for these links, but we want to avoid colliding with numbered anchors already used for other purposes higher up on the Phrasebook index page. So we use a set of anchors numbered 10000 and up, which is guaranteed not to coincide with any of those.

We omit source links to an adjectival phrase because these are polymorphic, that is, the phrase may have multiple definitions in different parts of the source text: so any single link would be potentially misleading.

⟨Icon with link to documentation, source or verb table, if any 15⟩ ≡

```
switch(lex->part_of_speech) {
    case NOUN_LEXE: {
        world_object *wo = RETRIEVE_POINTER_world_object(lex->entry_refers_to);
        if (wo->wo_documentation_symbol != NULL)
            index_doc_link(wo->wo_documentation_symbol);
        break;
    }
    case VERB_LEXE:
    case ABLE_VERB_LEXE:
        index_below_link_numbered(10000+verb_count++);
        break;
}
if ((lex->part_of_speech != ADJECTIVAL_PHRASE_LEXE) && (lex->w1 >= 0))
    index_link(lw_array[lex->w1].lw_source);
```

This code is used in §13.

§**16.** Recall that the `kind` of a kind points either to the kind it is a subkind of, or else to `kind_kind` if it is a kind of object and therefore at the top of the hierarchy.

⟨Description of noun entry 16⟩ ≡

```
world_object *wo = RETRIEVE_POINTER_world_object(lex->entry_refers_to);
if (wo->kind != kind_kind) {
    INDEX(", a kind of </i>");
    print_raw_text_to_file(wo->kind->word_ref1, wo->kind->word_ref2, ifl);
} else INDEX(", a kind</i>");
```

This code is used in §13.

§**17.** Simply the name of a world object.

⟨Description of proper noun entry 17⟩ ≡

```
world_object *wo = RETRIEVE_POINTER_world_object(lex->entry_refers_to);
if (wo->kind != kind_thing)
    print_raw_text_to_file(wo->kind->word_ref1, wo->kind->word_ref2, ifl);
INDEX("</i>");
```

This code is used in §13.

§**18.** As mentioned above, an adjectival phrase can be multiply defined in different contexts. We want to quote all of those.

⟨Description of adjectival phrase entry 18⟩ ≡
```
int ac = 0, nc;
adjective_meaning *am;
adjectival_phrase *aph =
    RETRIEVE_POINTER_adjectival_phrase(lex->entry_refers_to);
INDEX(": ");
LOOP_OVER_SORTED_MEANINGS(aph, am) ac++; nc = ac;
LOOP_OVER_SORTED_MEANINGS(aph, am) {
    ac--;
    if (nc > 1) INDEX("<br>%d. ", nc-ac);
    am_print_to_index(am);
    if (ac >= 1) INDEX("; ");
}
INDEX("</i>");
```
This code is used in §13.

§**19.** Lastly and most easily, the name of an enumerated value of some kind of value.

⟨Description of enumerated quantity entry 19⟩ ≡
```
int w1, w2;
quantity *qn = RETRIEVE_POINTER_quantity(lex->entry_refers_to);
kind_of_value *kov = qty_kind_of_value(qn);
INDEX(", value of </i>");
kov_get_name(kov, &w1, &w2, FALSE);
print_raw_text_to_file(w1, w2, ifl);
```
This code is used in §13.

§**20. The table of verbs.** This is used in two different ways: firstly, at the foot of the lexicon –

⟨Table of parts of verbs at the foot of the lexicon 20⟩ ≡
```
lexicon_entry *lex = sorted_lexicon;
int verb_count = 0;
for (lex = sorted_lexicon; lex; lex = lex->sorted_next)
    if ((lex->part_of_speech == VERB_LEXE) || (lex->part_of_speech == ABLE_VERB_LEXE)) {
        char entry_text[MAX_TEXT_FOR_LEXICON_ENTRY];
        INDEX("<p class=\"hang\">");
        index_anchor_numbered(10000+verb_count++);                    anchors from 10000: see above
        lexicon_copy_to_string(lex, entry_text);
        if (lex->part_of_speech == VERB_LEXE) INDEX("To <b>%s</b>", entry_text);
        else INDEX("To be able to <b>%s</b>", entry_text);
        if (lex->w1 >= 0) index_link(lw_array[lex->w1].lw_source);
        INDEX("</p>");
        tabulate_verb(lex, IS_TENSE, "present");
        tabulate_verb(lex, WAS_TENSE, "past");
        tabulate_verb(lex, HASBEEN_TENSE, "present perfect");
        tabulate_verb(lex, HADBEEN_TENSE, "past perfect");
    }
```
This code is used in §4.

§**21.** – and secondly, in the documentation for extensions, where we want to be able to print out a table of just those verbs created in that extension.

```
void lexicon_list_verbs_in_file(OUTPUT_STREAM, source_file *sf, extension_file *ef) {
    int verb_count = 0;
    lexicon_entry *lex;
    LOOP_OVER(lex, lexicon_entry)
        if (((lex->part_of_speech == VERB_LEXE) || (lex->part_of_speech == ABLE_VERB_LEXE))
            && (lex->verb_defined_at)
            && (lw_array[lex->verb_defined_at->word_ref1].lw_source.file_of_origin == sf)) {
            char entry_text[MAX_TEXT_FOR_LEXICON_ENTRY];
            lexicon_copy_to_string(lex, entry_text);
            if (verb_count++ == 0) WRITE("Verbs: "); else WRITE(", ");
            if (lex->part_of_speech == VERB_LEXE) WRITE("to <b>%s</b>", entry_text);
            else WRITE("to be able to <b>%s</b>", entry_text);
            new_dictionary_entry_str("verb", ef, entry_text);
        }
    if (verb_count > 0) WRITE("<p>");
}
```

The function lexicon_list_verbs_in_file is called from 4/edoc.

Progress Percentages 2/prog

Purpose

This tiny section, the Lichtenstein of Inform, prints percentage of completion estimates onto `stderr` so that the host application can intercept them and update its graphical progress bar.

---

§**1.** Clearly we can only estimate how far Inform has progressed. While we could in principle measure the number of CPU-seconds it has run for, we don't know how many more it will need. Instead, we rely on experience to suggest that its run can be broken down into the following five stages, which a given percentage of time spent in each stage: thus, for instance, semantic analysis takes up about ten percent of every run in which problems do not cause an early halt. Within each stage, we have a reasonable measure of how far we have got: what proportion of the phrases have been compiled, for instance, tells us how far "generating code" has got. The result is that (if the relevant command line setting has been set, so that `show_progress_indicator` is true) Inform prints about thirty lines like this one to `stderr`:

```
++ 32% (Binding rulebooks)
```

The Inform application can intercept and parse these lines to display a progress bar with a rubric beneath it.

```
int last_progress_pc = -100;
int progress_stage_from[] = { 0, 5, 15, 20, 40, 100 };
char *progress_stage_name[] = { "Lexical analysis", "Semantic analysis",
    "Drawing inferences", "Binding rulebooks", "Generating code" };

void progress_bar(int stage, float proportion) {
    int r1 = progress_stage_from[stage], r2 = progress_stage_from[stage+1];
    int pc = r1 + ((int) (proportion*(r2-r1)));
    if (show_progress_indicator == FALSE) return;
    if (pc-last_progress_pc < 3) return;
    STREAM_WRITE(STDERR, "++ %d%% (%s)\n", pc, progress_stage_name[stage]);
    STREAM_FLUSH(STDERR);
    last_progress_pc = pc;
}
```

The function progress_bar is called from 12/cs, 12/ph and 14/i6t.

Problems, Level 0 2/prob0

Purpose
To handle fatal errors.

---

§**1.** In my beginning is my end: this lowest level of the error-handling system deals with systemic collapses.

```
void fatal_error(char *message) {
    STREAM_WRITE(STDERR, message);
    STREAM_WRITE(STDERR, "\n");
    STREAM_FLUSH(STDERR);
    exit(2);
}
void fatal_error2(char *message, char *fn) {
    STREAM_WRITE(STDERR, message);
    STREAM_WRITE(STDERR, "\nOffending filename: <%s>\n", fn);
    STREAM_FLUSH(STDERR);
    exit(2);
}
```

The function fatal_error is called from 2/mem, 2/strm, 2/dl, 3/lex, 4/ext, 4/excen, 12/phtd, 12/cinv, 12/cph, 14/main and 14/i6t.
The function fatal_error2 is called from 2/index, 2/prob3, 2/dl, 3/read, 4/ext, 4/excen, 4/edict, 4/edoc, 4/head, 9/map, 10/bib and 14/i6t.

§**2.** Fatal errors are not necessarily a bad thing. When tracking down why NI issues certain problem messages (especially internal errors) it can be useful to provoke a deliberate crash of the application, in order to get a stack backtrace into the GNU debugger `gdb` (and/or onto the system console logs). We can force this using the following variables (which main sets with the command-line switch "-gdb").

```
int crash_on_all_errors = FALSE;
int crash_on_internal_errors = FALSE;
void force_crash(void) {
    STREAM_FLUSH(STDOUT);
    STREAM_FLUSH(dl);
    STREAM_WRITE(STDERR,
        "*** Intentionally crashing to force stack backtrace to console logs ***\n");
    STREAM_FLUSH(STDERR);
    parse_node *PN = NULL; log_subtree(PN->next, 1);
    exit(1);
}
```

The function force_crash is called from 2/prob2 and 2/prob3.

Problems, Level 1 2/prob1

Purpose

To render problem messages either as plain text or HTML, and write them out to files.

---

§**1.** Only one error text needs to be stored in memory at any one time, so we keep it in a single string array called the `problem_buffer`. Horrible things will happen if the bounds of this buffer are ever broken, so it has been made very large.

```
define PROBLEM_BUFFER_LENGTH 10000
define PBUFF problem_buffer+strlen(problem_buffer)

char problem_buffer[PROBLEM_BUFFER_LENGTH];
```

§**2.** Roughly speaking, text for error messages comes from two possible sources: fairly short standard texts inside NI, and quotations (direct or indirect) from the source text. The latter are inserted by the routines in this section, and they are the ones we should be wary of, since bizarre input might cause dangerously long quotations to be made. A quotation involves copying text from word `w1` to `w2`, so there are two dangers: copying a single very long word, or copying too many of them. We protect against the first by using the `print_modest_sized_text_to_string` routine, which truncates long literals. We protect against the second overflow hazard by limiting the amount of text we are prepared to quote from any sentence in one go:

```
define QUOTATION_TOLERANCE_LIMIT 100

void copy_text_into_problem_buffer(int w1, int w2) {
    if (w2 > w1 + QUOTATION_TOLERANCE_LIMIT) w2 = w1 + QUOTATION_TOLERANCE_LIMIT - 1;
    print_modest_sized_text_to_string(w1, w2, PBUFF);
}
```

The function copy_text_into_problem_buffer is called from 2/prob2.

§**3.** References to source code need careful handling because they may need to be transcribed both as HTML links (in the `Problems.html` file) and as plain text (to `stderr` and the debugging log). See "HTML Files" above.

```
void copy_source_reference_into_problem_buffer(int w1, int w2) {
    char *filename, *paraphrase;
    if (w1 < 0) { sprintf(PBUFF, "<no text>"); return; }
    source_file *referred = lw_array[w1].lw_source.file_of_origin;
    if (referred) {
        filename = sf_get_filename(referred);
        if (bundle_name && (strncmp(filename,bundle_name,strlen(bundle_name)) == 0))
            filename += strlen(bundle_name) + 1;
    } else filename = "(no file)";
    sprintf(PBUFF, "'");
    copy_text_into_problem_buffer(w1, w2);
    paraphrase = "source text";
    extension_file *ef = sf_get_extension_corresponding(referred);
    if (ef) {
        extension_identifier *eid = ef_get_eid(ef);
        paraphrase = filename;
        if (eid) {
```

```
            if (eid_is_standard_rules(eid)) paraphrase = "the Standard Rules";
        }
    }
    sprintf(PBUFF, "' %c%s%c%s%c%d%c",
        SOURCE_REF_CHAR, paraphrase,
        SOURCE_REF_CHAR, filename,
        SOURCE_REF_CHAR, lw_array[w1].lw_source.line_number,
        SOURCE_REF_CHAR);
}
```

The function copy_source_reference_into_problem_buffer is called from 2/prob2.

§**4.** We allow for three whitespace characters in the error buffer, though in fact we will then handle any sequence of them as if it were a single space character:

```
int is_problem_buffer_whitespace(char c) {
    if ((c == ' ') || (c == '\t') || (c == '\n')) return TRUE;
    return FALSE;
}
```

§**5.** Once the error message is fully constructed, we will want to output it to a file: in fact, by default it will go in three directions, to `stderr`, to the debugging log and of course to the error log. The main thing is to word-wrap it, since it is likely to be a paragraph-sized chunk of text, not a single line. The unprintable `SOURCE_REF_CHAR` and `FORCE_NEW_PARA_CHAR` are simply filtered out for plain text output: for HTML, they are dealt with elsewhere.

```
void output_problem_buffer_to(OUTPUT_STREAM, int indentation) {
    int i, k, line_width = 0, html_flag = FALSE;
    if (OUT == problems_file) html_flag = TRUE;
    for (k=0; k<indentation; k++) { WRITE("  "); line_width+=2; }
    for (i=0; problem_buffer[i] != 0; i++) {
        char c = problem_buffer[i];
        ⟨In HTML mode, convert drawing-your-attention arrows 6⟩;
        ⟨In plain text mode, remove bold and italic HTML tags 7⟩;
        if ((html_flag == FALSE) && (c == SOURCE_REF_CHAR))
            ⟨Issue plain text paraphrase of source reference 8⟩
        else ⟨Output single character of problem message 9⟩;
    }
    if (html_flag) WRITE("<p>");
    WRITE("\n");
}
```

§**6.** The plain text "may I draw your attention to the following paragraph" marker,

```
>--> Which looks like this.
```

is converted into a suitable CSS-styled HTML paragraph with hanging indentation. And similarly for `>++>`, used to mark continuations.

⟨In HTML mode, convert drawing-your-attention arrows 6⟩ ≡

```
if ((html_flag) &&
    (problem_buffer[i] == '>') &&
    (problem_buffer[i+1] == '-') &&
    (problem_buffer[i+2] == '-') &&
    (problem_buffer[i+3] == '>')) {
    if (problem_count > 1) WRITE("</p><hr>");
    WRITE("<p class=\"hang\"><b>Problem.</b> ");
    i+=3; continue;
}
if ((problem_buffer[i] == '>') &&
    (problem_buffer[i+1] == '+') &&
    (problem_buffer[i+2] == '+') &&
    (problem_buffer[i+3] == '>')) {
    if (html_flag) WRITE("<p class=\"tightin2\">"); else WRITE("  ");
    i+=3; continue;
}
```

This code is used in §5.

§**7.** The problem messages are put together (by Level 2 below) in a plain text way, but with a little formatting included: in particular, they contain HTML-style `<i>` and `<b>` tags, which the following code strips out when writing to plain text format.

⟨In plain text mode, remove bold and italic HTML tags 7⟩ ≡

```
if ((problem_buffer[i] == '<') &&
    ((problem_buffer[i+1] == 'i') || (problem_buffer[i+1] == 'b')) &&
    (problem_buffer[i+2] == '>')) {
    if (html_flag) WRITE("<%c>", problem_buffer[i+1]);
    i+=2; continue;
}
if ((problem_buffer[i] == '<') &&
    (problem_buffer[i+1] == '/') &&
    ((problem_buffer[i+2] == 'i') || (problem_buffer[i+2] == 'b')) &&
    (problem_buffer[i+3] == '>')) {
    if (html_flag) WRITE("</%c>", problem_buffer[i+2]);
    i+=3; continue;
}
```

This code is used in §5.

§**8.** Okay, so the format for a source reference here is:

`XparaphraseXfilenameXnumberX`

e.g., `Xmain textXsource/story.niX102`, where `X` is the unprintable `SOURCE_REF_CHAR`. The counter `i` is at the first `X`, and we must now convert this to something fit for printing to `stdout`, finishing up with `i` pointing to the last `X`.

We always use the paraphrase, not the filename, on `stdout` because (i) that's slightly easier to understand for the user, but more importantly (ii) it makes the output the same on all platforms when only main text and Standard Rules are referred to, and that simplifies `intest` and the Test Suite quite a bit, because we don't have to worry about trivial differences between OS X and Windows caused by the slashes going the wrong way, and so on.

⟨Issue plain text paraphrase of source reference 8⟩ ≡

```
WRITE("("); line_width++;
while (problem_buffer[++i] != SOURCE_REF_CHAR) ⟨Output single character of problem message 9⟩;
while (problem_buffer[++i] != SOURCE_REF_CHAR) ;
WRITE(", line "); line_width += 7;
while (problem_buffer[++i] != SOURCE_REF_CHAR) ⟨Output single character of problem message 9⟩;
WRITE(")"); line_width++;
```

This code is used in §5.

§**9.**

⟨Output single character of problem message 9⟩ ≡

```
c = problem_buffer[i];
if (is_problem_buffer_whitespace(c)) {                                  this starts a run of whitespace
    int k = i; while (is_problem_buffer_whitespace(problem_buffer[k])) k++;
    if (problem_buffer[k] == 0) break;                                  omit any trailing spaces
    i = k - 1;                                                          skip to final whitespace character of the run
    if (html_flag) html_char_out(OUT, ' ');
    else ⟨In plain text mode, wrap the line or print a space as necessary 10⟩;
} else {
    line_width++;
    if (html_flag) html_char_out(OUT, c);
    else if ((c != SOURCE_REF_CHAR) && (c != FORCE_NEW_PARA_CHAR)) WRITE("%c", c);
}
```

This code is used in §5,8,5,8,5,8.

§**10.** At this point, `k` is the position of the first non-whitespace character after the sequence of whitespace.

define `PROBLEM_WORD_WRAP_WIDTH 80`

⟨In plain text mode, wrap the line or print a space as necessary 10⟩ ≡

```
int word_width = 0;
while ((!is_problem_buffer_whitespace(problem_buffer[k])) && (problem_buffer[k] != 0)
    && (problem_buffer[k] != SOURCE_REF_CHAR))
    k++, word_width++;
if (line_width + word_width + 1 >= PROBLEM_WORD_WRAP_WIDTH) {
    WRITE("\n"); line_width = 0;
    for (k=0; k<indentation+1; k++) { line_width+=2; WRITE("  "); }
} else {
    WRITE(" "); line_width++;
}
```

This code is used in §9.

§**11.** The following handles the three-way distribution of problems, but also allows us to route individual messages to only one output of our choice by temporarily setting the `probl` variable: which is a convenience for informational messages such as appear in index files, for instance.

```
int telemetry_recording = FALSE;

void output_problem_buffer(int indentation) {
    if (probl == NULL) {
        output_problem_buffer_to(problems_file, indentation);
        STREAM_WRITE(problems_file, "\n");
        output_problem_buffer_to(STDOUT, indentation);
        STREAM_WRITE(dl, "\n");
        output_problem_buffer_to(dl, indentation);
        STREAM_WRITE(dl, "\n");
        if (telemetry_recording) {
            STREAM_WRITE(telmy, "\n");
            output_problem_buffer_to(telmy, indentation);
            STREAM_WRITE(telmy, "\n");
        }
    } else output_problem_buffer_to(probl, indentation);
}
```

The function output_problem_buffer is called from 2/prob2.

Problems, Level 2 2/prob2

Purpose

To assemble and format problem messages within the problem buffer.

2/prob2.§6-12 Problem quotations; §13-14 Short and long forms; §15 How problems begin and end; §16-20 Issuing a segment of a problem message; §21-24 Problems report and index

---

Template interpreter commands

```
1   {-callv:empty_all_headings}
21  {-callv:complete_problems_report}
```

---

§**1.** Problem messages begin with an indication of where in the source text the problem occurs, in terms of headings and subheadings written in the source text, and it is this indication that we consider first. For example,

> In Part the First, Chapter 1 - Attic Area:

There can be up to 10 levels in the hierarchy of headings and subheadings, with level 0 the top level and level 9 the lowest. Recall that for a `HEADING_NT` type node, the `flag` field contains this level number. The current hierarchical position can be stored in the following array:

```
parse_node *problem_headings[NO_HEADING_LEVELS];
void empty_all_headings(void) {
    empty_headings(0);
}
void empty_headings(int from_level) {
    int i;
    for (i=from_level; i<NO_HEADING_LEVELS; i++) problem_headings[i] = NULL;
}
```

The function empty_all_headings is invoked by a command in a `.i6t` template file.

The function empty_headings is called from 4/iext.

§**2.** When we need to issue a problem at sentence `S`, we work out what the current heading is (if any) at each of the 10 levels. We do this by trekking right through the whole linked list of sentences until we reach `S`, changing the current headings whenever we pass one. This sounds inefficient, but of course few problems are issued, and in any case we cannot optimise by simply cacheing the heading level from one problem to the next because it is not true that problems are always issued in source code order.

(We must not use the `TREE_START` and `TREE_NEXT` macros for the traverse below, as they would change the value of `current_sentence`.)

```
void find_headings_at(parse_node *sentence) {
    parse_node *p;
    empty_headings(0);
    if (sentence == NULL) return;
    for (p = tree_root->down; p != NULL; p = p->next) {
        if (pn_contains(p, sentence)) return;
        if (pn_get_node_type(p) == HEADING_NT) {
            problem_headings[pn_int_annotation(p, heading_level_ANNOT)] = p;
            empty_headings(pn_int_annotation(p, heading_level_ANNOT) + 1);
        }
        if (pn_get_node_type(p) == ENDHERE_NT) {
            empty_all_headings();
        }
    }
}
```

§**3.** A further refinement is that we remember the last set of headings used for an error message, and only mention what has changed about the location. Thus we might next print:

> In Chapter 2 - Cellar Area:

omitting to mention "Part the First" this time, since that part has not changed. (And we never print internally made level 0, File, headings.)

```
parse_node *last_problem_headings[NO_HEADING_LEVELS];
```

§**4.** Now for the actual displaying of the location text. The outcome image is a trickier thing to get right than might appear. By being in this routine, we know that a problem has been issued: the run will therefore not have been a success, and we can issue the "NI failed" outcome image. A success image cannot be placed until right at the end of the run, when all possibility of problems has been passed: so there's no single point in NI where a single line of code could choose between the two possibilities.

```
int do_not_locate_problems = FALSE;

void show_problem_location(void) {
    int i, f = FALSE;
    if (problem_count == 0) {
        html_outcome_image(problems_file, "ni_failed");
        for (i=0; i<NO_HEADING_LEVELS; i++) last_problem_headings[i] = NULL;
    }
    if (do_not_locate_problems) return;
    find_headings_at(current_sentence);
    for (i=0; i<NO_HEADING_LEVELS; i++) if (problem_headings[i] != NULL) f = TRUE;
    if (f)
        for (i=1; i<NO_HEADING_LEVELS; i++)
            if (last_problem_headings[i] != problem_headings[i]) {
```

```
                ⟨Print the heading position 5⟩;
                break;
            }
    for (i=0; i<NO_HEADING_LEVELS; i++) last_problem_headings[i] = problem_headings[i];
}
```

§**5.** We print only the part of the heading position which differs from that of the previous one quoted: `i` is at this point the highest level at which they differ.

⟨Print the heading position 5⟩ ≡

```
    sprintf(problem_buffer, "In<b>");
    for (f=FALSE; i<NO_HEADING_LEVELS; i++)
        if (problem_headings[i] != NULL) {
            if (f) strcat(problem_buffer, ", ");
            else strcat(problem_buffer, " ");
            f = TRUE;
            copy_text_into_problem_buffer(
                problem_headings[i]->word_ref1, problem_headings[i]->word_ref2);
        }
    strcat(problem_buffer, "</b>:");
    output_problem_buffer(0);
```

This code is used in §4.

§**6. Problem quotations.** Problem messages are printed using a printf-like formatting system. Unlike printf, though, where `%s` means a string and `%d` a number, here the escape codes do not indicate the type of the data: they are simply `%1`, `%2`, `%3`, ..., `%9`. This is to prevent horrendous crashes when type mismatches occur: using a pointer to a phrase when trying to print a source code reference, for instance.

The texts to be substituted in place of `%1`, `%2`, ..., are called the "quotations". The value is either a range of words in the source text, or else a pointer to some data structure, depending on the type. The type is a single character code. (This coding system is used only here, and could easily be changed, but there seems no reason to.)

The type codes are S(ource), W(ords), B(inary predicate), E(xtension), (p)H(rase), I(nvocation), N(umber), O(bject), P(roperty name), T(ext), (t)Y(pe specification).

```
typedef struct problem_quotation {
    char quotation_type;                                   one of the above
    void *structure_quoted;                  except for S and W, when this is null
    int range_quoted_w1, range_quoted_w2;                  for S and W only
} problem_quotation;

problem_quotation problem_quotations[10];
```

The structure problem_quotation is private to this section.

§**7.** When some higher-level part of NI wants to issue a formatted problem message, it first declares the contents of any quotations it will make. It does this using the routines `quote_object`, `quote_spec`, ... below. Thus `quote_spec(2, SP)` specifies that `%2` should be printed as the inference `SP`.

```
void problem_quote(int t, char type, void *v) {
    if ((t<0) || (t > 10)) internal_error("problem quotation number out of range");
    problem_quotations[t].structure_quoted = v;
    problem_quotations[t].quotation_type = type;
    problem_quotations[t].range_quoted_w1 = -1;
    problem_quotations[t].range_quoted_w2 = -1;
}
void problem_quote_textual(int t, char type, int w1, int w2) {
    if ((t<0) || (t > 10)) internal_error("problem quotation number out of range");
    problem_quotations[t].structure_quoted = NULL;
    problem_quotations[t].quotation_type = type;
    problem_quotations[t].range_quoted_w1 = w1;
    problem_quotations[t].range_quoted_w2 = w2;
}
```

§**8.** Here are the three public routines for quoting from text: either via a node in the parse tree, or with a literal word range.

```
void quote_source(int t, parse_node *p) {
    if (p == NULL) problem_quote_textual(t, 'S', -1, -1);
    else problem_quote_textual(t, 'S', p->word_ref1, p->word_ref2);
}
void quote_source_eliding_begin(int t, parse_node *p) {
    if (p == NULL) problem_quote_textual(t, 'S', -1, -1);
    else {
        int w1 = p->word_ref1, w2 = p->word_ref2;
        [[w1, w2 == ... begin --> w1, w2]];
        problem_quote_textual(t, 'S', w1, w2);
    }
}
void quote_words(int t, int w1, int w2) { problem_quote_textual(t, 'W', w1, w2); }
```

The function quote_source is called from 2/prob3, 2/dl, 4/sent, 4/ext, 4/iext, 4/rtree, 5/rel, 5/litp, 5/mlc, 6/treec, 6/asp, 6/defer, 7/data, 7/tc, 8/tass, 8/creat, 8/mass, 8/knowc, 8/knowp, 9/qty, 9/kind, 9/prop, 9/pp, 10/tab, 10/eqns, 10/bib, 11/act, 11/ap, 11/av, 12/phud, 12/phtd, 12/phod, 12/stv, 12/cinv, 12/rb, 12/rps, 13/gv, 13/gtok and 13/test.

The function quote_source_eliding_begin is called from 4/rtree.

The function quote_words is called from 2/prob3, 2/dl, 4/ext, 4/iext, 5/rel, 5/litp, 6/treec, 6/tcpr, 6/asp, 6/defer, 7/kov, 7/data, 7/ttts, 7/tc, 8/tass, 8/creat, 8/mass, 8/knowp, 9/qty, 9/prop, 9/pp, 10/str, 10/eqns, 11/act, 11/ap, 11/av, 12/ph, 12/phud, 12/phod, 12/stv, 12/cinv, 12/rb, 12/rps and 13/gtok.

§**9.** And here are the public routines for quoting structures in NI:

```
void quote_relation(int t, binary_predicate *bp) { problem_quote(t, 'B', (void *) bp); }
void quote_extension(int t, extension_file *ef) { problem_quote(t, 'E', (void *) ef); }
void quote_phrase(int t, phrase *p) { problem_quote(t, 'H', (void *) p); }
void quote_invocation(int t, invocation *inv) { problem_quote(t, 'I', (void *) inv); }
void quote_number(int t, int *num) { problem_quote(t, 'N', (void *) num); }
void quote_object(int t, world_object *wo) { problem_quote(t, 'O', (void *) wo); }
void quote_property(int t, property_name *p) { problem_quote(t, 'P', (void *) p); }
void quote_text(int t, char *message) { problem_quote(t, 'T', (void *) message); }
void quote_spec(int t, specification *spec) { problem_quote(t, 'Y', (void *) spec); }
```

The function quote_relation is called from 6/tcpr.
The function quote_extension is called from 2/prob3, 4/ext and 4/iext.
The function quote_phrase is called from 12/phod.
The function quote_invocation is called from 7/tc.
The function quote_number is called from 2/prob3, 5/litp and 7/tc.
The function quote_object is called from 2/prob3, 7/kov, 7/tc, 8/mass, 8/knowc, 9/kind, 9/model and 11/ap.
The function quote_property is called from 2/prob3, 6/treec, 7/tc, 8/knowp, 9/pp, 9/cmpbp, 9/vpbp and 9/model.
The function quote_text is called from 2/prob3, 5/rel, 5/litp, 6/defer, 7/kov, 7/tc, 8/mass, 9/pp, 10/eqns, 11/act, 11/ap, 12/phud, 12/cinv, 13/gv and 13/gtok.
The function quote_spec is called from 7/tc, 8/mass, 8/knowp, 9/pp and 10/eqns.

§**10.** We also provide refinements for various ways to talk about kinds of value (or data types) within problem messages. First, we quote not a literal constant but its kind of value, changing (say) the actual constant 15 to the generic constant "number":

```
void quote_type_of(int t, specification *spec) {
    if ((spec) && (species_is(spec, CONSTANT_SPC)))
        spec = new_generic_CONSTANT_type(spec_get_kind_of_value(spec));
    quote_spec(t, spec);
}
```

The function quote_type_of is called from 7/tc, 8/mass, 8/knowp, 9/prop, 10/tab and 13/gtok.

§**11.** Relatedly, and for the case of a SP which evaluates to a description of one or more objects:

```
void quote_kind_of(int t, specification *spec) {
    if (spec_get_described_kind(spec)) { quote_object(t, spec_get_described_kind(spec)); return; }
    if (spec_get_described_object(spec)) { quote_object(t, spec_get_described_object(spec)->kind); return;
}
    if (spec_is_CONSTANT_of_kova(spec, OBJECT_TY)) {
        world_object *wo = OBJECT_spec_to_world_object(spec);
        quote_object(t, wo->kind);
        return;
    }
    quote_type_of(t, spec);
}
```

The function quote_kind_of is called from 12/cinv.

§**12.** To quote a kind of value, we take care of the two special cases separately: firstly when it's the null KOV (meaning "of unknown type"), and secondly when it's a kind of object. There's no actual need to treat this second case separately, but it does mean that we can print a more helpful description: "kind of container", say, rather than "kind of object".

```
void quote_kov(int t, kind_of_value *kov) {
    if (kov == NULL) { quote_spec(t, new_UNKNOWN_spec()); return; }
    if (is_kova(kov, OBJECT_TY)) {
        world_object *k = kovko_get_kind(kov);
        if (k) { quote_object(t, k); return; }
    }
    quote_spec(t, new_generic_CONSTANT_type(kov));
}
```

The function quote_kov is called from 5/litp, 6/treec, 6/tcpr, 6/equal, 7/kov, 7/tc, 8/creat, 8/mass, 9/qty, 9/pp, 9/provr, 9/vpbp, 10/qnbp, 10/tab and 10/eqns.

§**13. Short and long forms.** Most of the error messages have a short form, giving the main factual information, and a long form which also has an explanation attached. Some of the text is common to both versions, but other parts are specific to either one or the other, and variables record the status of our current position in scanning and transcribing the problem message.

```
int shorten_problem_message;                    give short form of this previously-seen problem
int reading_text_specific_to_short_version;     modes during problem message writing
int reading_text_specific_to_long_version;
```

§**14.** We do not want to keep wittering on with the same old explanations, so we remember which ones we've given before (i.e., in previous problem messages during the same run of NI). Eventually our patience is exhausted and we give no further explanation in any circumstances.

```
define PATIENCE_EXHAUSTION_POINT 100

char *explanations[PATIENCE_EXHAUSTION_POINT];
int no_explanations = 0;

int explained_before(char *explanation) {
    int i;
    if (no_explanations == PATIENCE_EXHAUSTION_POINT) return TRUE;
    for (i=0; i<no_explanations; i++)
        if (explanation == explanations[i]) return TRUE;
    explanations[no_explanations++] = explanation;
    return FALSE;
}
```

§15. How problems begin and end. During the construction of a problem message, we will be running through a standard text, and at any point might be considering matter which should appear only in the long form, or only in the short form.

If the text of a message begins with an asterisk, then it is a continuation of a message already partly issued. Otherwise we can sensibly find out whether this is one we've seen before. Either way, we set `shorten_problem_message` to remember whether to use the short or long form.

```
void issue_problem_begin(char *message) {
    problem_buffer[0] = 0;
    if (strcmp(message, "*") == 0) {
        strcpy(problem_buffer, ">++>");
        shorten_problem_message = FALSE;
    } else if (strcmp(message, "**") == 0) {
        shorten_problem_message = FALSE;
    } else {
        show_problem_location();
        problem_count++;
        strcpy(problem_buffer, ">--> ");
        shorten_problem_message = explained_before(message);
    }
    reading_text_specific_to_short_version = FALSE;
    reading_text_specific_to_long_version = FALSE;
}
void issue_problem_end(void) {
    if (compiling_text_routines_mode) append_text_routine_proviso();
    output_problem_buffer(1);
    problem_documentation_links(problems_file);
    if (crash_on_all_errors) force_crash();
}
```

The function issue_problem_begin is called from 2/prob3 and 7/tc.

The function issue_problem_end is called from 2/prob3, 2/dl, 4/sent, 4/ext, 4/iext, 4/rtree, 5/rel, 5/litp, 5/mlc, 6/treec, 6/asp, 6/defer, 7/kov, 7/data, 7/tc, 8/tass, 8/creat, 8/mass, 8/knowc, 8/knowp, 9/qty, 9/kind, 9/prop, 9/pp, 9/model, 10/tab, 10/eqns, 10/bib, 11/act, 11/ap, 11/av, 12/phud, 12/phtd, 12/phod, 12/stv, 12/cinv, 12/rb, 12/rps, 13/gv, 13/gtok and 13/test.

§16. Issuing a segment of a problem message. Here is the routine which performs the substitution of quotations into problem messages and sends them on their way: which is called `issue_problem_segment` since it only appends a further piece of text, and may be used several times to build up complicated messages.

We have seen that, within problem message texts, the escapes `%1` to `%9` are to produce quotations. Four further escape codes switch between problem message versions, as follows: we have `%L`, which indicates that the text which follows should only be used in the long form of the error message; `%S`, the same for the short form; `%%`, which cancels either of these settings and restores the text to appearing in both forms, which is the default. A percentage sign followed by a vertical stroke acts more simply as a divider between the brief message and the explanation text in many simple problem messages which do not use the elaborations of the other three escapes.

```
void issue_problem_segment(char *message) {
    int i;
    for (i=0; i<strlen(message); i++) {
        if (message[i] == '%') {
            switch (message[i+1]) {
                case 'L': reading_text_specific_to_long_version = TRUE; i++; continue;
                case 'S': reading_text_specific_to_short_version = TRUE; i++; continue;
```

```
                case '%': reading_text_specific_to_short_version = FALSE;
                    reading_text_specific_to_long_version = FALSE; i++; continue;
                case '|': reading_text_specific_to_short_version = FALSE;
                    reading_text_specific_to_long_version = TRUE;
                    if (shorten_problem_message) strcat(problem_buffer, ".");
                    i++; continue;
            }
        }
        if ((reading_text_specific_to_short_version) &&
            (shorten_problem_message == FALSE)) continue;
        if ((reading_text_specific_to_long_version) &&
            (shorten_problem_message == TRUE)) continue;
        ⟨Act on the problem message text, since it is now contextually allowed 17⟩;
    }
}
```

The function issue_problem_segment is called from 2/prob3, 2/dl, 4/sent, 4/ext, 4/iext, 4/rtree, 5/rel, 5/litp, 5/mlc, 6/treec, 6/asp, 6/defer, 7/kov, 7/data, 7/tc, 8/tass, 8/creat, 8/mass, 8/knowc, 8/knowp, 9/qty, 9/kind, 9/prop, 9/pp, 9/model, 10/str, 10/tab, 10/eqns, 10/bib, 11/act, 11/ap, 11/av, 12/ph, 12/phud, 12/phtd, 12/phod, 12/stv, 12/cinv, 12/rb, 12/rps, 13/gv, 13/gtok and 13/test.

§**17.** Ordinarily we just append the new character, but we also act on the escapes `%P` and `%1` to `%9`. `%P` forces a paragraph break, or at any rate, it does in the eventual HTML version of the problem message. Note that these escapes are acted on only if they occur in a contextually allowed part of the problem message (e.g., if they occur in the short form only, they will only be acted on when the shortened form is the one being issued).

⟨Act on the problem message text, since it is now contextually allowed 17⟩ ≡

```
int len;
if (message[i] == '%') {
    switch (message[i+1]) {
        case 'P': sprintf(problem_buffer+strlen(problem_buffer), "%c",
            FORCE_NEW_PARA_CHAR);
            i++; continue;
    }
    if (isdigit(message[i+1])) {
        int t = ((int) (message[i+1]))-((int) '0'); i++;
        if ((t>=1) && (t<=9)) ⟨Expand numbered problem message escape 18⟩;
        continue;
    }
}
len = strlen(problem_buffer);
problem_buffer[len] = message[i]; problem_buffer[len+1] = 0;
```

This code is used in §16.

§**18.** This is where a quotation escape, such as %2, is expanded: by looking up its type, stored internally as a single character.

⟨Expand numbered problem message escape 18⟩ ≡

```
property_name *pr; phrase *ph; specification *spec; extension_file *ef; invocation *inv;
switch(problem_quotations[t].quotation_type) {
    Text range-based quotations
    case 'S': copy_source_reference_into_problem_buffer(
            problem_quotations[t].range_quoted_w1, problem_quotations[t].range_quoted_w2);
        break;
    case 'W': copy_text_into_problem_buffer(
            problem_quotations[t].range_quoted_w1, problem_quotations[t].range_quoted_w2);
        break;
    Binary structure-based quotations
    case 'B': ⟨Quote a binary predicate in a problem message 19⟩;
        break;
    case 'E':
        ef = (extension_file *) (problem_quotations[t].structure_quoted);
        ef_write_full_title_to_string(ef, problem_buffer+strlen(problem_buffer));
        break;
    case 'H':
        ph = (phrase *) (problem_quotations[t].structure_quoted);
        ph_write_HTML_representation(ph, problem_buffer+strlen(problem_buffer));
        break;
    case 'I':
        inv = (invocation *) (problem_quotations[t].structure_quoted);
        inv_write_HTML_representation(inv, problem_buffer+strlen(problem_buffer));
        break;
    case 'N':
        sprintf(problem_buffer+strlen(problem_buffer), "%d",
            *((int *) (problem_quotations[t].structure_quoted)));
        break;
    case 'O': ⟨Quote a world object in a problem message 20⟩;
        break;
    case 'P': pr = (property_name *) problem_quotations[t].structure_quoted;
        copy_text_into_problem_buffer(pr->word_ref1, pr->word_ref2);
        break;
    case 'T': strcat(problem_buffer, (char *) (problem_quotations[t].structure_quoted));
        break;
    case 'Y': spec = (specification *) problem_quotations[t].structure_quoted;
        write_specification_out_in_English(spec, problem_buffer+strlen(problem_buffer));
        break;
    default: internal_error("unknown error token type");
}
```

This code is used in §17.

§**19.** This one we delegate:

⟨Quote a binary predicate in a problem message 19⟩ ≡

```
binary_predicate *bp = (binary_predicate *) problem_quotations[t].structure_quoted;
bp_describe_for_problems(bp, problem_buffer);
```

This code is used in §18.

§**20.** Since numerous world objects are created without explicit and distinct names, for instance by sentences like

Four coins are in the box.

...it's prudent to quote objects without names carefully, and not to ignore this as some kind of marginal will-never-happen case.

⟨Quote a world object in a problem message 20⟩ ≡

```
world_object *wo = (world_object *) problem_quotations[t].structure_quoted;
if (wo == NULL) break;
if (wo->word_ref1 >= 0)
    copy_text_into_problem_buffer(wo->word_ref1, wo->word_ref2);
else {
    strcat(problem_buffer, "object I am looking at (");
    strcat(problem_buffer, "a nameless ");
    if ((wo->kind) && (wo->kind->word_ref1 >= 0))
        copy_text_into_problem_buffer(
            wo->kind->word_ref1, wo->kind->word_ref2);
    else strcat(problem_buffer, "thing");
    if (wo->creating_sentence != NULL) {
        strcat(problem_buffer, " created in the sentence ");
        copy_source_reference_into_problem_buffer(wo->creating_sentence->word_ref1,
            wo->creating_sentence->word_ref2);
    }
    strcat(problem_buffer, ")");
}
```

This code is used in §18.

§**21. Problems report and index.** That gives us enough infrastructure to produce the final report. Note the use of error redirection to `probl` in order to put pseudo-problem messages – actually informational – into the report. In the case where the run was successful and there we no Problem messages, we have to be careful to reset `problem_count` back down to 0 – it will have been increased by the issuing of these pseudo-problems, and we need it to remain 0 so that `main()` can finally return back to the operating system without an error code.

```
void complete_problems_report(void) {
    write_reports(FALSE);
}
void write_reports(int disaster_struck) {
    int total_words;
    crash_on_all_errors = FALSE;
    if (problem_count > 0) {
        probl = problems_file;
        issue_problem_begin("*");
        if (disaster_struck) ⟨Issue problem summary for an internal error 22⟩
        else ⟨Issue problem summary for a run with problem messages 23⟩;
        issue_problem_end();
        probl = NULL;
    } else {
        html_outcome_image(problems_file, "ni_succeeded");
        quote_number(1, &(kind_room->instance_count));
        if (kind_room->instance_count == 1) quote_text(2, "room");
        else quote_text(2, "rooms");
```

```
        quote_number(3, &(kind_thing->instance_count));
        if (kind_thing->instance_count == 1) quote_text(4, "thing");
        else quote_text(4, "things");
        total_words = sf_total_word_count(FIRST_OBJECT(source_file));
        quote_number(5, &total_words);
        ⟨Issue problem summaries for a run without problems 24⟩;
        problem_count = 0;
    }
}
```

The function complete_problems_report is invoked by a command in a `.i6t` template file.
The function write_reports is called from 2/prob3.

§**22.** One of the slightly annoying things about internal errors is that Inform's users persistently refer to them as "crashes" on bug report forms. I mean, the effort we go to! They are entirely clean exits from the program! The ingratitude of some – oh, all right.

⟨Issue problem summary for an internal error 22⟩ ≡

```
    issue_problem_segment(
        "What has happened here is that one of the checks Inform carries "
        "out internally, to see if it is working properly, has failed. "
        "There must be a bug in this copy of Inform. It may be worth "
        "checking whether you have the current, up-to-date version. "
        "If so, please report this problem using the Bug Report Form "
        "posted at www.inform-fiction.org. %P"
        "As for fixing your source text to avoid this bug, the last thing "
        "you changed is probably the cause, if there is a simple cause. "
        "Your source text might in fact be wrong, and the problem might be "
        "occurring because Inform has failed to find a good way to say so. "
        "But even if your source text looks correct, there are "
        "probably rephrasings which would achieve the same effect.");
```

This code is used in §21.

§**23.** Singular and plural versions of the same message, really:

⟨Issue problem summary for a run with problem messages 23⟩ ≡

```
    if (problem_count == 1)
        issue_problem_segment(
            "Because of this problem, the source could not be translated "
            "into a working game. (Correct the source text to "
            "remove the difficulty and click on Go once again.)");
    else
        issue_problem_segment(
            "Problems occurring in translation prevented the game "
            "from being properly created. (Correct the source text to "
            "remove these problems and click on Go once again.)");
```

This code is used in §21.

§**24.** The success message needs to take different forms in `stdout` and in the Problems log file. In the latter, we write as though the subsequent conversion of NI's output to a story file via Inform 6 had already been completed successfully – this is because the Problems log is intended to be viewed inside the Inform application, which will instead divert to an error page if I6 should fail. So although the Problems file contains an unwarranted claim, if not an actual falsehood, no human eye should see it unless and until it comes true.

We don't want to make similar claims on `stdout`, where the user – who might well not be running in the Inform application, but only on the command line – deserves the truth.

⟨Issue problem summaries for a run without problems 24⟩ ≡

```
probl = problems_file;
issue_problem_begin("**");
issue_problem_segment(
    "The %5-word source text has successfully been translated "
    "into a world with %1 %2 and %3 %4, and the index has been "
    "brought up to date.");
issue_problem_end();

if (telemetry_recording) {
    ensure_telemetry_file();
    probl = telmy;
    issue_problem_begin("**");
    issue_problem_segment(
        "The %5-word source text has successfully been translated "
        "into a world with %1 %2 and %3 %4, and the index has been "
        "brought up to date.");
    issue_problem_end();
    STREAM_WRITE(telmy, "\n");
}

probl = STDOUT;
STREAM_WRITE(STDOUT, "\n");
issue_problem_begin("**");
issue_problem_segment(
    "The %5-word source text has successfully been translated "
    "into an intermediate description which can be run through "
    "Inform 6 to complete compilation. There were %1 %2 and %3 %4.");
issue_problem_end();
STREAM_FLUSH(STDOUT);
probl = NULL;
```

This code is used in §21.

Problems, Level 3 2/prob3

Purpose

Here we provide some convenient semi-standardised problem messages, which also serve as examples of how to use the Level 2 problem message routines.

---

§**1.** The following internal errors should never occur, whatever the provocation: if they do, they are symptoms of incorrect code in NI.

The internal error "functions" used by the rest of NI are in fact macros, in order that they can supply the current filename and line number automatically to the actual internal error functions. The result is, for instance,

> Problem. An internal error has occurred: Unknown verb code. The current sentence is "A room is a kind"; the error was detected at line 133 of "Chapter 5/Traverse for Objects.w". This should never happen, and I am now halting in abject failure.

```
define internal_error(X) internal_error_fn(X, __FILE__, __LINE__)
define internal_error_tree_unsafe(X) internal_error_tu_fn(X, __FILE__, __LINE__)
define nodal_error(X, Y) nodal_error_fn(X, Y, __FILE__, __LINE__)
define internal_error_if_node_type_wrong(X, Y) nodal_check(X, Y, __FILE__, __LINE__)
define internal_error_on_node_type(X) internal_error_on_node_type_fn(X, __FILE__, __LINE__)
```

§**2.** Internal errors are generated much like any other problem message, except that we use a variant form of the "end" routine which salvages what it can from the wreckage, then either forces a crash (to make the stack backtrace visible in a debugger) or simply exits to the operating system with error code 1:

```
void internal_error_end(void) {
    issue_problem_end();
    log_mlc_backtrace();
    write_reports(TRUE);
    if (crash_on_internal_errors) force_crash();
    exit(1);
}
```

§**3.** And now for the functions which the above macros invoke. There are two versions: one which cites the current sentence, and another which doesn't, for use if either there is no current sentence (because NI wasn't traversing the parse tree at the time) or if the parse tree is unsafe – it's possible that the internal error occurred during parse tree construction, so we need to be cautious.

```
void internal_error_fn(char *p, char *filename, int linenum) {
    if (current_sentence == NULL) {
        internal_error_tu_fn(p, filename, linenum);
        return;
    }
    quote_source(1, current_sentence);
    quote_text(2, p);
    quote_text(3, filename);
    quote_number(4, &linenum);
    issue_problem_begin(p);
    issue_problem_segment(
        "An internal error has occurred: %2. The current sentence is %1; the "
        "error was detected at line %4 of \"%3\". This should never happen, "
        "and I am now halting in abject failure.");
    internal_error_end();
}
void internal_error_tu_fn(char *p, char *filename, int linenum) {
    quote_text(1, p);
    quote_text(2, filename);
    quote_number(3, &linenum);
    issue_problem_begin(p);
    issue_problem_segment(
        "An internal error has occurred: %1. The error was detected at "
        "line %3 of \"%2\". This should never happen, and I am now halting "
        "in abject failure.");
    internal_error_end();
}
```

§**4. Nodal errors.** Very many routines are designed to work only on nodes within the parse tree of a particular node type. If NI is in working order, then they will never be called at any other nodes; but it seems best to check this. Any failure of such an invariant produces a form of internal error called a "nodal error".

```
void nodal_error_fn(parse_node *pn, char *p, char *filename, int linenum) {
    LOG("Internal nodal error at:\n");
    log_subtree(pn, 1);
    internal_error_fn(p, filename, linenum);
}
```

§**5.** Here is a convenient function to check said invariant.

```
void nodal_check(parse_node *pn, int node_type_required, char *filename, int linenum) {
    char internal_message[128];
    if (pn == NULL) {
        sprintf(internal_message, "NULL node found where type %s expected",
            pnt_get_name(node_type_required));
        internal_error_tu_fn(internal_message, filename, linenum);
    }
    if (pn_get_node_type(pn) == node_type_required) return;
    if ((pn_get_node_type(pn) < 1) || (pn_get_node_type(pn) > HIGHEST_NODE_TYPE)) {
        sprintf(internal_message, "Node with corrupt type found where type %s expected",
            pnt_get_name(node_type_required));
        internal_error_tu_fn(internal_message, filename, linenum);
    }
    sprintf(internal_message, "Node of type %s found where type %s expected",
        pnt_get_name(pn_get_node_type(pn)),
        pnt_get_name(node_type_required));
    nodal_error_fn(pn, internal_message, filename, linenum);
}
```

§**6.** Nodal errors also turn up as the default clauses in switch statements which act on various selections of node types, and those use the `internal_error_on_node_type` macro, which invokes the following:

```
void internal_error_on_node_type_fn(parse_node *pn, char *filename,
    int linenum) {
    char internal_message[128];
    if (pn == NULL)
        internal_error_tu_fn("Unexpected NULL node found", filename, linenum);
    if ((pn_get_node_type(pn) < 1) || (pn_get_node_type(pn) > HIGHEST_NODE_TYPE))
        internal_error_tu_fn("Node found with corrupt type", filename, linenum);
    sprintf(internal_message, "Unexpectedly found node of type %s",
        pnt_get_name(pn_get_node_type(pn)));
    nodal_error_fn(pn, internal_message, filename, linenum);
}
```

§**7.** The following routines are relics of an era of horrific, primordial upheaval, when the meaning list conversion code was being debugged. (An S-subtree is a portion of a meaning list which represents a sentence.)

```
meaning_list *latest_s_subtree = NULL;
void s_subtree_error_set_position(meaning_list *ml) {
    latest_s_subtree = ml;
}
void s_subtree_error(char *mess) {
    char internal_message[128];
    sprintf(internal_message, "S-subtree error: %s", mess);
    LOG("%s", internal_message);
    if (latest_s_subtree) LOG("Applied to the subtree:\n$m", latest_s_subtree);
    internal_error(internal_message);
}
```

The function s_subtree_error_set_position is called from 5/mlc and 6/sconv.
The function s_subtree_error is called from 5/mlc and 6/sconv.

§**8. Sigils.** Every problem message in Inform is identified by a *sigil*, a short alphanumeric symbol. The `_P_` notation is used to write these; see almost every section in later chapters for examples. The naming rules for sigils are as follows:

(a) A problem which is thought never to be generated has the sigil `BelievedImpossible`. Inform is quite defensively coded, so there are several dozen of these – they are safety nets to catch cases we didn't think of.

(b) A problem which either cannot be tested by `intest`, or is just impracticable to do so, has the sigil `Untestable`.

(c) A problem which can be tested, but for which nobody has yet written a test case, has the sigil ... (these are gradually declining in number, and eventually, of course, will disappear altogether).

(d) Otherwise a problem should have a unique sigil beginning `C` and then the chapter number in which it is found: say, `C6NoSuchHieroglyph`. The sigil should have the same name as an `intest` test case which demonstrates the problem.

(e) A sigil which ends `-G` should be used for those few problems which appear only when the virtual machine is Glulx.

It would be easy for all this to fall out of sync, or for us just to lose track of odd cases, since there are more than 750 problem messages; so a shell script called `listproblems.sh` exists to verify that the above rules have been adhered to.

§**9.** As can be seen, `_P_` is a macro expanding to the sigil's name in double quotes followed by the source section and line number at which it is generated. This provides three function arguments matching the `SIGIL_ARGUMENTS` prototype, which appears as a pseudo-argument in all of the problem routines below.

Each such routine should either `ACT_ON_SIGIL` itself or else pass over to another problem routine, using `PASS_SIGIL` as the pseudo-argument.

```
define _P_(sigil) #sigil, __FILE__, __LINE__

define SIGIL_ARGUMENTS char *sigil, char *file, int line

define ACT_ON_SIGIL
    LOG("Problem %s issued from %s, line %d\n", sigil, file, line);
    if (telemetry_recording) {
        ensure_telemetry_file();
        STREAM_WRITE(telmy, "Problem %s issued from %s, line %d\n", sigil, file, line);
    }
    sigil_of_latest_problem = sigil;
    if (echo_problem_message_sigils) printf("Problem:: %s\n", sigil);

define PASS_SIGIL sigil, file, line

char *sigil_of_latest_problem = NULL;

void problem_documentation_links(OUTPUT_STREAM) {
    if (sigil_of_latest_problem == NULL) return;
    char *chap = NULL, *sec = NULL;
    char *leaf = dref_link_if_possible_once(sigil_of_latest_problem, &chap, &sec);
    if (leaf) {
        open_html_paragraph(OUT, 2, "tight");
        WRITE("<a href=inform:/%s.html><img border=0 src=inform:/help.png></a>", leaf);
        if ((chap) && (sec)) {
            WRITE(" <i>See the manual: %s &gt; %s</i></p>\n", chap, sec);
        } else {
            WRITE(" <i>See the manual.</i></p>\n");
        }
        if (telemetry_recording) {
```

```
            STREAM_WRITE(telmy, "See the manual: %s > %s\n\n", chap, sec);
        }
    }
    sigil_of_latest_problem = NULL;
}
```

The function problem_documentation_links is called from 2/prob2.

§**10.** The command-line switch `-sigils` causes the following flag to be set, which in turn causes the sigil of any problem to be echoed to standard output (i.e., printed). This is useful in testing, as it makes it easier to be sure that the test case `C6NoSuchHieroglyph.txt` does indeed generate the problem `C6NoSuchHieroglyph`, and so on.

```
int echo_problem_message_sigils = FALSE;
```

§**11. Handmade problems.** Those made without using the convenient shorthand forms below:

```
void handmade_problem(SIGIL_ARGUMENTS) {
    ACT_ON_SIGIL
    issue_problem_begin("");
}
```

The function handmade_problem is called from 2/dl, 4/sent, 4/ext, 4/iext, 4/rtree, 5/rel, 5/litp, 5/mlc, 6/treec, 6/asp, 6/defer, 7/kov, 7/data, 7/tc, 8/tass, 8/creat, 8/mass, 8/knowc, 8/knowp, 9/qty, 9/kind, 9/prop, 9/pp, 9/model, 10/tab, 10/eqns, 10/bib, 11/act, 11/ap, 11/av, 12/phud, 12/phtd, 12/phod, 12/stv, 12/cinv, 12/rb, 12/rps, 13/gv, 13/gtok and 13/test.

§**12. Limit problems.** Running out of memory, irretrievably: the politest kind of fatal error, though let's face it, fatal is fatal.

```
void limit_problem(SIGIL_ARGUMENTS, char *what_has_run_out, int how_many) {
    ACT_ON_SIGIL
    quote_text(1, what_has_run_out);
    quote_number(2, &how_many);
    issue_problem_begin("");
    issue_problem_segment(
        "I have run out of memory for %1 - there's room for %2, but no more. "
        "This is a 'hard limit', hard in the sense of deadlines, or luck: "
        "there is no getting around it. You will need to rewrite your source "
        "text so that it needs fewer %1.");
    issue_problem_end();
    write_reports(FALSE);
    exit(1);
}
void memory_allocation_problem(SIGIL_ARGUMENTS, char *what_has_run_out) {
    ACT_ON_SIGIL
    quote_text(1, what_has_run_out);
    issue_problem_begin("");
    issue_problem_segment(
        "I am unable to persuade this computer to let me have memory in "
        "which to store %1. This rarely happens on a modern desktop of laptop, "
        "but might occur on a small handheld device - if so, it may be a "
        "symptom that the device isn't powerful enough to run me. (See how "
        "I pass the blame?)");
```

```
    issue_problem_end();
    write_reports(FALSE);
    exit(1);
}
```

The function limit_problem is called from 4/ofs and 11/chron.
The function memory_allocation_problem is called from 2/mem.

§**13. Problem messages unlocated in the source text.** And now the regular problem messages, the ones which are *not my fault*. We begin with lexical problems happening when the run is hardly begun:

```
void lexical_problem(SIGIL_ARGUMENTS, char *message, char *concerning, char *exp) {
    ACT_ON_SIGIL
    char *lexical_explanation =
        "This is a low-level problem happening when I am still reading in the "
        "source. Such problems sometimes arise because I have been told to "
        "read a source file which is not text at all.";
    if (exp != NULL) lexical_explanation = exp;
    quote_text(1, message);
    quote_text(2, concerning);
    quote_text(3, lexical_explanation);
    issue_problem_begin(lexical_explanation);
    issue_problem_segment("%1: %2%L.%%%| %3");
    issue_problem_end();
}
```

The function lexical_problem is called from 3/lex.

§**14.** Clearly lexical problems cannot cite positions in the source text, and some other problems can't either, so:

```
void unlocated_problem(SIGIL_ARGUMENTS, char *message) {
    ACT_ON_SIGIL
    do_not_locate_problems = TRUE;
    issue_problem_begin(message);
    issue_problem_segment(message);
    issue_problem_end();
    do_not_locate_problems = FALSE;
}
```

The function unlocated_problem is called from 9/model and 14/i6t.

§**15. Problem messages keyed to positions in the source text.** The following routine is used to produce more than 300 different problem messages, making it the most prolific of all the problem routines: perhaps that isn't surprising, since it simply quotes the entire sentence at fault (which is always the current sentence) and issues a message.

```
void sentence_problem(SIGIL_ARGUMENTS, char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_source(1, current_sentence);
    quote_text(2, message);
    quote_text(3, explanation);
    issue_problem_begin(explanation);
    issue_problem_segment("You wrote %1: %Sagain, %%%Lbut %%%2%|, %3");
    issue_problem_end();
}
```

The function sentence_problem is called from 2/isn, 2/lns, 3/read, 3/lwb, 4/iext, 4/head, 4/verb, 4/ofs, 4/rtree, 5/rel, 5/conj, 5/aph, 5/litp, 5/em, 5/unitr, 5/lit, 5/candp, 5/mlc, 6/sconv, 6/tcpr, 6/equal, 6/asp, 6/atoms, 6/defer, 6/cdefp, 7/dim, 7/ttts, 7/cmsp, 7/tc, 8/tass, 8/sob, 8/refpt, 8/creat, 8/mass, 8/assem, 8/knowp, 8/relv, 8/imp, 9/qty, 9/scene, 9/kind, 9/spabp, 9/mapbp, 9/exrel, 9/prop, 9/pp, 9/vpbp, 9/inf, 9/model, 9/cot, 10/str, 10/tab, 10/eqns, 10/bib, 10/fig, 10/sfx, 10/exf, 10/isin, 11/chron, 11/act, 11/ap, 11/av, 12/ph, 12/phud, 12/phrcd, 12/phtd, 12/phod, 12/phsf, 12/cinv, 12/def, 12/br, 12/rb, 13/tfg, 13/gv, 13/gl, 13/gty, 13/gtok, 13/test and 14/i6t.

§**16.** And a variant which adds a note in a subsequent paragraph.

```
void sentence_problem_with_note(SIGIL_ARGUMENTS,
        char *message, char *explanation, char *note) {
    ACT_ON_SIGIL
    quote_source(1, current_sentence);
    quote_text(2, message);
    quote_text(3, explanation);
    quote_text(4, note);
    issue_problem_begin(explanation);
    issue_problem_segment("You wrote %1: %Sagain, %%%Lbut %%%2%|, %3 %P%4");
    issue_problem_end();
}
```

The function sentence_problem_with_note is called from 5/litp and 7/tc.

§**17.** And this is a variant which draws particular attention to a word range which is part of the current sentence.

```
void sentence_in_detail_problem(SIGIL_ARGUMENTS,
        int w1, int w2, char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_source(1, current_sentence);
    quote_text(2, message);
    quote_text(3, explanation);
    quote_words(4, w1, w2);
    issue_problem_begin(explanation);
    issue_problem_segment(
        "You wrote %1, and in particular '%4': %Sagain, %%%Lbut %%%2%|, %3");
    issue_problem_end();
}
```

The function sentence_in_detail_problem is called from 7/tc.

§**18.** A not always helpful problem message which is needed in several places, and therefore is kept here:

```
void negative_sentence_problem(SIGIL_ARGUMENTS) {
    sentence_problem(PASS_SIGIL,
        "assertions about the initial state of play must be positive, not negative",
        "so 'The cat is an animal' is fine but not 'The cat is not a container'. "
        "I have only very feeble powers of deduction - sometimes the implications "
        "of a negative statement are obvious to a human reader, but not to me.");
}
```

The function negative_sentence_problem is called from 4/verb and 8/mass.

§**19.** Similarly:

```
void kind_of_object_problem(SIGIL_ARGUMENTS) {
    sentence_problem(PASS_SIGIL,
        "you aren't allowed to create kinds of 'object'",
        "because that is too vague a description. If what you need is "
        "a kind for places or items to appear during play, then you should "
        "create a 'kind of thing', a 'kind of room', a 'kind of man', etc., "
        "as appropriate (see the Kinds index for a list). If you want values "
        "rather than physical things, make a 'kind of value'. (Technically, "
        "it is also possible to make something just a 'kind', but this is not "
        "at all recommended unless you know exactly what you are doing.)");
}
```

The function kind_of_object_problem is called from 8/refpt and 8/mass.

§**20.** This is a much more elaborate form of the standard `sentence_problem`, used when an assertion sentence has gone wrong. Experience from the early builds of the Public Beta showed that many people tried syntaxes which Inform did not recognise, and which cause Inform to misread the primary verb of the sentence. It would then issue a Problem – because the sentence would be peculiar – but this problem report would itself be odd, and make little sense to the user. So we look to see if the current sentence is an assertion with a primary verb: and if it is, we hunt through it for alternative verbs which might have been intended, and try to produce a message which diagnoses the problem rather better.

```
void assertion_problem(SIGIL_ARGUMENTS, char *message, char *explanation) {
    int i, w1, w2, rather_than_w1 = -1, rather_than_w2 = -1;
    ACT_ON_SIGIL
    if ((current_sentence == NULL) || (current_sentence->down == NULL) ||
        (pn_get_node_type(current_sentence->down) != VERB_NT)) {
        LOG("(Assertion error reverting to sentence error.)\n");
        sentence_problem(PASS_SIGIL, message, explanation);
        return;
    }
    w1 = current_sentence->word_ref1;
    w2 = current_sentence->word_ref2;
    LOG("(Assertion error: looking for alternative verbs in <$W>.)\n", w1, w2);
    for (i=w1+1; i<=w2-1; i++)
        if (i != current_sentence->down->word_ref1) {
            verb_usage *vu;
            LOOP_OVER(vu, verb_usage) {
                if ((vu_get_tense_used(vu) == IS_TENSE) &&
                    (unexpectedly_upper_case(i) == FALSE)) {
```

```
                    int j = vu_parse_text_against(i, w2, vu);
                    if (j >= 0) {
                        rather_than_w1 = i;
                        rather_than_w2 = j-1;
                        LOG("(Verb phrase <$W> found.)\n",
                            rather_than_w1, rather_than_w2);
                    }
                }
            }
        }
    quote_source(1, current_sentence);
    quote_text(2, message);
    quote_text(3, explanation);
    issue_problem_begin(explanation);
    issue_problem_segment("You wrote %1: %Sagain, %%%Lbut %%%2%|, %3");
    if (rather_than_w1 >= 0) {
        quote_words(4, current_sentence->down->word_ref1,
            current_sentence->down->word_ref2);
        quote_words(5, rather_than_w1, rather_than_w2);
        issue_problem_segment(                                    see also C2AmbiguousVerb
            " %P(It may help to know that I am reading the primary verb here "
            "as '%4', not '%5'.)");
    }
    issue_problem_end();
}
```

The function assertion_problem is called from 6/treec, 8/creat and 8/mass.

§**21. Definition problems.** Sentence problems are a nuisance for "Definition:" definitions, because those usually occur when the current sentence is rather unhelpfully just the word "Definition" alone. So we use this routine instead:

```
void definition_problem(SIGIL_ARGUMENTS, parse_node *q,
        char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_source(1, q);
    quote_text(2, message);
    quote_text(3, explanation);
    issue_problem_begin(explanation);
    issue_problem_segment("You gave as a definition %1: %Sagain, %%%Lbut %%%2%|, %3");
    issue_problem_end();
}
void adjective_problem(SIGIL_ARGUMENTS, int ix1, int ix2, int d1, int d2,
        char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_words(1, ix1, ix2);
    quote_words(2, d1, d2);
    quote_text(3, message);
    quote_text(4, explanation);
    issue_problem_begin(explanation);
    issue_problem_segment("You defined an adjective by '%1' intending that "
        "it would apply to '%2': %Sagain, %%%Lbut %%%3%|, %4");
    issue_problem_end();
}
```

The function definition_problem is called from 9/madj and 12/def.
The function adjective_problem is called from 5/aph.

§**22. Contradictions.** As soon as we combine information from two sentences, we are at risk of a contradiction of some kind:

```
void two_sentences_problem(SIGIL_ARGUMENTS, parse_node *other_sentence,
    char *message, char *explanation) {
    ACT_ON_SIGIL
    if (current_sentence == other_sentence) {
        sentence_problem(PASS_SIGIL, message, explanation);
        return;
    }
    quote_source(1, current_sentence);
    quote_source(2, other_sentence);
    quote_text(3, message);
    quote_text(4, explanation);
    issue_problem_begin(explanation);
    issue_problem_segment(
        "You wrote %1, but in another sentence %2: %Sagain, %%%Lbut %%%3%|, %4");
    issue_problem_end();
}
```

The function two_sentences_problem is called from 5/conj and 9/inf.

§**23.** Almost exactly the same thing, but happening at arbitrary positions in the parse tree, and concerning a world object:

```
void contradiction_problem(SIGIL_ARGUMENTS, parse_node *A, parse_node *B,
        world_object *wo, char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_source(1, A);
    quote_source(2, B);
    quote_object(3, wo);
    quote_text(4, message);
    quote_text(5, explanation);
    issue_problem_begin(explanation);
    if ((B->word_ref1 != A->word_ref1) || (B->word_ref2 != A->word_ref2))
        issue_problem_segment("You wrote %1, but in another sentence %2: ");
    else issue_problem_segment("You wrote %1: ");
    issue_problem_segment("%Sagain, %%%3 %4%|, %5");
    issue_problem_end();
}
```

The function contradiction_problem is called from 8/sob and 9/model.

§**24. Table problems.** In principle we could treat these as sentence problems, but the "sentence" for a table can be enormous: so we need something which can show which table we are in, yet still only cite a small part of it –

```
void table_problem(SIGIL_ARGUMENTS, table *t, table_column *tc, parse_node *data,
    char *message, char *explanation) {
    ACT_ON_SIGIL
    int tw1, tw2;
    table_get_identifying_name(t, &tw1, &tw2);
    quote_words(1, tw1, tw2);
    if (tc != NULL) quote_words(2, tc->word_ref1, tc->word_ref2);
    if (data != NULL) quote_source(3, data);
    issue_problem_begin(explanation);
    issue_problem_segment(message);
    issue_problem_end();
}
```

The function table_problem is called from 10/tab.

§**25. Equation problems.** So this is where hopes are generically dashed about equations:

```
void equation_problem(SIGIL_ARGUMENTS, equation *eqn, char *p, char *text) {
    ACT_ON_SIGIL
    char plenty[1000];
    quote_source(1, current_sentence);
    quote_words(2, eqn->word_ref1, eqn->word_ref2);
    quote_text(3, p);
    strcpy(plenty, "In %1, you define an equation '%2': but ");
    truncated_strcpy(plenty + strlen(plenty), text, 900);
    issue_problem_begin("");
    issue_problem_segment(plenty);
    issue_problem_end();
}
void equation_symbol_problem(SIGIL_ARGUMENTS, equation *eqn, int w1, int w2, char *text) {
    ACT_ON_SIGIL
    quote_source(1, current_sentence);
    quote_words(2, w1, w2);
    quote_text(3, text);
    issue_problem_begin("");
    issue_problem_segment(
        "In %1, you define an equation which mentions the symbol '%2': but %3");
    issue_problem_end();
}
```

The function equation_problem is called from 10/eqns.
The function equation_symbol_problem is called from 10/eqns.

§**26. Proposition type-checking problems.** Are mostly issued thus:

```
void tcp_problem(SIGIL_ARGUMENTS, tc_problem_kit *tck, char *prototype) {
    if (tck->issue_error) {
        ACT_ON_SIGIL
        quote_source(1, current_sentence);
        quote_words(2, tck->ew1, tck->ew2);
        quote_text(3, tck->intention);
        issue_problem_begin("");
        issue_problem_segment("In the sentence %1, it looks as if you intend '%2' to %3, but ");
        issue_problem_segment(prototype);
        issue_problem_end();
    }
    tck->flag_problem = TRUE;
}
```

The function tcp_problem is called from 6/tcpr, 6/equal, 9/provr, 9/cmpbp, 9/vpbp and 10/qnbp.

§**27. World object problems.** Objects can be created rather indirectly (for instance, in the course of assemblies of other objects), and their properties are sometimes inferred from information in sentences far distant, so we can't always locate object problems at any particular sentence.

```
void object_problem(SIGIL_ARGUMENTS, world_object *wo,
        char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_object(1, wo);
    quote_text(2, message);
    quote_text(3, explanation);
    issue_problem_begin(explanation);
    if (wo->kind_flag)
    issue_problem_segment("The kind %1 %2%|, %3");
    else
    issue_problem_segment("The %1 %2%|, %3");
    issue_problem_end();
    log_knowledge_about_object(wo);
}
void object_problem_at_sentence(SIGIL_ARGUMENTS, world_object *wo,
        char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_source(1, current_sentence);
    quote_text(2, message);
    quote_text(3, explanation);
    quote_object(4, wo);
    issue_problem_begin(explanation);
    issue_problem_segment("You wrote %1, but the %4 %2%|, %3");
    issue_problem_end();
}
```

The function object_problem is called from 8/assem, 8/relv, 9/model and 9/cot.
The function object_problem_at_sentence is called from 8/knowc.

§**28.** When objects are created with bizarre names, this is usually a symptom of some other malaise, and so we issue the following message with a little more tact (and in particular, we don't assert very confidently that what we are dealing with is genuinely an object).

```
void object_creation_problem(SIGIL_ARGUMENTS, world_object *wo,
        char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_object(1, wo);
    quote_text(2, message);
    quote_text(3, explanation);
    if (wo->word_ref1 >= 0) {
        parse_node *creator = new_nounphrase_raw(wo->word_ref1, wo->word_ref2);
        quote_source(4, creator);
        issue_problem_begin(explanation);
        issue_problem_segment(
            "I've made something called %4 but it %2%|, %3");
        issue_problem_end();
        log_knowledge_about_object(wo);
    } else {
        issue_problem_begin(explanation);
        issue_problem_segment(
            "I've made something called '%1' but it %2%|, %3");
        issue_problem_end();
        log_knowledge_about_object(wo);
    }
}
```

The function object_creation_problem is called from 9/model.

§**29.** Information about objects is assembled in a mass of inferences. When these contradict each other, that is usually the occasion for a contradiction problem (see above); the following routine is used only when inferences are implied which necessarily make no sense, rather than merely contingently making no sense.

```
void inference_problem(SIGIL_ARGUMENTS, world_object *wo, inference *inf,
        char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_object(1, wo);
    quote_source(2, inf_inferred_from(inf));
    quote_text(3, message);
    quote_text(4, explanation);
    quote_property(5, inf_get_property_name(inf));
    issue_problem_begin(explanation);
    issue_problem_segment(
        "You wrote %2: but the property %5 for the %1 %3%|, %4");
    issue_problem_end();
    log_knowledge_about_object(wo);
}
```

The function inference_problem is called from 9/model.

§**30.** The cutest of all the object problems is the one which results when NI would need to construct a world model which was not well-founded, in the mathematical sense: one in which a given object must, directly or indirectly, contain itself.

```
void foundation_problem(SIGIL_ARGUMENTS, world_object *wo) {
    ACT_ON_SIGIL
    world_object *wo2, *wo3;
    quote_object(1, wo);
    issue_problem_begin("");
    issue_problem_segment("The %1 seems to be containing itself: ");
    wo2 = wo;
    while (TRUE) {
        parse_node *creator = new_nounphrase_raw(wo2->word_ref1, wo2->word_ref2);
        quote_object(2, wo2);
        quote_source(3, creator);
        issue_problem_segment("%2 (created by %3) ");
        wo3 = wo2->object_tree_parent;
        if (wo3) issue_problem_segment("in ");
        else { wo3 = wo2->part_of; issue_problem_segment("part of "); }
        wo2 = wo3;
        if (wo2 == wo) break;
    }
    issue_problem_segment("%1... and so on. This is forbidden.");
    issue_problem_end();
}
```

The function foundation_problem is called from 9/model.

§**31. Property problems.** Just occasionally there is a problem with the definition of a property in the abstract, rather than with the actual property of some specific object.

```
void property_problem(SIGIL_ARGUMENTS, property_name *prn, char *message, char *explanation) {
    ACT_ON_SIGIL
    quote_property(1, prn);
    quote_text(2, message);
    quote_text(3, explanation);
    issue_problem_begin(explanation);
    issue_problem_segment("The %1 %2%|, %3");
    issue_problem_end();
}
```

The function property_problem is called from 9/pp.

§**32. Extension problems.** These are generated when the user tries to employ a malformed extension.

```
void extension_problem(SIGIL_ARGUMENTS, extension_file *ef, char *message) {
    ACT_ON_SIGIL
    quote_extension(1, ef);
    quote_text(2, message);
    issue_problem_begin(message);
    issue_problem_segment(
        "The extension %1, which your source text makes use of, %2.");
    issue_problem_end();
}
```

The function extension_problem is called from 4/sent and 4/ext.

§**33. Releasing problems.** These occur when the release instructions do not make sense. Sometimes it's possible to pin down an exact place where the difficulty occurs, but sometimes not.

```
void release_problem(SIGIL_ARGUMENTS, char *message, char *filename) {
    ACT_ON_SIGIL
    quote_text(1, message);
    quote_text(2, filename);
    issue_problem_begin(message);
    issue_problem_segment("A problem occurred with the 'Release along with...': "
        "instructions: %1 (with the file '%2')");
    issue_problem_end();
}
void release_problem_at_sentence(SIGIL_ARGUMENTS, char *message, char *filename) {
    ACT_ON_SIGIL
    quote_text(1, message);
    quote_text(2, filename);
    quote_source(3, current_sentence);
    issue_problem_begin(message);
    issue_problem_segment("A problem occurred with the 'Release along with...': "
        "instructions (%3): %1 (with the file '%2')");
    issue_problem_end();
}
```

The function release_problem is called from 10/bib.
The function release_problem_at_sentence is called from 10/bib.

§**34. Cartographical problems.** The map-maker used for the World index and also the EPS-file output has its own quaint syntax, and where there is syntax, there are error messages:

```
void map_problem(SIGIL_ARGUMENTS, parse_node *q, char *message) {
    ACT_ON_SIGIL
    quote_source(1, q);
    quote_text(2, message);
    issue_problem_begin("");
    issue_problem_segment("You gave as a hint in map-making: %1. %2");
    issue_problem_end();
}
void map_problem_wanted_but(SIGIL_ARGUMENTS, parse_node *q, char *i_wanted_a, int vw1) {
    ACT_ON_SIGIL
    quote_source(1, q);
    quote_text(2, i_wanted_a);
    quote_words(3, vw1, vw1);
    issue_problem_begin("");
    issue_problem_segment(
        "You gave as a hint in map-making: %1. But the value '%3' did not "
        "fit - it should have been %2.");
    issue_problem_end();
}
```

The function map_problem is called from 9/map.
The function map_problem_wanted_but is called from 9/map.

§**35. Creating the Problems report.** We are at last able to print the text which appears at the top of the Problems report, sneakily treating this as if it were an error in its own right (except that it is sent only to the Problems file, not to `stderr` or the debugging log, and except that we temporarily disable the force-crash option); and this completes the code for errors. In my end is my beginning.

```
void start_problems_report(void) {
    int coae = crash_on_all_errors;
    char *fn = build_filename(PROBLEM_LOG_LEAFNAME);
    if (STREAM_OPEN_TO_FILE(problems_file, fn, UTF8_ENC) == FALSE)
        fatal_error2("Can't open problem log", fn);
    html_header(problems_file, "Translating the Source", NULL, NULL);
    crash_on_all_errors = FALSE;
    probl = problems_file;
    quote_text(1, NI_VERSION);
    quote_text(2, NI_BUILD);
    issue_problem_begin("**");
    issue_problem_segment(
        "This is the report produced by %1 (build %2) on its most recent "
        "run through:\n");
    issue_problem_end();
    probl = NULL;
    crash_on_all_errors = coae;
}
```

The function start_problems_report is called from 2/dl.

Debugging Log 2/dl

Purpose

To write to the debugging log, a plain text file which traces what NI is doing, in order to assist those lost souls debugging it.

2/dl.¶3-0 Debugging aspects; §2-3 Telemetry; §4 Subheadings; §5-10 Aspects; §11 The sentence trace; §12 Wrapping up; §13 Meaning list conversion backtrace; §14-19 Pretty printing

---

Definitions

¶1. Almost all of NI's algorithms are able to write a plain text trace of what they are doing in the debugging log file. To write to the log, we must in principle `fprintf` to `dl`, the file handle to which debugging log output is currently assigned. In practice we more often use a pair of pseudo-functions called `LOG` and `LOGIF`, which are macros defined below. For instance, the pseudo-function-call

```
LOGIF(HEADINGS, "Heading %d skipped\n", n);
```

prints the line in question to the debugging log only if the given aspect (see below) is currently switched on. Plain `LOG` does the same, but unconditionally.

```
#define LOG(args...) dlprintf(args)
#define LOGIF(aspect, args...) { \
    if (dl_this(aspect##_DA)) dlprintf(args); \
}
```

¶2. What makes this niftier than your common or garden `fprintf` is that in addition to `%d`, `%s`, and so forth, the log macros also support a number of NI-specific string escapes prefaced by a dollar sign. These pretty-print NI data structures as follows. Note that some dollar escapes soak up a pair of arguments, not just a single argument as `printf` escapes do.

`$A`	Action pattern (`action_pattern *`)
`$a`	Adjectival phrase (`adjectival_phrase *`)
`$B`	Table (`table *`)
`$b`	Booking for a rule (`booked_rule *`)
`$C`	Column (`table_column *`)
`$D`	Discourse representation (`pcalc_prop *`)
`$d`	Extension dictionary entry (`extension_dictionary_entry *`)
`$E`	Invocation list (`invocation_list *`)
`$e`	Invocation (`invocation *`)
`$F`	Word range showing formatting of white space (`int`, `int`)
`$G`	Grammar verb (`grammar_verb *`)
`$g`	Grammar line (`grammar_line *`)
`$H`	Heading (`heading *`)
`$h`	Phrase type (`ph_type_data *`)
`$I`	Inference (`inference *`)
`$i`	Inform 6 schema (`i6_schema *`)
`$j`	Inference subject (`inference_subject *`)
`$K`	Rulebook contents (`rulebook *`)
`$k`	Local variable (`local_variable *`)
`$L`	Action name list (`action_name_list *`)
`$l`	Action name (`action_name *`)
`$M`	Excerpt meaning (`excerpt_meaning *`)

`$m` Excerpt meaning list (`meaning_list *`)
`$N` Parse tree node type (`int`)
`$n` Inference type (`int`)
`$O` Object reference (`world_object *`)
`$o` Atom (`pcalc_prop *`)
`$P` Single parse tree node (`parse_node *`)
`$p` Production number (`int`)
`$Q` Quantity (`quantity *`)
`$q` Equation (`equation *`)
`$R` Rule (`phrase *`)
`$r` Type reference (`adjective_list_entry *`)
`$S` Type specification (`specification *`)
`$s` Type ID (`int`)
`$T` Subtree of parse tree (`parse_node *`)
`$t` Time period (`time_period *`)
`$U` Usage data for phrase (`ph_usage_data *`)
`$u` Kind of value (`kind_of_value *`)
`$V` Verb number (`int`)
`$v` Vocabulary entry (`vocabulary_entry *`)
`$W` Word range (`int`, `int`)
`$X` Exhaustive look at a SP (`specification *`)
`$x` Extension (`extension_file *`)
`$Y` Property (`property_name *`)
`$0` Predicate calculus term (`pcalc_term *`)
`$2` Binary predicate (`binary_predicate *`)

¶3. Debugging aspects. There are many different things which can go into the debugging file, or need not: since even a simple half-page source can result in a debugging log 5MB in size, we generally don't want everything included unless we ask for it with sentences in the source like:

Include object creations in the debugging log.

Inevitably, such sentences can only be parsed once NI has already done some work, so don't take effect until then.

A "debugging aspect" is a category of information that can be included, or not, as we please. Each has a unique number and a name of up to three words in length: "object creations" being a two-word example.

```
typedef struct debugging_aspect {
    char *da_word1;                                   first word of name
    char *da_word2;                                   second word, or "" if there is none
    char *da_word3;                                   third word, or "" if there is none
    int on_or_off;                                    whether or not active when writing to debugging log
    int alternate;                                    whether or not active when writing to trace log
} debugging_aspect;
```

The structure debugging_aspect is private to this section.

¶4. And now we must define all those constants and names. Note that the `TRUE` or `FALSE` settings below are the defaults, and apply unless the source says otherwise. The `alternate` settings are those used in trace-sentences mode, that is, between asterisk sentences.

---

§**1.** Two log files are generated by NI as it runs: the HTML report called "Problems", which accumulates the text of all error messages issued, and the debugging log, which provides an opportunity to see what has been happening behind the scenes. Such a log file is normally buffered by the filing system, so that a sudden crash of NI may result in the loss of recent data written to the log. Which is a pity, since this is exactly the most useful evidence as to the cause of the crash in the first place. Accordingly, we fairly often `fflush` the debug log file, forcing any buffered output to be written to disc, and in extreme cases NI can be run in a mode which directs all debugging information to `stdout`, which should ensure that no data is lost even in the event of a crash.

In this rest of this section, we always assume that `dl` is open. Note that it is possible this has been switched to be `stdout`, or even that it is temporarily the sentence tracing file: but we don't care.

```
void open_log_files(void) {
    char *fn = build_filename(DEBUG_LOG_LEAFNAME);
    if (STREAM_OPEN_TO_FILE(debug_log_file, fn, ISO_ENC) == FALSE)
        fatal_error2("Can't open debug log", fn);
    dl = debug_log_file;
    LOG("Debugging log of %s\n", NI_VERSION);
    start_problems_report();
```

```
}
void close_log_files(void) {
    show_debugging_contents();
    STREAM_CLOSE(debug_log_file); dl = NULL;
    if (trl) STREAM_CLOSE(trl); trl = NULL;
    if (telmy) {
        STREAM_WRITE(telmy, "End of telemetry for this run.\n");
        STREAM_CLOSE(telmy); telmy = NULL;
    }
    html_footer(problems_file); STREAM_CLOSE(problems_file);
}
```

The function open_log_files is called from 14/main.
The function close_log_files is called from 14/main.

§**2. Telemetry.** The telemetry file is optional, and transcribes the outcome of each run. This is mainly for testing Inform, but may also be useful for teachers who want to monitor how a whole class is using the system.

```
int attempts_to_open_telemetry = 0;
void ensure_telemetry_file(void) {
    if (telmy) return;
    if (attempts_to_open_telemetry++ > 0) return;
    if (STREAM_OPEN_TO_FILE_APPEND(telemetry_file, filename_of_telemetry, ISO_ENC) == FALSE)
        fatal_error2("Can't open telemetry file", filename_of_telemetry);
    telmy = telemetry_file;
    STREAM_WRITE(telmy, "\n-- -- -- -- -- -- -- --\n%s build %s: telemetry.\n",
        NI_VERSION, NI_BUILD);
    int this_month = the_present->tm_mon + 1;
    int this_day = the_present->tm_mday;
    int this_year = the_present->tm_year + 1900;
    STREAM_WRITE(telmy, "Running on %4d-%02d-%02d at %02d:%02d.\n\n",
        this_year, this_month, this_day, the_present->tm_hour, the_present->tm_min);
    LOG("Opening telemetry file.\n");
}
void write_telemetry_note(char *m) {
    ensure_telemetry_file();
    STREAM_WRITE(telmy, "The user says:\n\n%s\n\n", m);
}
```

The function ensure_telemetry_file is called from 2/prob2 and 2/prob3.
The function write_telemetry_note is called from 8/tass.

§**3.** The following reads in the text of the optional file of use options, when this has been created.

```
void read_further_mandatory_text(void) {
    FILE *FMAN = iso_fopen(filename_of_options, "r");
    if (FMAN == NULL) return;
    char line_buffer[300];
    while (TRUE) {
        int len = truncated_iso_fgets(FMAN, line_buffer, 255);
        if (len < 0) break;
        strcat(line_buffer, " | ");
        int w1 = lexer_wordcount, w2;
        feed_into_lexer(line_buffer, FALSE, FALSE);
        w2 = lexer_wordcount - 2;
        if [[w1, w2 == use ... FULLSTOP --> w1, w2]]
            set_immediate_option_flags(w1, w2, NULL);
    }
    fclose(FMAN);
}
```

The function read_further_mandatory_text is called from 3/read.

§**4. Subheadings.** To provide signposts in what is otherwise a huge amorphous pile of text, the debugging log is divided into "phases". And phases are themselves subdivided into "stages". This is how.

```
char debug_log_phase[32];
int debug_log_subheading = 1;
void log_new_phase_of_NIs_run(char *p, char *q) {
    strcpy(debug_log_phase, p);
    LOG("\n\n-------------------------------------------------------\n");
    LOG("Phase %s ... %s", p, q);
    LOG("\n-------------------------------------------------------\n\n");
    STREAM_FLUSH(dl);
    debug_log_subheading = 1;
}
void log_new_stage_of_NIs_run(char *p) {
    LOG("\n\n==== Phase %s.%d ... %s ====\n\n", debug_log_phase, debug_log_subheading, p);
    debug_log_subheading++;
    STREAM_FLUSH(dl);
}
```

The function log_new_phase_of_NIs_run is called from 14/i6t.
The function log_new_stage_of_NIs_run is called from 13/gv and 14/i6t.

§**5. Aspects.** As mentioned in Chapter 2 above, a wide range of activities can be logged to the debugging log: these are called "aspects" and we can switch logging of them off or on independently. The following routine tests whether a given aspect is currently being logged, and is used by our main macros. Aspect 0 mandates writing to the debug log, and is used when errors occur.

```
int dl_this(int aspect) {
    int decision = the_debugging_aspects[aspect].on_or_off;
    if (aspect == 0) decision = TRUE;
    if (decision) STREAM_FLUSH(dl);
    return decision;
}
```

The function dl_this is called from 3/read, 4/pn, 4/ext, 5/ml, 5/parse, 7/tids, 8/assem, 9/model, 12/toph and 12/br.

§**6.** We sometimes want to switch everything on, or switch everything off:

```
void set_all_aspects(int new_state) {
    int i;
    if (dl) LOGIF(SET_DAS, "Set debugging aspect: everything -> %s\n",
        new_state?"TRUE":"FALSE");
    for (i=0; ; i++) {
        debugging_aspect *da = &(the_debugging_aspects[i]);
        if (*(da->da_word1) == 0) break;
        da->on_or_off = new_state;
    }
}
```

§**7.** Here we parse a request to change the current logging state:

```
void set_debugging_aspect(int w1, int w2, int new_state) {
    LOGIF(SET_DAS, "Set contents of debugging log: $W -> %s\n",
        w1, w2, new_state?"TRUE":"FALSE");
    ⟨See if this is a compound request for debugging information 8⟩;
    ⟨See if this is a simple request for debugging information 9⟩;
    quote_source(1, current_sentence);
    quote_words(2, w1, w2);
    handmade_problem(_P_(C2UnknownDA));
    issue_problem_segment(
        "In the sentence %1, you asked to include '%2' in the "
        "debugging log, but there is no such debugging log topic.");
    issue_problem_end();
}
```

The function set_debugging_aspect is called from 4/verb.

§**8.** Requests can be divided as "R and S" (and can even use the serial comma), and we also understand "only R" and "everything" and "nothing".

⟨See if this is a compound request for debugging information 8⟩ ≡

```
if (is_list_divided(w1, w2, LOOK_FOR_AND)) {
    int lw1 = left_w1, lw2 = left_w2, rw1 = right_w1, rw2 = right_w2;
    set_debugging_aspect(lw1, lw2, new_state);
    set_debugging_aspect(rw1, rw2, new_state);
    return;
}
if [[w1, w2 == only ...]] {
    set_all_aspects(1-new_state);
    set_debugging_aspect(w1+1, w2, new_state);
    return;
}
if [[w1, w2 == everything]] { set_all_aspects(new_state); return; }
if [[w1, w2 == nothing]] { set_all_aspects(1-new_state); return; }
```

This code is used in §7.

§**9.** Otherwise a request must be the name of a single debugging aspect.

⟨See if this is a simple request for debugging information 9⟩ ≡

```
int i;
debugging_aspect *da;
for (i=0; ; i++) {
    da = &(the_debugging_aspects[i]);
    if (*(da->da_word1) == 0) break;
    if (strcmp(lw_array[w1].lw_text, da->da_word1) != 0) continue;
    if (w2 > w1) {
        if (*(da->da_word2) == 0) continue;
        if (strcmp(lw_array[w1+1].lw_text, da->da_word2) != 0) continue;
    }
    if (w2 > w1+1) {
        if (*(da->da_word3) == 0) continue;
        if (strcmp(lw_array[w1+2].lw_text, da->da_word3) != 0) continue;
    }
    if (w2 > w1+2) continue;
    da->on_or_off = new_state;
    return;
}
```

This code is used in §7.

§**10.** We need the ability to change debugging log settings from the command line so that `intest` can collect the debugging information of its choice from a range of source texts. As can be seen, the command line form is derived from the textual form by replacing every space with a hyphen: for instance, the effect of

> Include property provision in the debugging log.

can be duplicated at the command line by running NI with the following switch:

```
--log=property-provision
```

We also recognise `no-property-provision` to switch this off again, `everything` and `nothing` with the obvious meanings, and `list` to print out a list of debugging aspects to `stdout`.

```
void set_dl_from_command_line(char *text) {
    int i, parity = TRUE, list_mode = FALSE;
    debugging_aspect *da;
    if (strcmp(text, "everything") == 0) { set_all_aspects(TRUE); return; }
    if (strcmp(text, "nothing") == 0) { set_all_aspects(FALSE); return; }
    if (strcmp(text, "list") == 0) list_mode = TRUE;
    parity = TRUE;
    if ((text[0] == 'n') && (text[1] == 'o') && (text[2] == '-')) {
        parity = FALSE;
        text += 3;
    }
    for (i=0; ; i++) {
        char tomatch[100];
        da = &(the_debugging_aspects[i]);
        if (*(da->da_word1) == 0) break;
        sprintf(tomatch, "%s", da->da_word1);
        if (*(da->da_word2)) sprintf(tomatch+strlen(tomatch), "-%s", da->da_word2);
        if (*(da->da_word3)) sprintf(tomatch+strlen(tomatch), "-%s", da->da_word3);
        if (list_mode) {
            STREAM_WRITE(STDOUT, "--log=%s  (%s)\n", tomatch, (da->on_or_off)?"on":"off");
        } else {
            if (strcmp(text, tomatch) == 0) {
                da->on_or_off = parity;
                return;
            }
        }
    }
    if (list_mode) return;
    STREAM_WRITE(STDOUT, "No such debugging log aspect as '%s'.\n"
        "(Try running --log=list for a list of the valid aspects.)\n", text);
    fatal_error("No such debugging log aspect.");
}
```

The function set_dl_from_command_line is called from 14/main.

§**11. The sentence trace.** This is a sort of abbreviated extract of the debug log which shows what was done with given assertions: how they were broken down into inferences, and so on. The sentence trace file has its own debugging aspect settings, independently of the main log, and only logs those sentences between asterisks.

```
void debug_log_tracing(int starred, char *heading) {
    int i, j;
    if (starred) {
        if (trl == NULL) {
            char *fn = filename_of_tracefile;
            STREAM_OPEN_TO_FILE(trace_log, fn, ISO_ENC);
            trl = trace_log;
        }
        if (trl) {
            LOG("\n*** Switching to trace log here for a while ***\n");
            dl = trace_log;
            LOG("*** %s ***\n\n", heading);
        }
    } else {
        if (trl != NULL) STREAM_WRITE(trl, "\n\n");
        dl = debug_log_file;
    }
    for (i=0; ; i++) {
        debugging_aspect *da = &(the_debugging_aspects[i]);
        if (*(da->da_word1) == 0) break;
        j = da->on_or_off;
        da->on_or_off = da->alternate;
        da->alternate = j;
    }
}
```

The function debug_log_tracing is called from 8/tass.

§**12. Wrapping up.** At the end of the debugging log we list what was in it, mostly to provide the reader with a list of other things which could have been put into it, but weren't.

```
void show_debugging_settings_with_state(int state) {
    int i, c;
    debugging_aspect *da;
    for (i=0, c=0; ; i++) {
        da = &(the_debugging_aspects[i]);
        if (*(da->da_word1) == 0) break;
        if (da->on_or_off == state) {
            c++;
            LOG("%s %s %s\n", da->da_word1, da->da_word2, da->da_word3);
        }
    }
    if (c == 0) { LOG("(Nothing.)\n"); }
}
void show_debugging_contents(void) {
    if (dl_this(TABLE_OF_DAS_DA) == FALSE) return;
    LOG("\n\nThat concludes the debugging log from this run of NI.\n"
        "Its contents were as follows, and can be changed by placing\n"
```

```
        "text like 'Include property creations in the debugging log.'\n"
        "or 'Omit everything from the debugging log.' in the source.\n\n");
    LOG("Included:\n"); show_debugging_settings_with_state(TRUE);
    LOG("Omitted:\n"); show_debugging_settings_with_state(FALSE);
}
```

§13. **Meaning list conversion backtrace.** It turns out to be convenient to produce a form of stack backtrace to the debugging log when strange problems turn up with the meaning-list conversion algorithm. This does nothing functional, i.e., does nothing other than write to the debugging log, unless a ludicrously massive backtrace occurs, which must be the result of a bug and so results in an internal error.

```
define MAXIMUM_MLC_BACKTRACE 1000
define CLEAR_MLC_BACKTRACE mlc_backtrace_sp = 0;
define RECORD_MLC_BACKTRACE
    if (mlc_backtrace_sp >= MAXIMUM_MLC_BACKTRACE)
        internal_error("MLC backtrace stack overflow");
    mlc_backtrace[mlc_backtrace_sp] = ml;
    mlc_backtrace_at[mlc_backtrace_sp++] = (char *) __func__;

int mlc_backtrace_sp = 0;
meaning_list *mlc_backtrace[MAXIMUM_MLC_BACKTRACE];
char *mlc_backtrace_at[MAXIMUM_MLC_BACKTRACE];

void log_mlc_backtrace(void) {
    int i;
    if (mlc_backtrace_sp == 0) return;
    LOG("MLC backtrace:\n");
    for (i=0; i<mlc_backtrace_sp; i++) {
        LOG("%d: %s\n$m", i, mlc_backtrace_at[i], mlc_backtrace[i]);
    }
    LOG("End of MLC backtrace\n");
}
```

The function log_mlc_backtrace is called from 2/prob3.

§14. **Pretty printing.** We can print formatted text to any stream with `STREAM_WRITE` or `WRITE`, and this offers `printf`-style escapes, but for the debugging log stream we want to supplement these with a much richer set of pretty-printing features. This means adding a new `$` escape, which is a signal to pretty-print internal Inform data structures.

```
void dlprintf(char *fmt, ...) {
    va_list ap;                                          the variable argument list signified by the dots
    char *p;
    if (dl == NULL) return;                              in case logging occurs for an error very early on
    STREAM_FLUSH(dl);
    va_start(ap, fmt);                                   macro to begin variable argument processing
    for (p = fmt; *p; p++)
        switch (*p) {
            case '%': ⟨Recognise traditional escape sequences 15⟩; break;
            case '$': ⟨Recognise new NI debugging log escape sequences 16⟩; break;
            case '\n': if (logging_to_I6_text) STREAM_PUT(dl, '^'); else STREAM_PUT(dl, '\n'); break;
            default: STREAM_PUT(dl, *p); break;
        }
    va_end(ap);                                          macro to end variable argument processing
}
```

§**15.** We don't trouble to check that correct `printf` escapes have been used: instead, we pass anything in the form of a percentage sign, followed by up to four nonalphabetic modifying characters, followed by an alphabetic category character, straight through to `STREAM_WRITE`, which in turn will forward the escape on to either `sprintf` or `fprintf` – so that we can use the implementation in the standard C library.

The only exception is `%%`, which makes a literal percentage sign. (It is an error to leave an escape half-finished at the end of the string.)

⟨Recognise traditional escape sequences 15⟩ ≡

```
int ival; double dval; char *sval;
char format_string[8], category = ' ';
int i = 1;
format_string[0] = '%';
p++;
while (*p) {
    format_string[i++] = *p;
    if ((islower(*p)) || (isupper(*p)) || (*p == '%')) category = *p;
    p++;
    if ((category != ' ') || (i==6)) break;
}
format_string[i] = 0; p--;
switch (category) {
    case 'c': case 'd': case 'x':                    char is promoted to int in variable arguments
        ival = va_arg(ap, int); STREAM_WRITE(dl, format_string, ival); break;
    case 'f':
        dval = va_arg(ap, double); STREAM_WRITE(dl, format_string, dval); break;
    case 's':
        for (sval = va_arg(ap, char *); *sval; sval++) STREAM_PUT(dl, *sval); break;
    case '%': STREAM_PUT(dl, '%'); break;
    default:
        STREAM_WRITE(dl, "*** Bad escape: <%s> ***\n", format_string);
        internal_error("Unknown % string escape in dlprintf");
}
```

This code is used in §14.

§**16.** Here the syntax is simpler: it's just a dollar sign followed by an identifying letter. `$$` makes a literal dollar; and it is, for some reason, legal for the text to end with a single `$`, which is treated similarly as a literal.

⟨Recognise new NI debugging log escape sequences 16⟩ ≡

```
p++;
switch (*p) {
    case 0: STREAM_PUT(dl, '$'); p--; break;          a literal dollar was last character
    case '$': STREAM_PUT(dl, '$'); break;             a double dollar means a literal dollar
    SINGLE_ESCAPE('0', pcalc_term *, log_pcalc_term)
    escape $1 is vacant

        SINGLE_ESCAPE('Y', property_name *, log_property_name)
        escape $y is vacant
        escape $Z is vacant
        escape $z is vacant
        default:
            STREAM_WRITE(dl, "*** Bad escape: '$%c' ***\n", *p);
            internal_error("Unknown % string escape in dlprintf");
    }
```

This code is used in §14.

§**17.** All of those cases were built by the following macros, which extract data from the variable argument list, using the supplied type, and pass it to the supplied routine. One macro handles single-argument escapes, the other double-argument escapes.

```
define SINGLE_ESCAPE(ch, tp, rt)
    case ch: {
        tp data1;
        data1 = va_arg(ap, tp);                          extract next argument as tp
        rt(data1);
        break;
    }
define DOUBLE_ESCAPE(ch, tp1, tp2, rt)
    case ch: {
        tp1 data1; tp2 data2;
        data1 = va_arg(ap, tp1);                         extract next argument as tp1
        data2 = va_arg(ap, tp2);                         extract next argument as tp2
        rt(data1, data2);
        break;
    }
```

§**18.** That concludes the debugging log routines, and with them the service levels of NI. We can at last start the actual main stream of the program: reading the source text and breaking it into words.

3 Characters and Words

`3/lex`: *Lexer.w* To break down a stream of characters into a numbered sequence of words, literal strings and literal I6 inclusions, removing comments and unnecessary whitespace.

`3/read`: *Read Source Text.w* This is where source text is read in, whether from extension files or from the main source text file, and fed into the lexer.

`3/lwb`: *Lexical Writing Back.w* Feeding modified text back into the lexer, to ensure that inflected versions of phrases are also within the word stream.

`3/lexs`: *Lexical Services.w* A small suite of routines to examine the words stored by the lexer, which are provided as a utility to higher levels of NI. None are used by the lexer itself.

`3/vocab`: *Vocabulary.w* To classify the words in the lexical stream, where two different words are considered equivalent if they are unquoted and have the same text, taken case insensitively.

`3/words`: *Built-In Words.w* To stock up NI's vocabulary with words which are needed in order to compare the source text against various syntaxes known to NI.

Lexer 3/lex

Purpose

To break down a stream of characters into a numbered sequence of words, literal strings and literal I6 inclusions, removing comments and unnecessary whitespace.

3/lex.¶4-6 The lexical structure of source text; ¶7-0 What the lexer stores for each word; §5 External lexer states; §6 Definition of punctuation; §7 Definition of white space; §8-11 Internal lexer states; §12-15 Feeding the lexer; §16 Lexing one character at a time; §17-20 Dealing with whitespace; §21-23 Completing a word; §24-25 Entering and leaving literal mode; §26-28 Breaking strings up at text substitutions

---

Template interpreter commands

```
1   {-callv:start_lexer}
```

Definitions

¶1. Lexical analysis is the process of reading characters from the source text files and forming them into globs which we call "words": the part of Inform which does this is the "lexical analyser", or lexer for short. The algorithms in this chapter are entirely routine, but occasional eye-opening moments come because natural language does not have the rigorous division between lexical and semantic parsing which programming language theory expects. For instance, we want NI to be case insensitive for the most part, but we cannot discard upper case entirely at the lexical stage because we will need it later to decide whether punctuation at the end of a quotation is meant to end the sentence making the quote, or not. Humans certainly read these differently:

> Say "Hello!" with alarm, ... Say "Hello!" With alarm, ...

And paragraph breaks can also have semantic meanings. A gap between two words does not end a sentence, but a paragraph break between two words clearly does. So semantic considerations occasionally infiltrate themselves into even the earliest parts of this chapter.

¶2. We must never lose sight of the origin of text, because we may need to print problem messages back to the user which refer to that original material. We record the provenance of text using the following structure; the `lexer_position` is such a structure, and marks where the lexer is currently reading.

```
typedef struct source_location {
    struct source_file *file_of_origin;                    or NULL if internally written and not from a file
    int line_number;                                           counting upwards from 1 within file (if any)
} source_location;

source_location lexer_position;
```

The structure source_location is shared with 2/html, 2/index, 2/lexi, 2/prob1, 3/read, 3/lwb, 4/sent, 4/edoc, 4/head, 8/sob, 10/isin, 12/cinv and 12/rb.

¶3. A word can be an English word such as `bedspread`, or a piece of punctuation such as `!`, or a number such as `127`, or a piece of quoted text of arbitrary size such as `"I summon up remembrance of things past"`.

The words found are numbered 0, 1, 2, ... in order of being read by the lexer. The first eight or so words come from the mandatory insertion text (see Read Source Text.w), then come the words from the primary source text, then those from the extensions loaded.

References to text throughout NI's data structure are often in the form of a pair of word numbers, usually called `w1` and `w2` or some variation on that, indicating the text which starts at word `w1` and finishes at `w2` (including both ends). Thus if the text is

> When to the sessions of sweet silent thought

then the eight words are numbered 0 to 7 and a reference to `w1=2`, `w2=5` would mean the sub-text "the sessions of sweet". The special null value `wn=-1` is used when no word reference has been made: never 0, as that would mean the first word in the list. The maximum legal word number is always one less than the following variable's value.

```
int lexer_wordcount;                                    Number of words read in to arrays
```

¶4. The lexical structure of source text. The following definitions are fairly self-evident: they specify which characters cause word divisions, or signal literals.

```
define STRING_BEGIN '"'                                 Strings are always double-quoted
define STRING_END '"'
define TEXT_SUBSTITUTION_BEGIN '['                      Inside strings, this denotes a text substitution
define TEXT_SUBSTITUTION_END ']'
define TEXT_SUBSTITUTION_SEPARATOR ','
define COMMENT_BEGIN '['                                Text between these, outside strings, is comment
define COMMENT_END ']'
define INFORM6_ESCAPE_BEGIN_1 '('                       Text beginning with this pair is literal I6 code
define INFORM6_ESCAPE_BEGIN_2 '-'
define INFORM6_ESCAPE_END_1 '-'
define INFORM6_ESCAPE_END_2 ')'
define INFORM7_ESCAPE_BEGIN_1 '('                       Text beginning with this pair is I7 text within I6 literals
define INFORM7_ESCAPE_BEGIN_2 '+'
define INFORM7_ESCAPE_END_1 '+'
define INFORM7_ESCAPE_END_2 ')'
define PARAGRAPH_BREAK '|'                              Inserted as a special word to mark paragraph breaks
define NEWLINE_IN_STRING ((char) 0x7f)                  Within quoted text, all newlines are converted to this
define PUNCTUATION_MARKS ".,:;?!(){}[]"                 Do not add to this list lightly: it could break much existing source
```

¶5. This seems a good point to describe how best to syntax-colour source text, something which the user interfaces do on every platform. By convention we are sparing with the colours: ordinary word-processing is not a kaleidoscopic experience (even when Microsoft Word's impertinent grammar checker is accidentally left switched on), and we want the experience of writing Inform source text to be like writing, not like programming. So we use just a little colour, and that goes a long way.

Because the Inform applications generally syntax-colour source text in the Source panel of the user interface, it is probably worth writing down the lexical specification. There are eight basic categories of text, and they should be detected in the following order, with the first category that applies being the one to determine the colour and/or font weight:

(1) Titling text (primary source text only: not found in extensions). If the first non-whitespace in the file is a double-quoted text (see (4a)), this is the title of the work.

(2) Documentation text (extension text only: not found in primary source). If a paragraph consists of a single non-whitespace token only, and that token is `----` (four hyphens in a row), then this paragraph and all subsequent text down to the bottom of the file.

(3) Heading text. If a paragraph consists of a single line only and which begins with one of the five words Volume, Book, Part, Chapter or Section, capitalised as here, then that paragraph is a heading. (A paragraph division is found at the start and end of a file, and also at any run of white space containing two or more newline characters: a newline can be any of the Unicode characters `0x000A`, `0x2028` or `0x2029`.)

(4a) Quoted text. Outside of (4b) and (4c), a double-quotation mark (in principle any of Unicode `0x0022`, `0x201C`, `0x201D`) begins quoted text provided it follows either whitespace, or the start of the file, or one of the punctuation marks in the `PUNCTUATION_MARKS` string defined above. Quoted text continues until the next double-quotation mark (or the end of the file if there isn't one, though NI would issue Problems if asked to compile this).

(4a1) Text substitution text. Within (4a) only, an open square bracket introduced text substitution matter which continues until the next close square bracket or the end of the quoted text. (Again, NI would issue problem messages if given a string malformed in this way.)

(4b) Comment text. Outside of (4a) and (4c), an open square bracket begins comment. Comment continues until the next *matching* close square bracket. (This is the case even if that is in double quotes within the comment, i.e., quotation marks should be ignored when matching `[` and `]` inside a comment.) Thus, nested comments are allowed, and the following text contains a single comment running from just after "the" through to the full stop:

```
Snow White and the [Seven Dwarfs [but not Doc]].
```

(4c) Literal I6 code. Outside of (4a) and (4b), the combination `(-` begins literal I6 matter. This matter continues until the next `-)` is reached. Within literal I6 matter, one can escape back into I7 source text using a matched pair of `(+` and `+)` tokens, but it really doesn't seem worth syntax colouring this very much. And the authors of Inform will lose no sleep if we miscolour this, for instance, especially if it deters people from such horrible coding practices:

```
(- Constant BLOB = (+ the total weight of things in (- selfobj -) +); -)
```

(5) Normal text. Everything else.

NI regards all of the Unicode characters `0x0009`, `0x000A`, `0x000D`, `0x0020`, `0x0085`, `0x00A0`, `0x02000` to `0x200A`, `0x2028` and `0x2029` as instances of white space. Of course, it's entirely open to the Inform user interfaces to not allow the user to key some of these codes, but we should bear in mind that projects using them might be created on one platform and then reopened on another one, so it's probably best to be careful.

¶6. These categories of text are conventionally displayed as follows:

(1) Titling text: black boldface.

(2) Documentation text: grey type.

(3) Heading text: black boldface, perhaps of a slightly larger point size.

(4a) Quoted text: dark blue boldface.

(4a1) Text substitution text: lighter blue and not boldface.

(4b) Comment text: darkish green type, perhaps of a slightly smaller point size.

(4c) Literal I6 code: grey type. (Inform for OS X rather coolly goes into I6 syntax-colouring, which is considerably harder, for this material: see *The Inform 6 Technical Manual* for an algorithm.)

(5) Normal text: black type.

¶7. What the lexer stores for each word. The lexer builds a small data structure for each individual word it reads.

```
typedef struct lexer_details {
    char *lw_text;                                  text of word after treatment to normalise
    char *lw_rawtext;                               original untouched text of word
    struct source_location lw_source;               where it was read from
    char lw_break;                                  the divider (space, tab, etc.) preceding it
    struct vocabulary_entry *lw_identity;           which distinct word
} lexer_details;

lexer_details *lw_array = NULL;                     a dynamically allocated (and mobile) array
int lexer_details_memory_allocated = 0;             bytes allocated to this array
int lexer_workspace_allocated = 0;                  bytes allocated to text storage
```

The structure lexer_details is shared with 2/isn, 2/java, 2/hdoc, 2/index, 2/lexi, 2/prob1, 2/dl, 3/read, 3/lwb, 3/lexs, 3/vocab, 4/sent, 4/ext, 4/iext, 4/edoc, 4/vm, 4/head, 4/rtree, 5/rel, 5/conj, 5/aph, 5/litp, 5/em, 5/unitr, 5/arch, 5/parse, 5/lit, 5/candd, 5/tandv, 5/candp, 7/kov, 7/data, 7/dim, 9/rsdt, 7/kix, 7/tc, 8/tass, 8/sob, 8/refpt, 8/mass, 9/qty, 9/wo, 9/mapbp, 9/prop, 9/madj, 9/cmpbp, 9/vpbp, 9/inf, 9/model, 9/cot, 9/inpw, 9/map, 9/tmap, 10/str, 10/tab, 10/eqns, 10/bib, 10/fig, 10/sfx, 10/exf, 10/isin, 11/act, 11/anl, 11/nap, 11/av, 12/ph, 12/phud, 12/phtd, 12/phsf, 12/cinv, 12/cph, 12/toph, 12/phin, 12/def, 12/tiph, 12/br, 12/rb, 13/tfg, 13/gv, 13/gl, 13/gtok, 13/gprv, 13/gpr and 13/test.

¶8. The following bounds on how much we can read are immutable without editing and recompiling Inform.

```
define TEXT_STORAGE_CHUNK_SIZE 600000       Must exceed MAX_VERBATIM_LENGTH+MAX_WORD_LENGTH
define MAX_STRING_LENGTH 3000               This is supposed to be interactive fiction...
define MAX_VERBATIM_LENGTH 200000           Largest quantity of Inform 6 which can be quoted verbatim.
define MAX_WORD_LENGTH 92                   Maximum length of any unquoted word
```

§**1.** The main text area of memory has a simple structure: it is allocated in one contiguous block, and at any given time the memory is used from the lowest address up to (but not including) the "high water mark", a pointer in effect to the first free character.

```
char *lexer_workspace;                                  Large area of contiguous memory for text
char *lexer_word;                                       Start of current word in workspace
char *lexer_hwm;                                        High water mark of workspace
char *lexer_workspace_end;          Pointer to just past the end of the workspace: HWM must not exceed this
```

```
void start_lexer(void) {
    lexer_wordcount = 0;
    ensure_lexer_space_up_to(50000);                    the Standard Rules are about 44,000 words
    allocate_lexer_workspace_chunk();
    vocab_start_hash_table();
}
```

The function start_lexer is invoked by a command in a `.i6t` template file.

§**2.** These are quite hefty memory allocations, with the expensive one – `lw_source` – also being the least essential to NI's running. But at least we use memory in a way at least vaguely related to the size of the source text, never using more than twice what we need, and we impose no absolute upper limits.

```
int current_lw_array_size = 0, next_lw_array_size = 75000;

void ensure_lexer_space_up_to(int n) {
    if (n < current_lw_array_size) return;
    int new_size = current_lw_array_size;
    while (n >= new_size) {
        new_size = next_lw_array_size;
        next_lw_array_size = next_lw_array_size*2;
    }
    lexer_details_memory_allocated = new_size*sizeof(lexer_details);
    lexer_details *new_lw_array =
        ((lexer_details *) (I7_calloc(new_size, sizeof(lexer_details), LEXER_WORDS_MREASON)));
    if (new_lw_array == NULL) fatal_error("Out of memory: unable to create lexer workspace");
    int i;
    for (i=0; i<new_size; i++) {
        if (i < current_lw_array_size) new_lw_array[i] = lw_array[i];
        else {
            new_lw_array[i].lw_text = NULL;
            new_lw_array[i].lw_rawtext = NULL;
            new_lw_array[i].lw_break = ' ';
            new_lw_array[i].lw_source.file_of_origin = NULL;
            new_lw_array[i].lw_source.line_number = -1;
            new_lw_array[i].lw_identity = NULL;
        }
    }
    if (lw_array) I7_free(lw_array, LEXER_WORDS_MREASON);
    lw_array = new_lw_array;
    current_lw_array_size = new_size;
}
```

The function ensure_lexer_space_up_to is called from 3/lwb.

§**3.** Inform would almost certainly crash if we wrote past the end of the workspace, so we need to watch for the water running high. The following routine checks that there is room for another `n` characters, plus a termination character, plus breathing space for a single character's worth of lookahead:

```
void ensure_lexer_hwm_can_be_raised_by(int n, int transfer_partial_word) {
    if (lexer_hwm + n + 2 >= lexer_workspace_end) {
        char *old_hwm = lexer_hwm;
        allocate_lexer_workspace_chunk();
        if (transfer_partial_word) {
            *(lexer_hwm++) = ' ';
            char *new_lword = lexer_hwm;
            while (lexer_word < old_hwm) *(lexer_hwm++) = *(lexer_word++);
            lexer_word = new_lword;
        }
        if (lexer_hwm + n + 2 >= lexer_workspace_end)
            internal_error("further allocation failed to liberate enough space");
    }
}
void allocate_lexer_workspace_chunk(void) {
    lexer_workspace = ((char *) (I7_malloc(TEXT_STORAGE_CHUNK_SIZE, LEXER_TEXT_MREASON)));
    lexer_workspace_allocated += TEXT_STORAGE_CHUNK_SIZE;
    lexer_hwm = lexer_workspace;
    lexer_workspace_end = lexer_workspace + TEXT_STORAGE_CHUNK_SIZE;
}
```

§**4.** We occasionally want to reprocess the text of a word again in higher-level parsing, and it's convenient to use the lexer workspace to store the results of such a reprocessed text. The following routine makes a persistent copy of its argument, then: it should never be used while the lexer is actually running.

```
char *copy_to_lexer_memory(char *p) {
    ensure_lexer_hwm_can_be_raised_by(strlen(p), FALSE);
    char *q = lexer_hwm;
    lexer_hwm = q + strlen(p) + 1;
    strcpy(q, p);
    return q;
}
```

The function copy_to_lexer_memory is called from 3/lexs.

§5. External lexer states. The lexer is a finite state machine at heart. Its current state is the collective value of an extensive set of variables, almost all of them flags, but with three exceptions this state is used only within the lexer.

The three exceptional modes are by default both off and by default they stay off: the lexer never goes into either mode by itself.

`lexer_divide_strings_at_text_substitutions` is used by some of the lexical writing-back machinery, when it has been decided to compile something like

say "[The noun] falls onto [the second noun]."

In its ordinary mode, with this setting off, the lexer will render this as two words, the second being the entire quoted text. But if `lexer_divide_strings_at_text_substitutions` is set then the text is reinterpreted as

say The noun, " falls onto ", the second noun, "."

which runs to eleven words, three of them commas (punctuation always counts as a word).

`lexer_wait_for_dashes` is set by the extension-reading machinery, in cases where it wants to get at the documentation text of an extension but does not want to have to fill NI's memory with the source text of its code. In this mode, the lexer ignores the whole stream of words until it reaches `----`, the special marker used in extensions to divide source text from documentation: it then drops out of this mode and back into normal running, so that subsequent words are lexed as usual.

`lexer_treat_slash_as_punctuation` is a mode used when lexically writing back grammar tokens, such as the one here:

Understand "get away/off/out" as exiting.

NI would ordinarily lex the text away/off/out as one single word – so that something like "on/off switch" would be regarded as two words not four – but with slash treated as a punctuation mark, we instead read "away / off / out", a sequence of five lexical words.

```
int lexer_divide_strings_at_text_substitutions;          Break up text substitutions in quoted text
int lexer_wait_for_dashes;                               Ignore all text until first ---- found
int lexer_treat_slash_as_punctuation;                    Regard / as a word-dividing punctuation mark
```

§6. Definition of punctuation. As we have seen, the question of whether something is a punctuation mark or not depends slightly on the context:

```
int is_punctuation(char c) {
    int i;
    for (i=0; PUNCTUATION_MARKS[i]; i++)
        if (c == PUNCTUATION_MARKS[i])
            return TRUE;
    if ((c=='/') && (lexer_treat_slash_as_punctuation)) return TRUE;
    return FALSE;
}
```

The function is_punctuation is called from 2/java, 2/hdoc, 3/read and 9/map.

§7. Definition of white space. The following macro (to save time over a function call) is highly dangerous, and of the kind which all books on C counsel against. If it were called with any argument whose evaluation had side-effects, disaster would ensue. It is therefore used only twice, with care, and only in this section below.

```
define is_whitespace(c) ((c == ' ') || (c == '\n') || (c == '\t'))
```

§**8. Internal lexer states.** The current situation of the lexer is specified by the collective values of all of the following. First, the start of the current word being recorded, and the current high water mark – those are defined above. Second, we need the feeder machinery to maintain a variable telling us the previous character in the raw, un-respaced source. We need to be a little careful about the type of this: it needs to be an `int` so that it can on occasion hold the pseudo-character value `EOF`. (The problem is not that we need to recognise an `EOF` accurately: we don't. The problem is that `EOF` accidentally cast into a `char` collides with a French accented letter on some platforms, depending on whether `char` is signed or not.)

```
int lxs_previous_char_in_raw_feed;
```
Preceding character in raw file read

§**9.** There are four kinds of word: ordinary words, [comments in square brackets], "strings in double quotes," and `(- I6_inclusion_text -)`. The latter three are kinds are collectively called literals. As each word is read, the variable `lxs_kind_of_word` holds what it is currently believed to be.

```
define ORDINARY_KW 0
define COMMENT_KW 1
define STRING_KW 2
define I6_INCLUSION_KW 3
```

```
int lxs_kind_of_word;
```
One of the defined values above

§**10.** While there are a pile of state variables below, the basic situation is that the lexer has two main modes: ordinary mode and literal mode, determined by whether `lxs_literal_mode` is false or true. It might look as if this variable is redundant – can't we simply see whether `lxs_kind_of_word` is `ORDINARY_KW` or not? – but in fact we return to ordinary mode slightly before we finish recording a literal, as we shall see, so it is important to be able to switch in and out of literal mode without changing the kind of word.

```
int lxs_literal_mode;
```
Are we in literal or ordinary mode?

significant in ordinary mode:

```
char lxs_most_significant_space_char;
```
Most significant whitespace character preceding

```
int lxs_number_of_tab_stops;
```
Number of consecutive tabs

```
int lxs_this_line_is_empty_so_far;
```
Current line white space so far?

```
int lxs_this_word_is_empty_so_far;
```
Looking for a word to start?

```
int lxs_scanning_text_substitution;
```
Used to break up strings at [substitutions]

significant in literal mode:

```
int lxs_comment_nesting;
```
For square brackets within square brackets

```
int lxs_string_soak_up_spaces_mode;
```
Used to fold strings which break across lines

§**11.** The lexer needs to be reset each time it is used on a given feed of text, whether from a file or internally. Note that this resets both external and internal states to their defaults (the default for external states always being "off").

```
void reset_lexer(void) {
    lexer_word = lexer_hwm;
    lxs_previous_char_in_raw_feed = EOF;
    reset the external states
    lexer_wait_for_dashes = FALSE;
    lexer_treat_slash_as_punctuation = FALSE;
    lexer_divide_strings_at_text_substitutions = FALSE;
    reset the internal states
    lxs_most_significant_space_char = '\n';                 we imagine each lexer feed starting a new line
    lxs_number_of_tab_stops = 0;                            but not yet indented with tabs
    lxs_this_line_is_empty_so_far = TRUE;                   clearly
    lxs_this_word_is_empty_so_far = TRUE;                   likewise
    lxs_literal_mode = FALSE;                               begin in ordinary mode...
    lxs_kind_of_word = ORDINARY_KW;                         ...expecting an ordinary word
    lxs_string_soak_up_spaces_mode = FALSE;
    lxs_scanning_text_substitution = FALSE;
    lxs_comment_nesting = 0;
}
```

§**12. Feeding the lexer.** The lexer takes its input as a stream of characters, sent from a "feeder routine": there are two of these, one sending the stream from a file, the other from a C string. A feeder routine is required to:

(1) call `lexer_feed_begins` before sending the first character,

(2) send ISO Latin-1 characters which also exist in ZSCII, in sequence, via `lexer_feed_triplet`,

(3) conclude by calling `lexer_feed_ends`.

Only one feeder can be active at a time, as the following routines ensure.

```
int lexer_feed_started_at = -1;
void lexer_feed_begins(source_location sl) {
    if (lexer_feed_started_at >= 0) internal_error("one lexer feeder interrupted another");
    lexer_feed_started_at = lexer_wordcount;
    lexer_position = sl;
    reset_lexer();
    LOGIF(LEXER, "Lexer feed began at %d\n", lexer_feed_started_at);
}
void lexer_feed_ends(int *range_read_w1, int *range_read_w2, int extra_padding,
    char *problem_source_description) {
    if (lexer_feed_started_at == -1) internal_error("lexer feeder ended without starting");
    ⟨Feed whitespace as padding 13⟩;
    *range_read_w1 = lexer_feed_started_at; *range_read_w2 = lexer_wordcount-1;
    lexer_feed_started_at = -1;
    LOGIF(LEXER, "Lexer feed ended at %d\n", *range_read_w2);
    ⟨Issue Problem messages if feed ended in the middle of quoted text, comment or verbatim I6 14⟩;
}
```

The function lexer_feed_begins is called from 3/read and 3/lwb.

The function lexer_feed_ends is called from 3/read and 3/lwb.

§**13.** White space padding guarantees that a word running right up to the end of the feed will be processed, since (outside literal mode) that white space signals to the lexer that a word is complete. (If we are in literal mode at the end of the feed, problem messages are produced. We code NI to ensure that this never occurs when feeding our own C strings through.)

At the end of each complete file, we also want to ensure there is always a paragraph break, because this simplifies the parsing of headings (which in turn is because a file boundary counts as a super-heading-break, and headings are only detected as stand-alone paragraphs). We add a bit more white space than is strictly necessary, because it saves worrying about whether it is safe to look ahead to characters further on in the lexer's workspace when we are close to the high water mark, and because it means that a source file which is empty or contains only a byte-order marker comes out as at least one paragraph, even if a blank one.

⟨Feed whitespace as padding 13⟩ ≡

```
if (extra_padding == FALSE) {
    feed_char_into_lexer(' ');
} else {
    feed_char_into_lexer(' ');
    feed_char_into_lexer('\n');
    feed_char_into_lexer('\n');
    feed_char_into_lexer('\n');
    feed_char_into_lexer('\n');
    feed_char_into_lexer(' ');
}
```

This code is used in §12.

§**14.** These problem messages can, of course, never result from text which NI is feeding into the lexer itself, independently of source files. That would be a bug, and NI is bug-free, so it follows that it could never happen.

⟨Issue Problem messages if feed ended in the middle of quoted text, comment or verbatim I6 14⟩ ≡

```
if (lxs_kind_of_word != ORDINARY_KW) {
    if (lexer_wordcount >= 20) {
        LOG("Last words: $W\n", lexer_wordcount-20, lexer_wordcount-1);
    } else if (lexer_wordcount >= 1) {
        LOG("Last words: $W\n", 0, lexer_wordcount-1);
    } else {
        LOG("No words recorded\n");
    }
}
if (lxs_kind_of_word == STRING_KW) {
    lexical_problem(_P_(C3UnendingQuote),
        "Source file ended in the middle of quoted text", problem_source_description,
        "This probably means that a quotation mark is missing "
        "somewhere. If you are using Inform with syntax colouring, "
        "look for where the quoted-text colour starts. (Sometimes "
        "this problem turns up because a piece of quoted text contains "
        "a text substitution in square brackets which in turn contains "
        "another piece of quoted text - this is not allowed, and causes "
        "me to lose track.)");
}
if (lxs_kind_of_word == COMMENT_KW) {
    lexical_problem(_P_(C3UnendingComment),
        "Source file ended in the middle of a comment", problem_source_description,
        "This probably means that a ']' is missing somewhere. "
```

```
            "(If you are using Inform with syntax colouring, look for "
            "where the comment colour starts.) Inform's convention on "
            "'nested comments' is that each '[' in a comment must be "
            "matched by a corresponding ']': so for instance '[This "
            "[even nested like so] acts as a comment]' is a single "
            "comment - the first ']' character matches the second '[' "
            "and so doesn't end the comment: only the second ']' ends "
            "the comment.");
    }
    if (lxs_kind_of_word == I6_INCLUSION_KW) {
        lexical_problem(_P_(C3UnendingI6),
            "Source file ended in the middle of a verbatim passage "
            "of Inform 6 code", problem_source_description,
            "This probably means that a '-)' is missing.");
    }
    lxs_kind_of_word = ORDINARY_KW;
```

This code is used in §12.

§**15.** The feeder routine is required to send us a triple each time: `cr` must be a valid character (see above) and may not be `EOF`; `last_cr` must be the previous one or else perhaps `EOF` at the start of feed; while `next_cr` must be the next or else perhaps `EOF` at the end of feed.

Spaces, often redundant, are inserted around punctuation unless the lexer is in literal mode (inside strings, for instance), and except in the case where a single punctuation mark occurs in between two digits. This is done so that, for instance, "0.91" does not split into three words in the lexer. We do not count square brackets here, because if we did, that would cause trouble in parsing

```
say "[if M is less than 10]0[otherwise]1";
```

where the `0]0` would go unbroken in `lexer_divide_strings_at_text_substitutions` mode, and therefore the `]` would remain glued to the preceding text.

```
void lexer_feed_triplet(int last_cr, int cr, int next_cr) {
    lxs_previous_char_in_raw_feed = last_cr;
    if ((lxs_literal_mode == FALSE) && (is_punctuation(cr))) {
        if ((isdigit(last_cr))
            && ((next_cr == '-') || (isdigit(next_cr)))
            && (cr != '[') && (cr != ']')) {
            feed_char_into_lexer(cr);
        } else {
            feed_char_into_lexer(' ');
            feed_char_into_lexer(cr);              which might take us into literal mode, so to be careful...
            if (lxs_literal_mode == FALSE) feed_char_into_lexer(' ');
        }
    } else feed_char_into_lexer(cr);
    if ((cr == '\n') && (lexer_position.file_of_origin))
        lexer_position.line_number++;
}
```

The function lexer_feed_triplet is called from 3/read and 3/lwb.

§**16. Lexing one character at a time.** We can think of characters as a stream of differently-coloured marbles, flowing from various sources into a hopper above our marble-sorting machine. The hopper lets the marbles drop through one at a time into the mechanism below, but inserts transparent glass marbles of its own on either side of certain colours of marble, so that the sequence of marbles entering the mechanism is no longer the same as that which entered the hopper. Moreover, the mechanism can itself cause extra marbles of its choice to drop in from time to time, further interrupting the original flow.

The following routine is the mechanism which receives the marbles. We want the marbles to run swiftly through and either be pulverised to glass powder, or dropped into the output bucket, as the mechanism chooses. (Whatever marbles from the original source survive will always emerge in their original order, though.) Every so often the mechanism decides that it has completed one batch, and moves on to dropping marbles into the next bucket.

The marbles are characters; transparent glass ones are whitespace, which will always now be `' '`, `'\t'` or `'\n'`; the routine `lexer_feed_triplet` above was the hopper; the routine `feed_char_into_lexer`, which occupies the whole of the rest of this section, is the mechanism which takes each marble in turn. (On occasion it calls itself recursively to cause extra characters of its choice to drop in.) The batches are words, and the bucket receiving the surviving marbles is the sequence of characters starting at `lexer_word` and extending to `lexer_hwm-1`.

```
void feed_char_into_lexer(char c) {
    ensure_lexer_hwm_can_be_raised_by(MAX_WORD_LENGTH, TRUE);
    if (lxs_literal_mode) {
        ⟨Contemplate leaving literal mode 25⟩;
        if (lxs_kind_of_word == STRING_KW) {
            ⟨Force string division at the start of a text substitution, if necessary 26⟩;
            ⟨Soak up whitespace around line breaks inside a literal string 20⟩;
        }
    }
    whitespace outside literal mode ends any partly built word and need not be recorded
    if ((lxs_literal_mode == FALSE) && (is_whitespace(c))) {
        ⟨Admire the texture of the whitespace 17⟩;
        if (lexer_word != lexer_hwm) ⟨Complete the current word 21⟩;
        if (c == '\n') ⟨Line break outside a literal 19⟩;
        return;
    }
    otherwise record the current character as part of the word being built
    *(lexer_hwm++) = c;
    if (lxs_scanning_text_substitution) {
        ⟨Force string division at the end of a text substitution, if necessary 27⟩;
    }
    if (lxs_this_word_is_empty_so_far) {
        ⟨Look at recent whitespace to see what break it followed 18⟩;
        ⟨Contemplate entering literal mode 24⟩;
    }
    lxs_this_word_is_empty_so_far = FALSE;
    lxs_this_line_is_empty_so_far = FALSE;
}
```

§**17. Dealing with whitespace.** Let's deal with the different textures of whitespace first, as these are surprisingly rich all by themselves.

The following keeps track of the biggest white space character it has seen of late, ranking newlines bigger than tabs, which are in turn bigger than spaces; and it counts up the number of tabs it has seen (cancelling back to none if a newline is found).

⟨Admire the texture of the whitespace 17⟩ ≡

```
if (c == '\t') {
    lxs_number_of_tab_stops++;
    if (lxs_most_significant_space_char == ' ') lxs_most_significant_space_char = '\t';
}
if (c == '\n') {
    lxs_number_of_tab_stops = 0;
    lxs_most_significant_space_char = '\n';
}
```

This code is used in §16.

§**18.** To recall: we need to know what kind of whitespace prefaces each word the lexer records.

When we record the first character of a new word, it cannot be whitespace, but it probably follows a sequence of one or more whitespace characters, and the code in the previous paragraph has been watching them for us.

⟨Look at recent whitespace to see what break it followed 18⟩ ≡

```
if ((lxs_most_significant_space_char == '\n') && (lxs_number_of_tab_stops >= 1))
    lw_array[lexer_wordcount].lw_break = '0' + lxs_number_of_tab_stops;    newline followed by 1 or
more tabs
else
    lw_array[lexer_wordcount].lw_break = lxs_most_significant_space_char;
lxs_most_significant_space_char = ' ';          waiting for the next run of whitespace, after this word
lxs_number_of_tab_stops = 0;
```

This code is used in §16.

§**19.** Line breaks are usually like any other white space, if we are outside literal mode, but we want to keep an eye out for paragraph breaks, because these are sometimes semantically meaningful in NI and so cannot be discarded. A paragraph break is converted into a special "divider" word.

⟨Line break outside a literal 19⟩ ≡

```
if (lxs_this_line_is_empty_so_far) {
    feed_char_into_lexer(PARAGRAPH_BREAK);
    feed_char_into_lexer(' ');
}
lxs_this_line_is_empty_so_far = TRUE;
```

This code is used in §16.

§**20.** When working through a literal string, a new-line together with any preceding whitespace is converted into a single space character, and we enter "soak up spaces" mode: in which mode, any subsequent whitespace is ignored until something else is reached. If we reach another new-line while still soaking up, then the literal text contained a paragraph break. In this instance, the splurge of whitespace is converted not to a single space `" "` but to two forced newlines in quick succession. In other words, paragraph breaks in literal strings are converted to codes which will make Inform print a paragraph break at run-time.

⟨Soak up whitespace around line breaks inside a literal string 20⟩ ≡

```
if (lxs_string_soak_up_spaces_mode) {
    switch(c) {
        case ' ': case '\t': lexer_hwm--; break;
        case '\n':
            *(lexer_hwm-1) = NEWLINE_IN_STRING;
            c = NEWLINE_IN_STRING;
            break;
        default: lxs_string_soak_up_spaces_mode = FALSE; break;
    }
}
if (c == '\n') {
    while (is_whitespace(*(lexer_hwm-1))) lexer_hwm--;
    lxs_string_soak_up_spaces_mode = TRUE;
}
```

This code is used in §16.

§**21. Completing a word.** Outside of whitespace, then, our word (whatever it was – ordinary word, literal string, I6 insertion or comment) has been stored character by character at the steadily rising high water mark. We have now hit the end by reaching whitespace (in the case of a literal, this has happened because we found the end of the literal, escaped literal mode, and then hit whitespace). The start of the word is at `lexer_word`; the last character is stored just below `lexer_hwm`.

⟨Complete the current word 21⟩ ≡

```
*lexer_hwm++ = 0;                                   terminate the current word as a C string
if ((lexer_wait_for_dashes) && (strcmp(lexer_word, "----") == 0))
    lexer_wait_for_dashes = FALSE;                   our long wait for documentation is over
if ((lexer_wait_for_dashes == FALSE) && (lxs_kind_of_word != COMMENT_KW)) {
    ⟨Issue problem message and truncate if over maximum length for what it is 22⟩;
    ⟨Store everything about the word except its break, which we already know 23⟩;
}
now get ready for what we expect by default to be an ordinary word next
lexer_word = lexer_hwm;
lxs_this_word_is_empty_so_far = TRUE;
lxs_kind_of_word = ORDINARY_KW;
```

This code is used in §16.

§**22.** Note that here we are recording either an ordinary word, a literal string or a literal I6 insertion: comments are also literal, but are thrown away, and do not come here.

Some readers will be wondering about Llanfairpwllgwyngyllgogerychwyrndrobwllllantysiliogogogochuchaf (the upper old part of the village of Llanfairpwllgwyngyllgogerychwyrndrobwllllantysiliogogogoch, on the Welsh isle of Anglesey), but this has a mere 63 letters, and in any case the name was "improved" by the village cobbler in the mid-19th century to make it a tourist attraction for the new railway age.

⟨Issue problem message and truncate if over maximum length for what it is 22⟩ ≡

```
int len = strlen(lexer_word), max_len = MAX_WORD_LENGTH;
if (lxs_kind_of_word == STRING_KW) max_len = MAX_STRING_LENGTH;
if (lxs_kind_of_word == I6_INCLUSION_KW) max_len = MAX_VERBATIM_LENGTH;
if (len > max_len) {
    lexer_word[max_len] = 0;                                    truncate to its maximum length
    if (lxs_kind_of_word == STRING_KW)
        lexical_problem(_P_(C3TooMuchQuotedText),
            "Too much text in quotation marks", lexer_word,
            "...\" The maximum length is very high, so this is more "
            "likely to be because a close quotation mark was "
            "forgotten.");
    else {
        if (lxs_kind_of_word == I6_INCLUSION_KW) {
            lexer_word[100] = 0;                    to avoid an absurdly long problem message
            lexical_problem(_P_(Untestable),                    well, not at all conveniently
                "Verbatim Inform 6 extract too long", lexer_word,
                "... -). The maximum length is quite high, so this "
                "may be because a '-)' was forgotten. Still, if "
                "you do need to paste a huge I6 program in, try "
                "using several verbatim inclusions in a row.");
        } else
            lexical_problem(_P_(C3WordTooLong),
            "Word too long", lexer_word,
            "(Individual words of unquoted text can run up to "
            "92 letters long, in order to allow for the longest "
            "recognised place name in the English speaking world: "
            "a hill in New Zealand called Taumatawhakatang-"
            "ihangakoauauot-amateaturipukaka-pikimaunga-"
            "horonuku-pokaiwhenuak-itanatahu. You say tomato, "
            "I say taumatawhakatang-...)");
    }
}
```

This code is used in §21.

§**23.** We recorded the break for the word when it started (recall that, even if the current word is a literal, its first character was read outside literal mode, so it started out in life as an ordinary word and therefore had its break recorded). So now we need to set everything else about it, and to increment the word-count. We must not allow this to reach its maximum, since this would allow the next word's break setting to overwrite the array.

For ordinary words (but not literals), the copy of a word in the main array `lw_text` is lowered in case. The original is preserved in `lw_rawtext` and is used to print more attractive error messages, and also to enable a few semantic parts of NI to be case sensitive. This copying means that in the worst case – when we complete an ordinary word of maximal length – we need to consume an additional `MAX_WORD_LENGTH+2` bytes of the lexer's workspace, which is why that was the amount we checked to ensure existed when the lexer was called. The lowering loop can therefore never overspill the workspace.

⟨Store everything about the word except its break, which we already know 23⟩ ≡

```
lw_array[lexer_wordcount].lw_rawtext = lexer_word;
lw_array[lexer_wordcount].lw_source = lexer_position;
if (lxs_kind_of_word == ORDINARY_KW) {
    int i;
    lw_array[lexer_wordcount].lw_text = lexer_hwm;
    for (i=0; lexer_word[i]; i++) *(lexer_hwm++) = tolower(lexer_word[i]);
    *(lexer_hwm++) = 0;
} else {
    lw_array[lexer_wordcount].lw_text = lw_array[lexer_wordcount].lw_rawtext;
}
vocab_identify_word(lexer_wordcount);          which sets lw_array[lexer_wordcount].lw_identity
lexer_wordcount++;
ensure_lexer_space_up_to(lexer_wordcount);
```

This code is used in §21.

§**24. Entering and leaving literal mode.** After a character has been stored, in ordinary mode, we see if it provokes us into entering literal mode, by signifying the start of a comment, string or passage of verbatim Inform 6.

In the case of a string, we positively want to keep the opening character just recorded as part of the word: it's the opening double-quote mark. In the case of a comment, we don't care, as we're going to throw it away anyhow; as it happens, we keep it for now. But in the case of an I6 escape we are in danger, because of the auto-spacing around brackets, of recording two words

```
( -something
```

when in fact we want to record

```
(- something
```

We do this by adding a hyphen to the previous word (the `(` word), and by throwing away the hyphen from the material of the current word.

⟨Contemplate entering literal mode 24⟩ ≡

```
switch(c) {
    case COMMENT_BEGIN:
        lxs_literal_mode = TRUE; lxs_kind_of_word = COMMENT_KW;
        lxs_comment_nesting = 1;
        break;
    case STRING_BEGIN:
        lxs_literal_mode = TRUE; lxs_kind_of_word = STRING_KW;
        break;
```

```
        case INFORM6_ESCAPE_BEGIN_2:
            if (lxs_previous_char_in_raw_feed != INFORM6_ESCAPE_BEGIN_1) break;
            lxs_literal_mode = TRUE; lxs_kind_of_word = I6_INCLUSION_KW;
            because of spacing around punctuation outside literal mode, the ( became a word
            if (lexer_wordcount > 0) {                    this should always be true: just being cautious
                lw_array[lexer_wordcount-1].lw_text = "(-";     change the previous word's text from ( to
(-
                lw_array[lexer_wordcount-1].lw_rawtext = "(-";
                vocab_identify_word(lexer_wordcount-1);                                   and re-identify
            }
            lexer_hwm--;                          erase the just-recorded INFORM6_ESCAPE_BEGIN_2 character
            break;
    }
```

This code is used in §16.

§**25.** So literal mode is used for comments, strings and verbatim passages of Inform 6 code. We are in this mode when scanning only the *middle* of the literal: after all, we scanned (and recorded) the start of the literal in ordinary mode, before noticing that the character(s) marked the onset of a literal.

Note that, when we leave literal mode, we set the current character to a space. This means the character forcing our departure is lost and not recorded: but we only actually want it in the case of strings (because we prefer to record them in the form `"frogs and lilies"` rather than `"frogs and lilies`, for tidiness's sake). And so for strings we explicitly record a close quotation mark.

The new current character, being a space and thus whitespace outside of literal mode, triggers the completion of the word, recording whatever literal we have just made. (Or, if it was a comment, discarding it.) `lxs_kind_of_word` continues to hold the kind of literal we have just finished.

⟨Contemplate leaving literal mode 25⟩ ≡

```
    switch(lxs_kind_of_word) {
        case COMMENT_KW:
            if (c == COMMENT_BEGIN) lxs_comment_nesting++;
            if (c == COMMENT_END) {
                lxs_comment_nesting--;
                if (lxs_comment_nesting == 0) lxs_literal_mode = FALSE;
            }
            break;
        case STRING_KW:
            if (c == STRING_END) {
                lxs_string_soak_up_spaces_mode = FALSE;
                *(lexer_hwm++) = c;                    record the STRING_END character as part of the word
                lxs_literal_mode = FALSE;
            }
            break;
        case I6_INCLUSION_KW:
            if ((c == INFORM6_ESCAPE_END_2) &&
                (lxs_previous_char_in_raw_feed == INFORM6_ESCAPE_END_1)) {
                *lexer_hwm--;                  erase the INFORM6_ESCAPE_END_1 character recorded last time
                lxs_literal_mode = FALSE;
            }
            break;
        default: internal_error("in unknown literal mode");
    }
    if (lxs_literal_mode == FALSE) c = ' ';                                  trigger completion of this word
```

This code is used in §16.

§**26. Breaking strings up at text substitutions.** When text contains text substitutions, these are ordinarily ignored by the lexer, but in `lexer_divide_strings_at_text_substitutions` mode, we need to force strings to end and resume at the two ends of each substitution. For instance:

"Hello, [greeted person]. Do you make it [supper time]?"

must be split as

```
"Hello, " , greeted person , ". Do you make it " , supper time , "?"
```

where our original single text literal is now three text literals, plus eight ordinary words (four of them commas).

Note that each open square bracket, and each close square bracket, has been removed and become a comma word. We see to open squares before we come to recording the character, so to get rid of the `[` character, we change `c` to a space:

⟨Force string division at the start of a text substitution, if necessary 26⟩ ≡

```
if ((lexer_divide_strings_at_text_substitutions) && (c == TEXT_SUBSTITUTION_BEGIN)) {
    feed_char_into_lexer(STRING_END);                                   feed " to close the old string
    feed_char_into_lexer(' ');
    feed_char_into_lexer(TEXT_SUBSTITUTION_SEPARATOR);                  feed , to start new word
    c = ' ';                              the lexer now goes on to record a space, which will end the , word
    lxs_scanning_text_substitution = TRUE;                  but remember that we must get back again
}
```

This code is used in §16.

§**27.** Whereas we see to close squares after recording the character, so we have to erase it to get rid of the `]`. Note that since this was read in ordinary mode, it was automatically spaced (being punctuation), and that therefore the feeder above has just sent the second of a sequence of three characters: space, `]`, space. That means we have recorded, so far, a one-character word in ordinary mode, whose text consists only of `]`. By overwriting this with a comma, we instead get a one-character word in ordinary mode whose text consists only of a comma. We then feed a space to end that word; then feed a double-quote to start text again.

But, it might be objected: surely the feeder above is still poised with that third character in its sequence space, `]`, space, and that means it will now feed a spurious space into the start of our resumed text? Happily, the answer is no: this is why the feeder above checks that it is still in ordinary mode before sending that third character. Having open quotes again, we have put the lexer into literal mode: and so the spurious space is never fed, and there is no problem.

⟨Force string division at the end of a text substitution, if necessary 27⟩ ≡

```
if ((lexer_divide_strings_at_text_substitutions) && (c == TEXT_SUBSTITUTION_END)) {
    lxs_scanning_text_substitution = FALSE;
    *(lexer_hwm-1) = TEXT_SUBSTITUTION_SEPARATOR;              overwrite recorded copy of ] with ,
    feed_char_into_lexer(' ');                                 then feed a space to end the , word
    feed_char_into_lexer(STRING_BEGIN);                          then feed " to open a new string
}
```

This code is used in §16.

§**28.** Finally, note that the breaking-up process may result in empty strings where square brackets abut each other or the ends of the original string. Thus

"[The noun] is on the [colour][style] table."

is split as: `"" , The noun , " is on the " , colour , "" , style , " table."` This is not a bug: empty strings are legal. It's for higher-level code to remove them if they aren't wanted.

Read Source Text 3/read

Purpose

This is where source text is read in, whether from extension files or from the main source text file, and fed into the lexer.

3/read.§5-8 Feeding whole files into the lexer; §9-12 Reading UTF-8 files

---

Template interpreter commands

```
1   {-callv:read_primary_source_text}
```

Definitions

¶1. The source text is drawn almost entirely from the primary source file and the extensions, but NI does also inject small amounts of source text of its own (for instance, when a new kind of value is created, the data types interpreter does this).

In particular, every source text read into NI is automatically prefixed by the following eight words – if NI were a computer, this would be the BIOS which boots up its operating system. (In that the rest of the creation of the I7 world model is handled by source text in the Standard Rules.) The stroke word at the end of the sentence is the lexer's representation of a paragraph break.

```
define MANDATORY_INSERTED_TEXT "Include the Standard Rules by Graham Nelson. | "
```

¶2. Because of this mandatory insertion, one extension, the Standard Rules, is compulsorily included in every run. So there will certainly be at least two files of source text to be read, and quite possibly more.

Each separate file of source text actually read has its identity docketed in a `source_file` structure, as follows. The "primary" source file is the one with allocation ID 0: the first to be opened, which is always the one described to NI on the command line. (If we use NI as part of Inform 7, this will be the text in the Source panel.) The Standard Rules then come next, with allocation ID 1.

```
typedef struct source_file {
    char filename[MAX_FILENAME_LENGTH];
    char leafname[MAX_FILENAME_LENGTH];
    int words_of_source;                          word count, omitting comments and verbatim matter
    int words_of_quoted_text;                     word count for text in double-quotes
    FILE *handle;                                 file handle while open
    struct extension_file *extension_provided;    meets this extension request
    MEMORY_MANAGEMENT
} source_file;

source_file *primary_source_file = NULL;          first to be opened
```

The structure source_file is private to this section.

---

§**1.** There is no real difference between the loading of the primary source text and the loading of an extension's text, except for the descriptions we supply in case of any problem messages which might need to be issued, and for the fact that the mandatory insertion text is loaded before the primary source text.

```
int read_extension_source_text(extension_file *EF, char *filename,
    char *synopsis, int documentation_only) {
    int rv = read_file(pathname_of_extensions, filename, synopsis, EF, documentation_only);
    if (dl_this(LEXER_DA)) log_lexer_output();
    return rv;
}
void read_primary_source_text(void) {
    feed_into_lexer(MANDATORY_INSERTED_TEXT, FALSE, FALSE);
    read_further_mandatory_text();
    if (bundle_name != NULL)
        read_file(bundle_name, source_filename_relative_to_bundle("story.ni"),
            "your source text", NULL, FALSE);
    else read_file(NULL, source_text_file, "the source text", NULL, FALSE);
}
```

The function read_extension_source_text is called from 4/iext.
The function read_primary_source_text is invoked by a command in a `.i6t` template file.

§**2.** Either way, we use the following code. The `read_file` function returns one of the following values to indicate the source of the source: the value only really tells us something we didn't know in the case of extensions, but in that event the Extensions.w routines do indeed want to know this. (Area 51 is reserved for extensions of alien origin, but the relevant source code is classified.)

```
define ORIGIN_WAS_PRIMARY_SOURCE 0
define ORIGIN_WAS_USER_EXTENSIONS_AREA 1
define ORIGIN_WAS_BUILT_IN_EXTENSIONS_AREA 2
```

```
int read_file(char *pathname, char *leafname, char *synopsis, extension_file *EF,
    int documentation_only) {
    int origin_tried;
    source_file *sf = CREATE(source_file);
    if (EF == NULL) {
        primary_source_file = sf;
        origin_tried = ORIGIN_WAS_PRIMARY_SOURCE;
    } else {
        origin_tried = ORIGIN_WAS_USER_EXTENSIONS_AREA;
    }
    sf->words_of_source = 0;
    sf->words_of_quoted_text = 0;
    sf->extension_provided = EF;
    ⟨Set pathname and filename, and open file 3⟩;
    if (EF) ef_set_corresponding_source_file(EF, sf);
    feed_file_into_lexer(sf, leafname, documentation_only);
    fclose(sf->handle);
    ⟨Tell console output about the file 4⟩;
    return origin_tried;
}
```

§**3.** The primary source text must be found where we expect it, or a fatal error is issued. An extension, however, can be in one of two places: the user's own repository of installed extensions, or the built-in stock. We must try each possibility – in that order, so that the user can supplant the built-in extensions by installing hacked versions of her own – and in the event of failing, we issue only a standard Inform problem message and continue. While meaningful compilation is unlikely to succeed now, this is not a fatal error, because fatality would cause the user interface application to communicate the problem badly.

⟨Set pathname and filename, and open file 3⟩ ≡

```
Retry:
if (pathname == NULL) strcpy(sf->filename, leafname);
else sprintf(sf->filename, "%s%c%s", pathname, FOLDER_SEPARATOR, leafname);
strcpy(sf->leafname, leafname);
if (EF) sf->handle = iso_fopen_caseless(sf->filename, "r");
else sf->handle = iso_fopen(sf->filename, "r");
if ((sf->handle == NULL) && (EF)) {
    char extended_name[MAX_FILENAME_LENGTH];
    sprintf(extended_name, "%s.i7x", sf->filename);
    sf->handle = iso_fopen_caseless(extended_name, "r");
    if (sf->handle) strcpy(sf->filename, extended_name);
}
if (sf->handle == NULL) {
    if (EF) {
        if (origin_tried == ORIGIN_WAS_USER_EXTENSIONS_AREA) {
            origin_tried = ORIGIN_WAS_BUILT_IN_EXTENSIONS_AREA;
            pathname = pathname_of_built_in_extensions;
            goto Retry;
        }
        LOG("Extension failed: '%s'\n", sf->filename);
        sentence_problem(_P_(C3BogusExtension),
            "I can't find that extension",
            "which seems not to be installed. (You can get hold of extensions "
            "which people have made public at the Inform website.)");
        return -1;
    } else {
        fatal_error2("Error: can't open source text file", sf->filename);
    }
}
```

This code is used in §2.

§**4.** This is where messages like

```
I've also read Standard Rules by Graham Nelson, which is 27204 words long.
```

are printed to `stdout` (not `stderr`), in something of an affectionate nod to TEX's traditional console output, though occasionally I think silence is golden and that the messages could go. It's a moot point for almost all users, though, because the console output is concealed from them by the Inform application.

⟨Tell console output about the file 4⟩ ≡

```
int wc;
char *message;
if (EF == NULL) message = "I've now read %s, which is %d words long.\n";
else message = "I've also read %s, which is %d words long.\n";
wc = sf_total_word_count(sf);
STREAM_WRITE(STDOUT, message, synopsis, wc);
STREAM_FLUSH(STDOUT);
LOG(message, synopsis, wc);
```

This code is used in §2.

§**5. Feeding whole files into the lexer.** This is one of the two feeder routines for the lexer, the other being in Lexical Writing Back.w: see Lexer.w for its obligations.

We feed characters from an open file into the lexer, and continue until there is nothing left in it. Inform is used on operating systems which between them use all four of the sequences `0a`, `0d`, `0a0d` and `0d0a` to divide lines in text files, so each of these is converted to a single `'\n'`. Tabs are treated as if spaces in most contexts, but not when parsing formatted tables, for instance, so they are not similarly converted.

```
void feed_file_into_lexer(source_file *sf, char *leafname, int documentation_only) {
    source_location top_of_file;
    int words_fed_w1, words_fed_w2;
    int cr, last_cr, next_cr, read_cr, newline_char = 0;
    top_of_file.file_of_origin = sf;
    top_of_file.line_number = 1;
    lexer_feed_begins(top_of_file);
    if (documentation_only) lexer_wait_for_dashes = TRUE;
    last_cr = ' '; cr = ' '; next_cr = utf8_fgetc(sf->handle, TRUE);
    if (next_cr == 0xFEFF) next_cr = utf8_fgetc(sf->handle, TRUE);                Unicode BOM code
    if (next_cr != EOF)
        while (((read_cr = utf8_fgetc(sf->handle, TRUE)), next_cr) != EOF) {
            last_cr = cr; cr = next_cr; next_cr = read_cr;
            switch(cr) {
                case '\x0a':
                    if (newline_char == '\x0d') {
                        newline_char = 0; continue;          suppress 0x000A when it follows 0x000D
                    }
                    newline_char = cr; cr = '\n';                    and otherwise convert to '\n'
                    break;
                case '\x0d':
                    if (newline_char == '\x0a') {
                        newline_char = 0; continue;          suppress 0x000D when it follows 0x000A
                    }
                    newline_char = cr; cr = '\n';                    and otherwise convert to '\n'
                    break;
                default:
                    newline_char = 0;
```

```
                    break;
                }
                lexer_feed_triplet(last_cr, cr, next_cr);
            }
        if (primary_source_file == sf) leafname = "main source text";
        lexer_feed_ends(&words_fed_w1, &words_fed_w2, TRUE, leafname);
        ⟨Word count the new material 6⟩;
}
```

§**6.** We word count all source files, both as to their source text and their quoted text (i.e., their text within double-quotes).

⟨Word count the new material 6⟩ ≡

```
    int wc;
    for (wc=words_fed_w1; wc<=words_fed_w2; wc++) {
        char *p = lw_array[wc].lw_text;
        if (*p == '"') {
            inside quoted text, each run of non-whitespace counts as 1 word
            p++;                                                    skip opening quotation mark
            while (*p != 0) {
                while ((*p == ' ') || (*p == NEWLINE_IN_STRING)) p++;        move past white space
                if ((*p == '"') || (*p == 0)) break;                stop if this reaches the end
                sf->words_of_quoted_text++;                          otherwise we have a word
                while ((*p != ' ') && (*p != NEWLINE_IN_STRING)
                    && (*p != '"') && (*p != 0)) p++;                move to white space or end
            }
        } else {
            outside quoted text, each lexer word not wholly composed of punctuation scores 1
            for (; *p != 0; p++)
                if ((is_punctuation(*p) == FALSE) && (*p != '|')) {
                    sf->words_of_source++;
                    break;
                }
        }
    }
```

This code is used in §5.

§**7.** At present, though, the only use made of these two word counts is via the following routine, which combines them into one.

```
int sf_total_word_count(source_file *sf) {
    return sf->words_of_source + sf->words_of_quoted_text;
}
```

The function sf_total_word_count is called from 2/prob2.

§8. Finally, we translate between the tiresomely many representations of files we seem to be stuck with. The method used by `filename_to_source_file` looks vulnerable to case-insensitive filename issues, but isn't, because each filename is present in NI in only one form.

```
char *sf_get_filename(source_file *sf) {
    if (sf == NULL) internal_error("tried to read filename of null source file");
    return sf->filename;
}
extension_file *sf_get_extension_corresponding(source_file *sf) {
    if (sf == NULL) return NULL;
    return sf->extension_provided;
}
source_file *filename_to_source_file(char *filename) {
    source_file *sf;
    LOOP_OVER(sf, source_file) {
        if (strcmp(sf->filename, filename) == 0) return sf;
        if (strcmp(sf->leafname, filename) == 0) return sf;
    }
    return NULL;
}
```

The function sf_get_filename is called from 2/html, 2/prob1 and 4/head.
The function sf_get_extension_corresponding is called from 2/index, 2/prob1, 4/head, 8/sob, 10/isin and 12/rb.
The function filename_to_source_file is called from 2/html.

§9. **Reading UTF-8 files.** The following routine reads a sequence of Unicode characters from a UTF-8 encoded file, but returns them as a sequence of ISO Latin-1 characters, a trick it can only pull off by escaping non-ISO characters. This is done by taking character number N and feeding it out, one character at a time, as the text "[unicode N]", writing the number in decimal. Only one UTF-8 file like this will be being read at a time, and the routine will be repeatedly called until `EOF` or a line division.

Strictly speaking, we transmit not as ISO Latin-1 but as that subset of ISO which have corresponding (different) codes in the ZSCII character set. This excludes some typewriter symbols and a handful of letterforms, as we shall see.

There are two exceptions: `utf8_fgetc` can also return the usual C end-of-file pseudo-character `EOF`, and it can also return the Unicode BOM (byte-ordering marker) pseudo-character, which is legal at the start of a file and which is automatically prepended by some text editors and word-processors when they save a UTF-8 file (though in fact it is not required by the UTF-8 specification). Anyone calling `utf8_fgetc` must check the return value for `EOF` every time, and for `0xFEFF` every time we might be at the start of the file being read.

```
char unicode_feed_buffer[32];                    holds a single escape such as "[unicode 3106]"
int ufb_counter = -1;                                  position in the unicode feed buffer
int utf8_fgetc(FILE *from, int escape_oddities) {
    int c, conts;
    if (ufb_counter >= 0) {
        if (unicode_feed_buffer[ufb_counter] == 0) ufb_counter = -1;
        else return unicode_feed_buffer[ufb_counter++];
    }
    c = fgetc(from);
    if (c == EOF) return c;                      ruling out EOF leaves a genuine byte from the file
    if (c<0x80) return c;                    in all other cases, a UTF-8 continuation sequence begins
    ⟨Unpack one to five continuation bytes to obtain the Unicode character code 10⟩;
    ⟨Return non-ASCII codes in the intersection of ISO Latin-1 and ZSCII as literals 11⟩;
```

```
    ⟨Return Unicode fancy equivalents as simpler literals 12⟩;
    if (c == 0xFEFF) return c;                                    the Unicode BOM non-character
    if (escape_oddities == FALSE) return c;
    sprintf(unicode_feed_buffer, "[unicode %d]", c);
    ufb_counter = 1;
    return '[';
}
```

The function utf8_fgetc is called from 1/plat and 4/excen.

§**10.** Not every byte sequence is legal in a UTF-8 file: if we find a malformed continuation, we process it as a question mark rather than throwing a fatal error (which is pretty well the only alternative here). The user is likely to see problem messages later on which arise from the question marks, and that will have to do.

⟨Unpack one to five continuation bytes to obtain the Unicode character code 10⟩ ≡

```
    if (c<0xC0) return '?';                                                    malformed UTF-8
    if (c<0xE0) { c = c & 0x1f; conts = 1; }
    else if (c<0xF0) { c = c & 0xf; conts = 2; }
    else if (c<0xF8) { c = c & 0x7; conts = 3; }
    else if (c<0xFC) { c = c & 0x3; conts = 4; }
    else { c = c & 0x1; conts = 5; }
    while (conts > 0) {
        int d = fgetc(from);
        if (d == EOF) return '?';                                              malformed UTF-8
        c = c << 6;
        c = c + (d & 0x3F);
        conts--;
    }
```

This code is used in §9.

§**11.** For the ZSCII character set, see *The Inform 6 Designer's Manual*, or *The Z-Machine Standards Document*. It offers a range of west European accented letters which almost, but not quite, matches those on offer in ISO Latin-1. This omits certain obscure glyphs: among them, the Icelandic lower case eth, which is good because (as we saw in Chapter 2) this character value is used for hackery with error messages, so it is good to know that it cannot occur from the source text.

⟨Return non-ASCII codes in the intersection of ISO Latin-1 and ZSCII as literals 11⟩ ≡

```
    if ((c == 0xa1) || (c == 0xa3) || (c == 0xbf)) return c;                pound sign, inverted ! and ?
    if ((c >= 0xc0) && (c <= 0xff)) {                                  accented West European letters, but...
        if ((c != 0xd0) && (c != 0xf0) &&                                          not Icelandic eths
            (c != 0xde) && (c != 0xfe) &&                                          nor Icelandic thorns
            (c != 0xf7) && (c != 0xd7))                                nor multiplication or division signs
            return c;
    }
```

This code is used in §9.

§**12.** NI errs on the safe side, accepting em-rules and non-breaking spaces, etc., where it would normally expect hyphens and ordinary spaces: this is intended for the benefit of users with helpful word-processors which autocorrect hyphens into em-rules when they are flanked by spaces, and so on.

⟨Return Unicode fancy equivalents as simpler literals 12⟩ ≡

```
if (c == 0x85) return '\x0d';                                  NEL, or "next line"
if (c == 0xa0) return ' ';                                     non-breaking space
if ((c >= 0x2000) && (c <= 0x200a)) return ' ';                space variants
if ((c >= 0x2010) && (c <= 0x2014)) return '-';                rules and dashes
if ((c >= 0x2018) && (c <= 0x2019)) return '\'';               smart single quotes
if ((c >= 0x201c) && (c <= 0x201d)) return '"';                smart double quotes
if ((c >= 0x2028) && (c <= 0x2029)) return '\x0d';             fancy newlines
```

This code is used in §9.

Lexical Writing Back 3/lwb

Purpose

Feeding modified text back into the lexer, to ensure that inflected versions of phrases are also within the word stream.

3/lwb.§2-3 Splicing; §4-6 Stocking the plurals dictionary; §7-8 Searching the plural dictionary; §9 Constructing past participles; §10-11 Constructing comparatives and superlatives

---

Template interpreter commands

```
4   {-callv:traverse_for_plural_definitions}
```

Definitions

¶1. A modest dictionary of plurals is maintained, to allow the user to record better plurals than the ones we would make ourselves. This assumes that a plural can be constructed without knowledge of context, but that works in almost all cases. (Arguably "dwarf" should pluralise to "dwarfs" when discussing stars and to "dwarves" when reading Tolkien, but few works of IF will contain both at once.)

```
typedef struct plural_dictionary_entry {
    int singular_w1, singular_w2;                    words of singular form
    int plural_w1, plural_w2;                        words of plural form
    MEMORY_MANAGEMENT
} plural_dictionary_entry;
```

The structure plural_dictionary_entry is private to this section.

---

§**1.** I feel a certain embarrassment about the frequency with which the following routine is needed throughout NI, to create fresh source text from old. Is this a quick and dirty hack? Or a deep insight into the interdependency of lexical analysis and semantic understanding? The reader must decide.

Anyway, this is one of the two feeder routines for the lexer, the other being in Read Source Text.w: see Lexer.w for its obligations.

Our aim is to copy a string of text into the lexer, as if it had been read from a source file, to generate new words `(lexer_feed_w1, lexer_feed_w2)`.

When done, we call `vocab_identify_word_range`, because we are probably running long after the initial vocabulary identification phase of NI.

```
int lexer_feed_w1, lexer_feed_w2;                    word range made in last call to feed_into_lexer
void feed_into_lexer(char *text, int expand_strings, int grammar_mode) {
    int i;
    source_location as_if_from_nowhere;
    as_if_from_nowhere.file_of_origin = NULL;
    as_if_from_nowhere.line_number = 1;
    lexer_feed_begins(as_if_from_nowhere);
    lexer_divide_strings_at_text_substitutions = expand_strings;
    lexer_treat_slash_as_punctuation = grammar_mode;
    for (i=0; text[i] != 0; i++) {
        int last_cr, cr, next_cr;
```

```
        if (i > 0) last_cr = text[i-1]; else last_cr = EOF;
        cr = text[i];
        if (cr != 0) next_cr = text[i+1]; else next_cr = EOF;
        lexer_feed_triplet(last_cr, cr, next_cr);
    }
    lexer_feed_ends(&lexer_feed_w1, &lexer_feed_w2, FALSE, "<internal>");
    vocab_identify_word_range(lexer_feed_w1, lexer_feed_w2);
}
```

The function feed_into_lexer is called from 2/dl, 3/read, 4/excen, 4/edoc, 4/rtree, 5/litp, 5/candp, 7/dti, 8/creat, 9/scene, 9/mapbp, 9/prop, 9/madj, 9/vpbp, 10/str, 10/eqns, 10/bib, 11/act, 11/av, 12/phtd, 12/phsf, 12/cinv, 13/tfg, 13/gtok and 14/i6t.

§**2. Splicing.** A different form of lexer abuse is called for to overcome the fact that, once in a while, we need to have a run of words in the lexer which all do occur in the source text, but not contiguously, so that they cannot be represented by a pair `(w1, w2)`. In that event we use the following routine to splice duplicate references at the end of the word list (this does not duplicate the text itself, only references to it): for instance, if we start with 10 words (0 to 9) and then splice `(2,3)` and then `(6,8)`, we end up with 15 words, and the text of `(10,14)` contains the same material as words 2, 3, 6, 7, 8.

```
int splice_words(int w1, int w2) {
    int i;
    ensure_lexer_space_up_to(lexer_wordcount + w2 - w1 + 1);
    for (i=0; i<=w2-w1; i++) {
        lw_array[lexer_wordcount+i].lw_text = lw_array[w1+i].lw_text;
        lw_array[lexer_wordcount+i].lw_rawtext = lw_array[w1+i].lw_rawtext;
        lw_array[lexer_wordcount+i].lw_source = lw_array[w1+i].lw_source;
        lw_array[lexer_wordcount+i].lw_identity = lw_array[w1+i].lw_identity;
    }
    i = lexer_wordcount;
    lexer_wordcount += w2-w1+1;
    return i;
}
```

The function splice_words is called from 4/rtree, 5/litp, 9/scene, 9/prop, 10/str, 11/act and 11/av.

§**3.** The following is almost identical, but effectively forces words into lower case by splicing only the case-normalised originals (thus not preserving the original untouched style).

```
int lower_case_splice_words(int w1, int w2) {
    int i;
    ensure_lexer_space_up_to(lexer_wordcount + w2 - w1 + 1);
    for (i=0; i<=w2-w1; i++) {
        lw_array[lexer_wordcount+i].lw_text = lw_array[w1+i].lw_text;
        lw_array[lexer_wordcount+i].lw_rawtext = lw_array[w1+i].lw_text;
        lw_array[lexer_wordcount+i].lw_source = lw_array[w1+i].lw_source;
    }
    i = lexer_wordcount;
    lexer_wordcount += w2-w1+1;
    return i;
}
```

§**4. Stocking the plurals dictionary.** The user gives us plurals with special sentences, but we don't handle these during the two main source text traverses because that would be too late for some of the plurals we need. (Inform used to work this way, but with the consequent restriction that plurals had to be defined earlier in the source than anything needing them: this was much misunderstood by users, and generally tiresome, especially for extensions where the ordering was not obvious.)

```
sentence_handler PLURAL_SH_handler =
    { SENTENCE_NT, PLURAL_VB, 1, handle_plural_definition };
void handle_plural_definition(parse_node *p) {
    do nothing: these sentences have already been caught by the traverse below
}
void traverse_for_plural_definitions(void) {
    parse_node *p, *prevp;
    for (prevp=NULL, TREE_START(p); p; prevp=p, TREE_NEXT(p)) {
        if ((pn_get_node_type(p) == SENTENCE_NT)
            && (p->down)
            && (pn_int_annotation(p->down, verb_id_ANNOT) == PLURAL_VB)
            && (p->down->next) && (p->down->next->next))
            register_plural_form(p->down->next->word_ref1,
                p->down->next->word_ref2,
                p->down->next->next->word_ref1,
                p->down->next->next->word_ref2);
    }
}
```

The function traverse_for_plural_definitions is invoked by a command in a `.i6t` template file.

§**5.** Note that we are entirely allowed to register a new plural for a phrase which already has a plural in the dictionary (see below), which is why we do not trouble to search the existing dictionary here.

```
void register_plural_form(int sing_w1, int sing_w2, int pl_w1, int pl_w2) {
    plural_dictionary_entry *pde = CREATE(plural_dictionary_entry);
    [[sing_w1, sing_w2 == the plural of ... --> sing_w1, sing_w2]];
    pde->singular_w1 = sing_w1;
    pde->singular_w2 = sing_w2;
    pde->plural_w1 = pl_w1;
    pde->plural_w2 = pl_w2;
    ⟨Forbid plural declarations containing quoted text 6⟩;
    LOGIF(PLURALS, "[Registering plural of $W as $W]\n", sing_w1, sing_w2, pl_w1, pl_w2);
}
```

§**6.** In general names of things which we need plurals for cannot contain quoted text anyway, so the following problem messages are not too gratuitous.

⟨Forbid plural declarations containing quoted text 6⟩ ≡

```
int i;
for (i=sing_w1; i<=sing_w2; i++)
    if (vocab_test_flags(i, TEXT_MC)) {
        sentence_problem(_P_(C3PluralOfQuoted),
            "declares a plural for a phrase containing quoted text",
            "which is forbidden. Sentences like this are supposed to "
            "declare plurals without quotation marks: for instance, "
            "'The plural of attorney general is attorneys general.'");
        return;
    }
for (i=pl_w1; i<=pl_w2; i++)
    if (vocab_test_flags(i, TEXT_MC)) {
        sentence_problem(_P_(C3PluralIsQuoted),
            "declares a plural for a phrase using quoted text",
            "which is forbidden. Sentences like this are supposed to "
            "declare plurals without quotation marks: for instance, "
            "'The plural of procurator fiscal is procurators fiscal.'");
        return;
    }
```

This code is used in §5.

§**7. Searching the plural dictionary.** The following routine can either be called once only – in which case it yields up the best known plural for the phrase – or iteratively, in which case it serves up all known plurals of the given phrase, starting with the best (the earliest defined in the text, if any plural for this phrase has been so defined) and finishing up with the worst (a mechanically-made one not found in the dictionary).

```
int plw1, plw2;
plural_dictionary_entry *make_plural_of(int w1, int w2,
    plural_dictionary_entry *search_from) {
    int i;
    char pluralised[MAX_WORD_LENGTH+3];
    plural_dictionary_entry *pde;
    if ((w1 == -1) || (w2 < w1)) { plw1 = -1; plw2 = -1; return NULL; }
    if (search_from == NULL) search_from = FIRST_OBJECT(plural_dictionary_entry);
    else search_from = NEXT_OBJECT(search_from, plural_dictionary_entry);
    for (pde = search_from; pde; pde = NEXT_OBJECT(pde, plural_dictionary_entry)) {
        if (compare_word_range(w1, w2, pde->singular_w1, pde->singular_w2)) {
            plw1 = pde->plural_w1;
            plw2 = pde->plural_w2;
            return pde;
        }
    }
    ⟨Make a new plural by lexical writing back 8⟩;
    return NULL;
}
```

The function make_plural_of is called from 7/tids, 7/kov and 9/wo.

§**8.** When the dictionary fails us, we use lexical rewriting to construct plurals of phrases found only in the singular in the source. For instance, if the designer says that "A wicker basket is a kind of container" then NI will need to recognise not only "wicker basket" but also "wicker baskets", a pair of words not found in the source text anywhere. So the following routine takes the text `(w1, w2)` and feeds a suitable plural into the lexer, emerging with the text `(plw1, plw2)`.

The pluralising algorithm looks only at the ending of the final word, turning "-s" into "-ses" ("wine glass" to "wine glasses"), "-sh" into "-shes" ("wish" to "wishes"), "-y" into "-ies" ("nappy" to "nappies"; less happily, "time of day" to "time of daies") and otherwise tacking an "-s" on the end ("sheep" to "sheeps". Sigh...).

We do not write the new plural into the dictionary: there is no need, as it can be rebuilt quickly whenever needed again.

⟨Make a new plural by lexical writing back 8⟩ ≡

```
plw1 = lexer_wordcount;
if (w1<w2) splice_words(w1, w2-1);
if (*(lw_array[w2].lw_text) == '\"') strcpy(pluralised, "some-long-text");
else strcpy(pluralised, lw_array[w2].lw_text);
i = strlen(pluralised)-1;
switch (pluralised[i]) {
    case 's': case 'x': strcat(pluralised, "es"); break;
    case 'h':
        if ((i>0) && (pluralised[i-1]=='s')) strcat(pluralised, "es");
        else strcat(pluralised, "s"); break;
    case 'y':
        if ((i>0) && (pluralised[i-1]=='a')) { strcat(pluralised, "s"); break; }
        if ((i>0) && (pluralised[i-1]=='e')) { strcat(pluralised, "s"); break; }
        if ((i>0) && (pluralised[i-1]=='i')) { strcat(pluralised, "s"); break; }
        if ((i>0) && (pluralised[i-1]=='o')) { strcat(pluralised, "s"); break; }
        if ((i>0) && (pluralised[i-1]=='u')) { strcat(pluralised, "s"); break; }
        pluralised[i] = 0; strcat(pluralised, "ies"); break;
    default: strcat(pluralised, "s"); break;
}
feed_into_lexer(pluralised, FALSE, FALSE);
plw2 = lexer_wordcount-1;
LOGIF(PLURALS, "[Constructing plural of $W as $W]\n", w1, w2, plw1, plw2);
```

This code is used in §7.

§**9. Constructing past participles.** A similar construction works out the past participle of actions, such as "turning" to "turned", though here we don't need any dictionary because action definitions already have the option to specify their own irregularities.

English is replete with exceptions ("catching" must become "caught", for instance), and there are no sensible rules, so exceptions are mostly left to the Standard Rules or the user. ("Doing" is turned automatically into "done" because it makes life easier when we create the patterns for "doing something", and "going" to "gone" by analogy.)

```
void make_past_of_participle(int w1, int w2) {
    char pasturised[MAX_WORD_LENGTH+3];
    int i;
    plw1 = lexer_wordcount;
    i = w1;
    while (i <= w2) {
        if (*(lw_array[i].lw_text) == '\"') strcpy(pasturised, "some-long-text");
        else strcpy(pasturised, lw_array[i].lw_text);
```

```
        if ((strlen(pasturised) >= 5) &&
            (pasturised[strlen(pasturised)-3] == 'i') &&
            (pasturised[strlen(pasturised)-2] == 'n') &&
            (pasturised[strlen(pasturised)-1] == 'g')) {
            if (i > w1) splice_words(w1, i-1);
            pasturised[strlen(pasturised)-3] = 0;
            if (strcmp(pasturised, "do") == 0) strcpy(pasturised, "done");
            else if (strcmp(pasturised, "go") == 0) strcpy(pasturised, "gone");
            else strcat(pasturised, "ed");
            feed_into_lexer(pasturised, FALSE, FALSE);
            if (i < w2) splice_words(i+1, w2);
            break;
        }
        i++;
    }
    plw2 = lexer_wordcount-1;
    LOGIF(PAST_PARTICIPLES,
        "[Past participle of $W is $W]\n", w1, w2, plw1, plw2);
}
void set_past_participle(int *past_w1, int *past_w2, int irregular_pp) {
    plw1 = lexer_wordcount;
    splice_words(irregular_pp, irregular_pp);
    if (*past_w1 < *past_w2) splice_words(*past_w1 + 1, *past_w2);
    *past_w1 = plw1;
    *past_w2 = lexer_wordcount-1;
}
```

The function make_past_of_participle is called from 11/act.
The function set_past_participle is called from 11/act.

§**10. Constructing comparatives and superlatives.** And these are constructed very similarly. Thus "happy" to "happier" and "happiest"; "rich" to "richer" and "richest".

```
int make_comparative(int w1) {
    char comprised[MAX_WORD_LENGTH+3];
    plw1 = lexer_wordcount;
    if (*(lw_array[w1].lw_text) == '\"') strcpy(comprised, "some-long-text");
    else strcpy(comprised, lw_array[w1].lw_text);
    if (comprised[strlen(comprised)-1] == 'y')
        comprised[strlen(comprised)-1] = 'i';
    if (comprised[strlen(comprised)-1] != 'e')
        strcat(comprised, "e");
    strcat(comprised, "r");
    feed_into_lexer(comprised, FALSE, FALSE);
    strcpy(comprised, " than ");
    feed_into_lexer(comprised, FALSE, FALSE);
    plw2 = lexer_wordcount-1;
    LOG("[Comparative of $W is $W]\n", w1, w1, plw1, plw2);
    return plw1;
}
int make_superlative(int w1) {
    char comprised[MAX_WORD_LENGTH+3];
    if (*(lw_array[w1].lw_text) == '\"') strcpy(comprised, "some-long-text");
```

```
    else strcpy(comprised, lw_array[w1].lw_text);
    if (comprised[strlen(comprised)-1] == 'y')
        comprised[strlen(comprised)-1] = 'i';
    if (comprised[strlen(comprised)-1] != 'e')
        strcat(comprised, "e");
    strcat(comprised, "st");
    feed_into_lexer(comprised, FALSE, FALSE);
    LOG("[Superlative of $W is $W]\n", w1, w1, lexer_wordcount-1, lexer_wordcount-1);
    return lexer_wordcount-1;
}
```

The function make_comparative is called from 9/cmpbp.
The function make_superlative is called from 9/madj.

§**11.** There has to be a better term than "quiddity" for this grammatical construct, but what I mean is the property for which the given adjective makes a comparison: for instance, "tallness" for "tall", or "steeliness" for "steely".

```
int make_quiddity(int w1) {
    char comprised[MAX_WORD_LENGTH+3];
    if (*(lw_array[w1].lw_text) == '\"') strcpy(comprised, "some-long-text");
    else strcpy(comprised, lw_array[w1].lw_text);
    if (comprised[strlen(comprised)-1] == 'y')
        comprised[strlen(comprised)-1] = 'i';
    strcat(comprised, "ness");
    feed_into_lexer(comprised, FALSE, FALSE);
    LOG("[Quiddity of $W is $W]\n", w1, w1, lexer_wordcount-1, lexer_wordcount-1);
    return lexer_wordcount-1;
}
```

The function make_quiddity is called from 9/cmpbp.

Lexical Services 3/lexs

Purpose

A small suite of routines to examine the words stored by the lexer, which are provided as a utility to higher levels of NI. None are used by the lexer itself.

3/lexs.§3-4 Casing and sentence division; §5 Dequoting literal text; §6 Correct use of text substitutions; §7 Ordinals; §8 Digital times; §9 Title casing for extension names; §10-12 Comparing word ranges; §13-17 Searching word ranges; §18 Searching for unusual spacing in ranges; §19 Dividing lists; §20 Parenthesis matching; §21-22 A detour for encoding text; §23-24 Printing word ranges; §25-26 Printing raw word ranges; §27-29 Printing word ranges to the debugging log

---

Definitions

¶1. The following definitions are for use with a utility routine for looking through lists to pick off the first entry:

```
define LOOK_FOR_AND 1
define LOOK_FOR_OR 2

int left_w1, left_w2;                    words making up first entry in list
int right_w1, right_w2;                  words making up tail of list
```

---

§**1.** Comparison of the word at a given numbered position against some known word, say "rulebook", must be done very quickly. The whole point of the vocabulary bank identifying each distinct word was to enable this to be done by a single comparison of pointers: and to avoid the overhead of a function call, we perform this with macros.

Recall that words are numbered from 0 to `lexer_wordcount - 1` inclusive, and that the word range `(w1, w2)` means all words from `w1` to `w2` inclusive: it would be an error to use the routines below in any case where `w1` or `w2` are out of range, or where it is not true that `w1 <= w2`. For efficiency's sake these error conditions are not checked.

```
define compare_word(w, voc) (lw_array[w].lw_identity == (voc))
define compare_words(w1, w2) (lw_array[w1].lw_identity == lw_array[w2].lw_identity)
```

§**2.** We can also, more slowly, perform a direct string comparison. If carried out on the original, raw, text, this will be case sensitive – which is usually wrong for Inform purposes. On the `lw_text`, however, we are comparing a case-normalised version of the original word, which is likely to be safely case insensitive comparison, provided that the content of `t` is also normalised.

```
int compare_word_by_strcmp(int w, char *t) {
    return (strcmp(lw_array[w].lw_text, t) == 0);
}
int compare_raw_word_by_strcmp(int w, char *t) {
    return (strcmp(lw_array[w].lw_rawtext, t) == 0);
}
```

The function compare_word_by_strcmp is called from 2/index, 4/vm and 5/candp.

The function compare_raw_word_by_strcmp is called from 2/index and 10/isin.

§**3. Casing and sentence division.** Casing is only sometimes informative in English: for the first word in a sentence, we expect to find an upper-case letter, so that there is no easy way to tell the name of a person or institution from a common noun. But in other cases an upper case initial letter is unexpected, and can tell us something.

```
int unexpectedly_upper_case(int wn) {
    if (wn<1) return FALSE;
    if (compare_word(wn-1, FULLSTOP_V)) return FALSE;
    if (compare_word(wn-1, STROKE_V)) return FALSE;
    if (isupper(*(lw_array[wn].lw_rawtext))) {
        if (text_ending_sentence(wn-1)) return FALSE;
        return TRUE;
    }
    return FALSE;
}
```

The function unexpectedly_upper_case is called from 2/prob3, 4/verb, 4/noun, 4/ofs, 5/det, 5/conj, 8/refpt, 11/ap and 13/test.

§**4.** Does the word at `wn` appear to be a piece of quoted text which, because it ends with punctuation, may also end the sentence which quotes it?

```
int text_ending_sentence(int wn) {
    char *p = lw_array[wn].lw_rawtext;
    if (p[0] != '"') return FALSE;
    p += strlen(p) - 2;
    if ((p[0] == '.') && (p[1] == '"')) return TRUE;
    if ((p[0] == '?') && (p[1] == '"')) return TRUE;
    if ((p[0] == '!') && (p[1] == '"')) return TRUE;
    p--;
    if ((p[0] == '.') && (p[1] == ')') && (p[2] == '"')) return TRUE;
    if ((p[0] == '?') && (p[1] == ')') && (p[2] == '"')) return TRUE;
    if ((p[0] == '!') && (p[1] == ')') && (p[2] == '"')) return TRUE;
    if ((p[0] == '.') && (p[1] == '\'') && (p[2] == '"')) return TRUE;
    if ((p[0] == '?') && (p[1] == '\'') && (p[2] == '"')) return TRUE;
    if ((p[0] == '!') && (p[1] == '\'') && (p[2] == '"')) return TRUE;
    return FALSE;
}
```

The function text_ending_sentence is called from 4/sent and 12/cinv.

§**5. Dequoting literal text.** A utility for stripping double-quotes from literal text, along with initial or trailing spaces inside those quotes.

```
void dequote_word(int wn) {
    char *previous_text = lw_array[wn].lw_text;
    char *dequoted_text;
    if (previous_text[0] != '"') return;
    lw_array[wn].lw_rawtext = copy_to_lexer_memory(lw_array[wn].lw_rawtext);
    dequoted_text = previous_text + 1;
    while (*(dequoted_text) == ' ') dequoted_text++;
    if ((strlen(dequoted_text) > 0) &&
        (*(dequoted_text+strlen(dequoted_text)-1) == '"'))
        *(dequoted_text+strlen(dequoted_text)-1) = 0;
    while ((strlen(dequoted_text) > 0) &&
        (*(dequoted_text+strlen(dequoted_text)-1) == ' '))
        *(dequoted_text+strlen(dequoted_text)-1) = 0;
    lw_array[wn].lw_text = dequoted_text;
    LOGIF(VOCABULARY, "Dequoting word %d <%s> to <%s>\n",
        wn, previous_text, dequoted_text);
    vocab_identify_word(wn);
    vocab_set_raw_exemplar_to_text(wn);
}
```

The function dequote_word is called from 2/isn, 2/index, 8/sob, 8/mass, 9/map, 10/bib, 10/fig, 10/sfx, 10/isin, 11/act, 12/def, 13/tfg, 13/gtok and 13/test.

§**6. Correct use of text substitutions.** If a "word" is going to be quoted literal text, then it has to use the characters `[` and `]` in a matched way, and without nesting them. The following verifies that.

These rules are quite strict. It could be argued that nested brackets should be allowed, allowing comments in text substitutions, but the result would be hard to read and tricky for the user interface applications to syntax-colour.

```
int well_formed_text_routine(char *fw) {
    int i, escaped = NOT_APPLICABLE;
    for (i=0; fw[i] != 0; i++) {
        if (fw[i] == TEXT_SUBSTITUTION_BEGIN) {
            if (escaped == TRUE) return FALSE;
            escaped = TRUE;
        }
        if (fw[i] == TEXT_SUBSTITUTION_END) {
            if (escaped != TRUE) return FALSE;
            escaped = FALSE;
        }
    }
    if (escaped == NOT_APPLICABLE) return escaped;
    if (escaped) return FALSE;
    return TRUE;
}
```

The function well_formed_text_routine is called from 3/vocab and 13/tfg.

§**7. Ordinals.** The following parses the string to see if it is a non-negative integer, written as an English ordinal: 0th, 1st, 2nd, 3rd, 4th, 5th, ... Note that we don't bother to police the finicky rules on which suffix should accompany which value (22nd not 22th, and so on).

```
int an_ordinal_number(char *fw) {
    int i;
    for (i=0; fw[i] != 0; i++)
        if (!(isdigit(fw[i]))) {
            if ((i>0) &&
                (((fw[i] == 's') && (fw[i+1] == 't') && (fw[i+2] == 0)) ||
                ((fw[i] == 'n') && (fw[i+1] == 'd') && (fw[i+2] == 0)) ||
                ((fw[i] == 'r') && (fw[i+1] == 'd') && (fw[i+2] == 0)) ||
                ((fw[i] == 't') && (fw[i+1] == 'h') && (fw[i+2] == 0))))
                return atoi(fw);
            break;
        }
    return -1;
}
```

The function an_ordinal_number is called from 3/vocab.

§**8. Digital times.** Times, in other words, written in the style of a digital clock: "00:00", "5:21", "17:21". The syntax must be one or two digits, followed by a colon, followed by exactly two digits; it is permissible for the first of two digits to be zero; when that is discarded, the hours part must be in the range 0 to 23, and the minutes part in the range 0 to 59.

```
int is_a_digital_clock_time(int w1, int *time_minutes, int *time_hours) {
    int ratchet = 0, t, colons = 0, digits = 0;
    char *wd = lw_array[w1].lw_text;
    *time_hours = 0; *time_minutes = 0;
    for (t=0; wd[t]; t++) {
        if (((t==1) || (t==2)) && (wd[t] == ':') && (wd[t+1])) {
            if (ratchet >= 24) return FALSE;
            *time_hours = ratchet;
            ratchet = 0; digits = 0;
            colons++;
        } else if (isdigit(wd[t])) {
            ratchet = 10*ratchet + (wd[t]-'0'); digits++;
            if ((ratchet >= 60) || (digits > 2)) return FALSE;
        } else return FALSE;
    }
    if (colons != 1) return FALSE;
    *time_minutes = ratchet;
    return TRUE;
}
```

The function is_a_digital_clock_time is called from 5/lit.

§**9. Title casing for extension names.** Until the spring of 2008, extension titles and author names were case normalised, and the following routine was used to perform the necessary surgery on the word ranges used for these. That changed in the 5Sxx series of builds, and the routine is now no longer used. It is something of a trick – for once we break our promises and touch the raw lexical source text: but not the touched text, because that would wreck the vocabulary hash table.

```
void rewrite_raw_text_in_title_casing(int w1, int w2) {
    int w;
    for (w=w1; w<=w2; w++) {
        char *p = lw_array[w].lw_rawtext;
        if (*p == 0) continue;
        *p = toupper(*p);
        p++;
        while (*p != 0) {
            *p = tolower(*p);
            p++;
        }
    }
}
```

§**10. Comparing word ranges.** The calculation overhead makes it marginally not worth using a hash function to speed up the following comparison, which requires two excerpts to be absolutely equal.

```
int compare_word_range(int w1, int w2, int w3, int w4) {
    int j;
    if (w4-w3 != w2-w1) return FALSE;
    if ((w1<0) || (w3<0)) return FALSE;
    for (j=0; j<=w2-w1; j++)
        if (compare_words(w1+j, w3+j) == FALSE) return FALSE;
    return TRUE;
}
```

The function compare_word_range is called from 3/lwb, 4/iext, 4/head, 4/ofs, 5/conj, 5/litp, 8/creat, 9/qty, 9/scene, 9/vpbp, 10/tab, 11/act, 12/phud, 12/phod, 12/phsf, 12/stv, 12/phin, 12/rb and 13/gv.

§**11.** This alternative form does not use the identifications of vocabulary and resorts to `strcmp`, which has to look at every character of the raw text: so although it looks similar, it's much, much slower. Happily, it is now no longer used, and retained only in case of future need.

```
int compare_raw_word_range(int w1, int w2, int w3, int w4) {
    int j;
    if (w4-w3 != w2-w1) return FALSE;
    if ((w1<0) || (w3<0)) return FALSE;
    for (j=0; j<=w2-w1; j++)
        if (strcmp(lw_array[w1+j].lw_rawtext,
            lw_array[w3+j].lw_rawtext) != 0) return FALSE;
    return TRUE;
}
```

§**12.** And relatedly, used for sorting into alphabetical order, a direct analogue of `strcmp` but for word ranges:

```
int rangecmp(int x1, int x2, int y1, int y2) {
    if (x1 < 0) { if (y1 < 0) return 0; return -1; }
    if (y1 < 0) return 1;
    int n;
    int l1 = x2 - x1 + 1;
    int l2 = y2 - y1 + 1;
    for (n=0; (n<l1) && (n<l2); n++) {
        int delta = strcmp(lw_array[x1 + n].lw_text, lw_array[y1 + n].lw_text);
        if (delta != 0) return delta;
    }
    return l1 - l2;
}
```

The function rangecmp is called from 9/tmap and 11/ina.

§**13. Searching word ranges.** Look to see if a given text occurs as a word with number $w_1 < n < w_2$. In the second test, the word is not allowed to be inside brackets, nor to be unexpectedly capitalised. In the third, the ends are included. On success we return the word number n, which could be any non-negative number; on failure, we return -1.

```
int is_word_intermediate(vocabulary_entry *word, int w1, int w2) {
    int i;
    for (i=w1+1; i<=w2-1; i++) if (lw_array[i].lw_identity == word) return i;
    return -1;
}
int is_word_intermediate_unbracketed(vocabulary_entry *word, int w1, int w2) {
    int i, bl = 0;
    for (i=w1; i<=w2-1; i++) {
        if ((i>w1) && (bl==0) && (lw_array[i].lw_identity == word) && (unexpectedly_upper_case(i) ==
FALSE))
            return i;
        if ((lw_array[i].lw_identity == OPENBRACKET_V) || (lw_array[i].lw_identity == OPENBRACE_V))
bl++;
        if ((lw_array[i].lw_identity == CLOSEBRACKET_V) || (lw_array[i].lw_identity == CLOSEBRACE_V))
bl--;
    }
    return -1;
}
int is_word_intermediate_inc(vocabulary_entry *word, int w1, int w2) {
    int i;
    for (i=w1; i<=w2; i++) if (lw_array[i].lw_identity == word) return i;
    return -1;
}
```

The function is_word_intermediate is called from 4/sent, 4/noun, 7/data, 8/refpt, 9/qty, 9/map, 10/tab, 10/eqns, 11/act, 11/av, 12/phud, 12/phtd, 12/phsf, 12/def and 13/gtok.

The function is_word_intermediate_unbracketed is called from 5/candp.

The function is_word_intermediate_inc is called from 8/creat, 8/mass, 8/knowc, 11/anl, 11/ap, 12/phud and 12/phsf.

§**14.** We are going to need to look for paired brackets at the outside of an excerpt reasonably quickly, and the following routine performs that test.

```
int paired_brackets(int w1, int w2) {
    if [[w1, w2 == OPENBRACKET ... CLOSEBRACKET --> w1, w2]] {
        int i, bl = 1;
        for (i=w1+1; i<=w2-1; i++) {
            if [[word i == OPENBRACKET]] bl++;
            if [[word i == CLOSEBRACKET]] bl--;
            if (bl == 0) return FALSE;
        }
        if (bl == 1) return TRUE;
    }
    return FALSE;
}
```

The function paired_brackets is called from 4/head, 5/tandv and 5/candp.

§**15.** The following looks for "callings", that is, names occurring in noun phrases with the shape "blah blah (called the rhubarb rhubarb)".

```
int word_range_ends_with_calling(int w1, int w2, int *m1, int *m2, int *cw1, int *cw2) {
    int i, n1, n2;
    if (![[w1, w2 == ... CLOSEBRACKET]]) return FALSE;
    for (i=w2-3; i>w1; i--)
        if [[i, w2 == OPENBRACKET called ... CLOSEBRACKET --> n1, n2]] {
            [[n1, n2 == the ... --> n1, n2]];
            if (m1) { *m1 = w1; *m2 = i-1; }          the text before the bracketed clause, "blah blah"
            if (cw1) { *cw1 = n1; *cw2 = n2; }                the calling name, "rhubarb rhubarb"
            return TRUE;
        }
    return FALSE;
}
int word_range_includes_a_calling(int w1, int w2) {
    int j;
    for (j = w2; j > w1+2; j--)
        if (word_range_ends_with_calling(w1, j, NULL, NULL, NULL, NULL)) return TRUE;
    return FALSE;
}
```

The function word_range_ends_with_calling is called from 5/rel, 5/candd and 12/def.
The function word_range_includes_a_calling is called from 9/scene.

§**16.** A somewhat more specialised test, which happens to be useful in spotting multi-word verbs in sentences: we look for a run of one to three known words, starting and ending wholly within the range, and not occurring immediately after a word to avoid.

```
int is_sequence_intermediate(vocabulary_entry *word1, vocabulary_entry *word2,
    vocabulary_entry *word3, vocabulary_entry *avoid_word, int w1, int w2) {
    int i, c = 1;
    if (word2 != 0) c++;
    if (word3 != 0) c++;
    for (i=w1+1; i<=w2-c; i++)
        if ((lw_array[i].lw_identity == word1) &&
            ((c < 2) || (lw_array[i+1].lw_identity == word2)) &&
            ((c < 3) || (lw_array[i+2].lw_identity == word3)) &&
            (lw_array[i-1].lw_identity != avoid_word))
            return i;
    return -1;
}
```

The function is_sequence_intermediate is called from 4/verb.

§**17.** The following finds the first "in" between `w1` and `w2` inclusive. It is not really a loop, and iterates only to retry if it finds an "in" that we consider bogus for our own syntactic purposes: for instance, we don't want to count the "in" from "fixed in place", so if we should find it we retry the search starting from "place". The left wall thus moves rightwards until it reaches the right, in $\leq (w_2 - w_1 + 1)/2$ steps: the worst case is searching "is in is in is in is in ... is in".

```
int is_the_word_in_intermediate(int w1, int w2) {
    int left = w1, right = w2;
    while (left <= right) {
        int j = is_word_intermediate_inc(in_V, left, right);
        if (j >= 1) {
            int prev = j-1, next = j+1;
            if (compare_word(prev, is_V)) { left = next; continue; }
            if (compare_word(prev, are_V)) { left = next; continue; }
            if (compare_word(prev, was_V)) { left = next; continue; }
            if (compare_word(prev, were_V)) { left = next; continue; }
            if (compare_word(prev, been_V)) { left = next; continue; }
            if (compare_word(prev, listed_V)) { left = next; continue; }
            if ((compare_word(prev, fixed_V)) &&
                (next <= right) && (compare_word(next, place_V))) { left = next; continue; }
        }
        return j;
    }
    return -1;
}
```

The function is_the_word_in_intermediate is called from 11/anl and 11/ap.

§18. Searching for unusual spacing in ranges. Looking forward to see how far the current column or row extends, for formatted tables. The idea is that we have a range `w1` to `w2`, and that the current column or row extends from `w1` but may run only part-way through: we look for the first point at which there is a tab break (for column scanning) or a newline break (for row scanning), and return the word position just before that break. If we do not find one, it follows that the entire range holds the current column or row, and we return `w2`.

```
int last_word_of_formatted_text(int w1, int w2, int tab_flag) {
    int i;
    if (w2 == w1) return w1;
    for (i=w1+1; i<=w2; i++)
        if (((tab_flag) && (lw_array[i].lw_break == '\t')) ||
            (isdigit(lw_array[i].lw_break)) ||
            (lw_array[i].lw_break == '\n'))
                return i-1;
    return w2;
}
```

The function last_word_of_formatted_text is called from 10/tab and 10/eqns.

§19. Dividing lists. A little routine used to detect list divisions, paying great attention to the optional use of the serial comma, since this gives Emily such delight. It tries to divide `(w1, w2)` at the leftmost possible position, regarding either "and" or "or" as a divider, or both: the parameter `and_or` is a bitmap consisting of some sum of the constants `LOOK_FOR_AND` and `LOOK_FOR_OR`. If it succeeds, `(left_w1, left_w2)` and `(right_w1, right_w2)` hold the left and right material respectively: thus it is guaranteed that `(left_w1, left_w2)` is indivisible further. Note that, because these four variables are global, it is important to copy them into local variables in any routine making recursive use of `is_list_divided`.

```
int is_list_divided(int w1, int w2, int and_or) {
    int a, o, c, b;
    if ((w1<0) || (w2<0) || (w1>=w2)) return FALSE;
    a = is_word_intermediate_unbracketed(and_V, w1, w2);
    o = is_word_intermediate_unbracketed(or_V, w1, w2);
    c = is_word_intermediate_unbracketed(COMMA_V, w1, w2);
    if ((and_or & LOOK_FOR_AND) == 0) a = -1;
    if ((and_or & LOOK_FOR_OR) == 0) o = -1;
    b = -1;
    if ((a>=0) && ((b<0) || (a<=b))) b = a;
    if ((o>=0) && ((b<0) || (o<=b))) b = o;
    if ((c>=0) && ((b<0) || (c<=b))) b = c;
    if (b<0) return FALSE;
    left_w1 = w1; left_w2 = b-1; right_w1 = b+1; right_w2 = w2;
    if (compare_word(left_w2, COMMA_V)) left_w2--;
    if (compare_word(right_w1, COMMA_V)) right_w1++;
    if (compare_word(right_w1, and_V)) right_w1++;
    if (compare_word(right_w1, or_V)) right_w1++;
    if ((left_w1 <= left_w2) && (right_w1 <= right_w2))
        return TRUE;
    return FALSE;
}
```

The function is_list_divided is called from 2/dl, 4/iext, 4/vm, 4/noun, 5/litp, 7/tc, 9/map, 10/eqns, 10/bib, 10/isin, 11/anl, 11/av, 12/phud, 12/phod, 12/rb and 13/tfg.

§**20. Parenthesis matching.** Note that the empty word range is deemed to have balancing brackets, as is a range with no brackets at all.

```
int brackets_unbalanced(int w1, int w2) {
    int i, lev = 0;
    if ((w1<0) || (w2<w1)) return FALSE;
    for (i=w1; i<=w2; i++) {
        if (compare_word(i, OPENBRACKET_V)) lev++;
        if (compare_word(i, CLOSEBRACKET_V)) lev--;
        if (lev < 0) return TRUE;
    }
    if (lev != 0) return TRUE;
    return FALSE;
}
```

The function brackets_unbalanced is called from 5/rel and 8/tass.

§**21. A detour for encoding text.** XML escapes like `>` instead of `>` are needed when copying literal text into a file which uses HTML or XML.

```
void print_literal_string_to_file(OUTPUT_STREAM, char *p) {
    if (STREAM_ENCODING(OUT) == UTF8_ENC) STREAM_USE_XML_ESCAPES(OUT, TRUE);
    WRITE("%s", p);
    STREAM_USE_XML_ESCAPES(OUT, FALSE);
}
```

The function print_literal_string_to_file is called from 2/lexi, 4/ext, 4/eid, 4/edict, 5/aph and 5/litp.

§**22.** And the following is needed to deal with extension filenames on platforms whose locale is encoded as UTF-8.

```
void transcode_ISO_string_to_UTF8(char *p, char *dest) {
    int i, j;
    for (i=0, j=0; p[i]; i++) {
        int charcode = (int) (((unsigned char *)p)[i]);
        if (charcode >= 128) {
            dest[j++] = 0xC0 + (charcode >> 6);
            dest[j++] = 0x80 + (charcode & 0x3f);
        } else {
            dest[j++] = p[i];
        }
    }
    dest[j] = 0;
}
```

The function transcode_ISO_string_to_UTF8 is called from 1/plat.

§**23. Printing word ranges.** There are two complications here: first, whether to print the original raw text or whether to print the case-normalised text (which will be lower case except for literals); and second, if the destination is a file, what text encoding to use. When writing to a string, we always preserve the ISO Latin-1 encoding of the lexed text.

```
void print_text_to_file(int w1, int w2, OUTPUT_STREAM) {
    int j;
    for (j=w1; j<=w2; j++) {
        print_literal_string_to_file(OUT, lw_array[j].lw_text);
        if (j<w2) WRITE(" ");
    }
}
void print_text_to_string(int w1, int w2, char *str) {
    int j;
    str[0] = 0;
    for (j=w1; j<=w2; j++) {
        sprintf(str+strlen(str), "%s", lw_array[j].lw_text);
        if (j<w2) sprintf(str+strlen(str), " ");
    }
}
void print_text_to_string_truncated(int w1, int w2, char *str, int max) {
    int j;
    str[0] = 0;
    for (j=w1; j<=w2; j++) {
        char *p = lw_array[j].lw_text;
        char *p2 = "";
        int sp = FALSE;
        if (j<w2) { sp = TRUE; p2 = lw_array[j+1].lw_rawtext; }
        if (strlen(str) + strlen(p) + 2 > max) break;
        sprintf(str+strlen(str), "%s", p);
        if (strcmp(p2, ":")==0) sp = FALSE;
        if (strcmp(p2, ",")==0) sp = FALSE;
        if (strcmp(p2, ")")==0) sp = FALSE;
        if (strcmp(p, "(")==0) sp = FALSE;
        if (sp) sprintf(str+strlen(str), " ");
    }
}
```

The function print_text_to_file is called from 2/index, 4/vm, 5/bp, 5/litp, 9/rsdt, 7/kix, 9/pp, 11/act, 11/ina, 11/av and 12/rb.
The function print_text_to_string is called from 4/iext, 7/data, 9/mapbp, 9/madj, 9/map and 12/cinv.
The function print_text_to_string_truncated is called from 12/br.

§**24.** A variation on this tries to contain unreasonably long pastes of quoted literals, and is used in printing out problem messages, where quoting back the offending source text might make unhelpfully vast paragraphs in which the actual information is more or less hidden.

```
define STRING_TOLERANCE_LIMIT 70

void print_modest_sized_text_to_string(int w1, int w2, char *str) {
    int i, j, l; char *p;
    if (w1 < 0) {
        sprintf(str+strlen(str), "<no text>"); return;
    }
    str[0] = 0;
    for (i=w1; i<=w2; i++) {
        p = lw_array[i].lw_rawtext;
        if ((i>w1) && (strcmp(p, ",") != 0) && (strcmp(p, ":") != 0))
            sprintf(str+strlen(str), " ");
        l = strlen(p);
        if (l > STRING_TOLERANCE_LIMIT+5) {
            for (j=0; j<STRING_TOLERANCE_LIMIT/2; j++)
                sprintf(str+strlen(str), "%c", p[j]);
            sprintf(str+strlen(str), " [...] ");
            for (j=STRING_TOLERANCE_LIMIT/2; j>0; j--)
                sprintf(str+strlen(str), "%c", p[l-j]);
        } else {
            sprintf(str+strlen(str), "%s", p);
        }
    }
}
```

The function print_modest_sized_text_to_string is called from 2/prob1, 7/vasp, 9/vpbp and 12/phtd.

§**25. Printing raw word ranges.** Raw, in this context, means that it retains its original case, but not that it retains its original spacing. This is sometimes problematic: we need to go to some trouble to make punctuation look reasonably nice again, to obtain, say,

> The auctioneer said: "I'm not through yet -".

in preference to:

> The auctioneer said : "I'm not through yet -" .

Note that we are not actually preserving the spacing in the original source – that might have line breaks or other curiosities which we don't want: we are instead imposing what we think are normal English conventions. While this will sometimes be wrong, this is only likely to affect the index and problem messages, so the user is not likely to be bothered.

```
void print_raw_text_to_file(int w1, int w2, OUTPUT_STREAM) {
    int j;
    if ((w1 < 0) || (w1>w2)) { WRITE("?%d,%d?", w1, w2); return; }
    for (j=w1; j<=w2; j++) {
        char *p = lw_array[j].lw_rawtext;
        char *p2 = "";
        int sp = FALSE;
        if (j<w2) { sp = TRUE; p2 = lw_array[j+1].lw_rawtext; }
        print_literal_string_to_file(OUT, p);
        if (strcmp(p2, ":")==0) sp = FALSE;
        if (strcmp(p2, ",")==0) sp = FALSE;
```

```
        if (strcmp(p2, ")")==0) sp = FALSE;
        if (strcmp(p, "(")==0) sp = FALSE;
        if (sp) WRITE(" ");
    }
}
void print_raw_text_to_string(int w1, int w2, char *str) {
    int j;
    str[0] = 0;
    for (j=w1; j<=w2; j++) {
        char *p = lw_array[j].lw_rawtext;
        char *p2 = "";
        int sp = FALSE;
        if (j<w2) { sp = TRUE; p2 = lw_array[j+1].lw_rawtext; }
        sprintf(str+strlen(str), "%s", p);
        if (strcmp(p2, ":")==0) sp = FALSE;
        if (strcmp(p2, ",")==0) sp = FALSE;
        if (strcmp(p2, ")")==0) sp = FALSE;
        if (strcmp(p, "(")==0) sp = FALSE;
        if (sp) sprintf(str+strlen(str), " ");
    }
}
void print_raw_text_to_string_truncated(int w1, int w2, char *str, int max) {
    int j;
    str[0] = 0;
    for (j=w1; j<=w2; j++) {
        char *p = lw_array[j].lw_rawtext;
        char *p2 = "";
        int sp = FALSE;
        if (j<w2) { sp = TRUE; p2 = lw_array[j+1].lw_rawtext; }
        if (strlen(str) + strlen(p) + 2 > max) break;
        sprintf(str+strlen(str), "%s", p);
        if (strcmp(p2, ":")==0) sp = FALSE;
        if (strcmp(p2, ",")==0) sp = FALSE;
        if (strcmp(p2, ")")==0) sp = FALSE;
        if (strcmp(p, "(")==0) sp = FALSE;
        if (sp) sprintf(str+strlen(str), " ");
    }
}
```

The function print_raw_text_to_file is called from 2/index, 2/lexi, 4/ext, 4/edoc, 4/head, 5/rel, 5/aph, 5/litp, 7/kix, 9/qty, 9/scene, 9/prop, 9/pp, 9/cot, 9/inpw, 9/map, 9/tmap, 10/tab, 10/eqns, 10/fig, 10/sfx, 10/exf, 11/act, 11/nap, 12/phud, 12/phod, 12/phsf, 12/phin, 12/br, 12/rb, 13/gl and 13/test.
The function print_raw_text_to_string is called from 2/lexi, 4/ext, 4/iext, 4/edoc, 7/data, 8/creat, 9/map and 10/bib.
The function print_raw_text_to_string_truncated is called from 4/ext, 4/edict, 4/head, 12/br and 12/rb.

§**26.** And something similar, but formatted for use in I6 double-quoted text. In effect this is a further encoding again, but we only need it for this one routine. Here we don't care about punctuation spacing, because we are only writing in comments and I6 debugging routines, but we do need to use the I6 escape ~ for a double-quotation mark.

```
void print_raw_text_within_i6_literal(OUTPUT_STREAM, int w1, int w2) {
    int j, k;
    for (j=w1; j<=w2; j++) {
        char *str = lw_array[j].lw_rawtext;
        if (j>w1) WRITE(" ");
        for (k=0; str[k] != 0; k++) {
            char c = str[k];
            if (c == '"') c = '~';
            WRITE("%c", c);
        }
    }
}
```

The function print_raw_text_within_i6_literal is called from 4/ext, 5/aph, 12/phud, 12/br and 12/rb.

§**27. Printing word ranges to the debugging log.** The plain vanilla version of this routine is defended against malformed word ranges, since bugs can cause these to appear, and that is when we need the debugging log most.

```
void log_word_range(int w1, int w2) {
    if (w1 >= 0) {
        if (w2 < w1) w2 = w1;
        print_text_to_file(w1, w2, dl);
    }
}
```

The function log_word_range is called from 2/dl, 9/prop and 10/isin.

§**28.** Well, so this is useful because the form of breaks used between words is significant when parsing tables, which use tabs to divide columns.

```
void log_word_range_with_whitespace(int w1, int w2) {
    int i;
    if (w1<0) return;
    for (i=w1; i<=w2; i++) {
        char *del = "[sp]";
        if (lw_array[i].lw_break == '\n') del = "[cr]";
        if (lw_array[i].lw_break == '\t') del = "[tab]";
        if (isdigit(lw_array[i].lw_break)) del = "[cr+tab(s)]";
        LOG("%s%s", lw_array[i].lw_text, del);
        if (i<w2) LOG(" ");
    }
    LOG("\n");
}
```

The function log_word_range_with_whitespace is called from 2/dl.

§**29.** Not to be done lightly: the output can be enormous.

```
void log_lexer_output(void) {
    int i;
    LOG("Entire lexer output to date:\n");
    for (i=0; i<lexer_wordcount; i++) {
        LOG("%d: <%s> <%s> <%c>\n", i, lw_array[i].lw_text, lw_array[i].lw_rawtext, lw_array[i].lw_break);
    }
    LOG("------\n");
}
```

The function log_lexer_output is called from 3/read.

Vocabulary 3/vocab

Purpose

To classify the words in the lexical stream, where two different words are considered equivalent if they are unquoted and have the same text, taken case insensitively.

3/vocab.§10 Hash coding of words; §11-14 The hash table of vocabulary

---

Definitions

¶1. The following structure is created for each different word found in the source. (Recall that these are not necessarily words in the usual English sense: for instance, `17` is a word here.)

The vocabulary entry structure exists to make textual comparisons faster, which is essential to make NI run tolerably quickly: NI's speed on typical source texts increased by a factor of 5-10 when this structure was introduced. Firstly, the vocabulary is hashed so that it is not too painful to compare a newly-read word against the known vocabulary; secondly, each word stores linked lists of meanings which it begins, occurs in the middle of, ends, or is optionally part of (in the sense that "brown" is optionally part of the name "small brown shoe", which could also be written "small shoe"); and thirdly, each word also carries a bitmap of flags indicating the possible contexts in which it might be used. Finally, to avoid parsing the same text over and over for its possible meaning as a literal integer, we cache the result: for instance, 17 for the text `17`.

The meaning codes alluded to below are also used for excerpts of text (i.e., are not just for single words) and are defined in Excerpt Meanings.

```
typedef struct vocabulary_entry {
    int flags;                                        bitmap of "meaning codes" indicating possible usages
    int literal_number_value;                         evaluation as a literal number, if any
    char *exemplar;                                   text of one instance of this word
    char *raw_exemplar;                               text of one instance in its raw untreated form
    struct meaning_list *start_list;                  meanings starting with this
    struct meaning_list *end_list;                    meanings ending with this
    struct meaning_list *middle_list;                 meanings with this inside but at neither end
    struct meaning_list *subset_list;                 meanings allowing subsets which include this
    int subset_list_length;                           number of meanings in the subset list
    int hash;                                         hash code derived from text of word
    struct vocabulary_entry *next_in_vocab_hash;      next in list with this hash
    struct vocabulary_entry *lower_case_form;         or null if none exists
    struct vocabulary_entry *upper_case_form;         or null if none exists
} vocabulary_entry;
```

The structure vocabulary_entry is shared with 3/words, 5/em, 5/arch and 5/parse.

---

§**1.** Each distinct word is to have a unique `vocabulary_entry` structure, and the "identity" at word number `wn` is to point to the structure for the text at that word. Two words are distinct if their lower-case forms are different, except that two quoted literal texts are always distinct, even if they have the same content. So for instance,

Daleks conquer and destroy! "Ba-dum." Exterminate, exterminate! "Ba-dum."

would be identified as

```
ve0 ve1 ve2 ve3 ve4 ve5 ve6 ve6 ve4 ve7
```

where `ve4` is the common identity of both exclamation marks, and `ve6` that of the two "exterminate"s, even though they have different casings; while the quoted text `"Ba-dum."` came out with two different identities `ve5` and `ve7`.

When we want to set the identity for a given word, we call these front-door routines, either on a single word or on a range.

```
void vocab_identify_word(int wn) {
    lw_array[wn].lw_identity = vocab_entry_for_text(lw_array[wn].lw_text);
    lw_array[wn].lw_identity->raw_exemplar = lw_array[wn].lw_rawtext;
}
void vocab_identify_word_range(int w1, int w2) {
    int i;
    for (i=w1; i<=w2; i++) vocab_identify_word(i);
}
```

The function vocab_identify_word is called from 3/lex and 3/lexs.

The function vocab_identify_word_range is called from 3/lwb, 4/sent and 12/phsf.

§**2.** Should we ever change the text of a word, it's essential to re-identify it, as otherwise its `lw_identity` points to the wrong vocabulary entry.

```
void change_text_of_word(int wn, char *new) {
    lw_array[wn].lw_text = new;
    lw_array[wn].lw_rawtext = new;
    vocab_identify_word(wn);
}
```

The function change_text_of_word is called from 4/iext and 4/rtree.

§**3.** We now need some utilities for dealing with vocabulary entries. Here is a creator, and a debugging logger:

```
vocabulary_entry *vocab_entry_new(char *text, int hash_code, int flags, int val) {
    vocabulary_entry *ve;
    int l = strlen(text);
    ve = CREATE(vocabulary_entry);
    ve->exemplar = text; ve->raw_exemplar = text;
    ve->start_list = NULL; ve->end_list = NULL; ve->middle_list = NULL;
    ve->subset_list = NULL; ve->subset_list_length = 0;
    ve->next_in_vocab_hash = NULL;
    ve->lower_case_form = NULL; ve->upper_case_form = NULL;
    ve->hash = hash_code;
    ve->flags = flags;
    if ((l>3) && (text[l-3] == 'i') && (text[l-2] == 'n') && (text[l-1] == 'g'))
        ve->flags |= ING_MC;
    ve->literal_number_value = val;
    return ve;
}
void log_vocabulary_entry(vocabulary_entry *ve) {
    if (ve == NULL) { LOG("NULL"); return; }
    if (ve->exemplar == NULL) { LOG("NULL-EXEMPLAR"); return; }
    LOG("%08x-%s", ve->hash, ve->raw_exemplar);
}
```

The function log_vocabulary_entry is called from 2/dl.

§**4.** It's perhaps unexpected that a vocabulary entry not only stores a (pointer to) a copy of the text, the "exemplar" (since it is text which is an example of this vocabulary being used), but also a separate raw copy of the text: raw in the sense of retaining the original form in the source files which the word came from. This looks strange because we normally identify words on their case-lowered text, not on their raw text. In the source material:

> Former Marillion vocalist Fish derived his nickname not from a fish, but from habitual bathing.

words 4, "Fish", and 11, "fish", each have the same vocabulary entry as identity, even though their raw texts differ. Clearly the ordinary exemplar of this entry must be "fish". But what should the raw exemplar be, "Fish" or "fish"? The answer is the latter, or in general, the raw exemplar will always be the same as the exemplar; unless we have amended it by hand, using the following routine.

```
void vocab_set_raw_exemplar_to_text(int wn) {
    lw_array[wn].lw_identity->raw_exemplar = lw_array[wn].lw_text;
}
```

The function vocab_set_raw_exemplar_to_text is called from 3/lexs.

§**5.** Here are some access routines for the data stored in this structure:

```
char *vocab_get_exemplar(vocabulary_entry *ve, int raw) {
    if (raw) return ve->raw_exemplar;
    else return ve->exemplar;
}
```

The function vocab_get_exemplar is called from 2/lexi, 5/bp, 5/rel, 5/conj, 5/em, 7/tids, 7/data, 7/kix, 9/cmpbp, 9/vpbp, 9/model and 11/act.

§**6.** An integer is stored at each vocabulary entry, recording its value if it every turns out to parse as a literal number:

```
int vocab_get_literal_number_value(vocabulary_entry *ve) {
    return ve->literal_number_value;
}
void vocab_set_literal_number_value(vocabulary_entry *ve, int val) {
    ve->literal_number_value = val;
}
```

The function vocab_get_literal_number_value is called from 4/vm, 5/litp, 5/unitr, 5/lit, 5/candd, 8/refpt, 9/map and 10/isin.
The function vocab_set_literal_number_value is called from 5/lit and 7/tids.

§**7.** Almost all text is used case insensitively in Inform source, but we do occasionally need to distinguish "The" from "the" and the like, when parsing the names of text substitutions. When a new text substitution is declared whose first word, in the definition, begins with a capital letter, `vocab_make_case_sensitive` is called on the first word, and its identity is changed to the upper case variant form.

```
int vocab_used_case_sensitively(vocabulary_entry *ve) {
    if ((ve->upper_case_form) || (ve->lower_case_form)) return TRUE;
    return FALSE;
}
vocabulary_entry *vocab_get_lower_case_form(vocabulary_entry *ve) {
    return ve->lower_case_form;
}
vocabulary_entry *vocab_make_case_sensitive(vocabulary_entry *ve) {
    if (ve->upper_case_form) return ve->upper_case_form;
    ve->upper_case_form =
        vocab_entry_new(ve->exemplar, ve->hash, ve->flags, ve->literal_number_value);
    ve->upper_case_form->lower_case_form = ve;
    return ve->upper_case_form;
}
```

The function vocab_used_case_sensitively is called from 5/parse.
The function vocab_get_lower_case_form is called from 5/em.
The function vocab_make_case_sensitive is called from 5/em.

§**8.** Finally, each vocabulary entry comes with a bitmap of flags, and here we get to set and test them:

```
void vocab_set_flags(vocabulary_entry *ve, int t) {
    ve->flags |= t;
}
int vocab_test_flags(int wn, int t) {
    return (lw_array[wn].lw_identity->flags) & t;
}
```

The function vocab_set_flags is called from 5/conj, 7/tids and 7/dti.
The function vocab_test_flags is called from 2/isn, 2/java, 2/hdoc, 2/index, 3/lwb, 4/sent, 4/vm, 4/verb, 4/noun, 4/ofs, 5/conj, 5/aph, 5/litp, 5/unitr, 5/parse, 5/lit, 5/candd, 5/varc, 5/candp, 8/tass, 8/refpt, 8/creat, 8/mass, 9/wo, 9/model, 9/map, 10/tab, 10/eqns, 10/exf, 10/isin, 11/anl, 11/ap and 12/def.

§**9.** It can be useful to find the disjunction of the flags for all the words in a range, as that gives us a single bitmap which tells us quickly whether any of the words in that range is a number, or is a word ending in "-ing", and so on:

```
int vocab_disjunction_of_flags(int w1, int w2) {
    int i, d = 0;
    for (i=w1; i<=w2; i++) d |= (lw_array[i].lw_identity->flags);
    return d;
}
```

The function vocab_disjunction_of_flags is called from 11/ap.

§**10. Hash coding of words.** To find all the different words used in the source text, we need in principle to make an enormous number of comparisons of their texts. It is slow to make a correct identification of two texts as being equal: we have to compare their every characters against each other. Fortunately, it can be much faster to tell if they are different. We do this by rapidly deriving a number from their texts, and then comparing the numbers: if different, the texts were different.

The most obvious number would be the length of the text, but this produces too little variation, and too many false positives: "blue" and "cyan", for instance, would each produce the number 4.

Instead we use a standard method to derive a number traditionally called a "hash code". This is the algorithm called "X 30011" in Aho, Sethi and Ullman's standard reference *Compilers: Principles, Techniques and Tools* (1986). Because it is derived from constantly overflowing integer arithmetic, it will produce different codes on different architectures (say, where `int` is 64 bits long rather than 32, or where `char` is unsigned). All that matters is that it provides a good spread of hash codes for typical texts fed into it on any given occasion.

Good results depend on the number of possible codes being not too tiny compared to the number of different texts fed in, and also on the key value 30011 being coprime to this number (but 30011 is prime, so that's easily arranged). A typical source text of 50,000 words has an unquoted vocabulary of only about 2000 different words. The variation in vocabulary size between the smallest text source and the largest is only about a factor of three or four, so there is no need to make a dynamic estimate of the size of the source. We will always choose 997 as the number of possible hash codes produced by X 30011: we reserve a further three special codes to be the hashes of literals rather than ordinary words, and this brings us up to a round 1000.

Inside the lexer, decimal integers such as `-506` were treated as ordinary words, as there were no lexical difficulties in parsing them. Here they begin to semantically diverge from the way other ordinary words are handled: they're treated more like literal texts and I6 inclusions.

```
define HASH_TAB_SIZE 1000                    the possible hash codes are 0 up to this minus 1
define NUMBER_HASH 0                         literal decimal integers, and no other words, have this hash code
define TEXT_HASH 1                           double quoted texts, and no other words, have this hash code
define I6_HASH 2                             the (- word introducing an I6 inclusion uniquely has this hash code

int hash_code_from_word(char *text) {
    unsigned int hash_code = 0;
    char *p = text;
    switch(*p) {
        case '-': if (p[1] == 0) break;                    an isolated minus sign is an ordinary word
            and otherwise fall into...
        case '0': case '1': case '2': case '3': case '4':
        case '5': case '6': case '7': case '8': case '9':
            the first character may prove to be the start of a number: is this true?
            for (p++; *p; p++) if (isdigit(*p) == FALSE) goto Try_Text;
            return NUMBER_HASH;
        case ' ': return I6_HASH;
        case '(': if (p[1] == '-') return I6_HASH;
```

```
            break;
        case '"': return TEXT_HASH;
    }
    Try_Text:
    for (p=text; *p; p++) hash_code = hash_code*30011 + (*p);
    return (int) (3+(hash_code % (HASH_TAB_SIZE-3)));                    result of X 30011, plus 3
}
```

§**11. The hash table of vocabulary.** Armed with these hash codes, we now store the pointers to the vocabulary entry structures in linked lists, one for each possible hash code. These begin empty.

```
vocabulary_entry *list_of_vocab_with_hash[HASH_TAB_SIZE];
void vocab_start_hash_table(void) {
    int i;
    for (i=0; i<HASH_TAB_SIZE; i++) list_of_vocab_with_hash[i] = NULL;
}
```

The function vocab_start_hash_table is called from 3/lex.

§**12.** And that leaves only one routine: for finding the unique vocabulary entry pointer associated with the material in `text`. We search the hash table to see if we have the word already, and if not, we add it.

It is in order to set the initial values of the flags for the new word (if it does turn out to be new) that we mandated special hash codes for any number, any text, or any I6 inclusion.

```
int no_vocabulary_entries = 0;
vocabulary_entry *vocab_entry_for_text(char *text) {
    vocabulary_entry *new_entry;
    int hash_code = hash_code_from_word(text), f = 0, val = 0;
    switch(hash_code) {
        case NUMBER_HASH: f = NUMBER_MC; val = atoi(text); break;
        case TEXT_HASH:
            switch (well_formed_text_routine(text)) {
                case TRUE: f = TEXTWITHSUBS_MC; break;
                case FALSE: f = TEXT_MC; break;
                case NOT_APPLICABLE: f = TEXT_MC; break;
            }
            break;
        case I6_HASH: f = I6_MC; break;
        default:
            val = an_ordinal_number(text);
            if (val >= 0) f = NUMBER_MC;          so that "4th", say, picks up the NUMBER_MC flag
            break;
    }
    if (list_of_vocab_with_hash[hash_code] == NULL) {
        ⟨Pi-ty? That word is not in my vocabulary banks 13⟩;
    } else {
        vocabulary_entry *old_entry = NULL;
        int n;
        search the non-empty list of words with this hash code
        for (n=0, new_entry = list_of_vocab_with_hash[hash_code];
            new_entry != NULL;
            n++, old_entry = new_entry, new_entry = new_entry->next_in_vocab_hash)
            if (strcmp(new_entry->exemplar, text) == 0)
```

```
            return new_entry;
        and if we do not find text in there, then...
        ⟨My vision is impaired! I cannot see! 14⟩;
    }
}
```

The function vocab_entry_for_text is called from 3/words and 7/dti.

§**13.** (Cf. episode 6 of the Doctor Who serial *Genesis of the Daleks*, 1975.) Here the list for this word's hash code was empty, either meaning that this is a hash code never seen for any word before (in which case we start the list for that hash code with the new word), or that the word is a text literal – because, for efficiency's sake, we deliberately keep the hash list for all text literals empty.

⟨Pi-ty? That word is not in my vocabulary banks 13⟩ ≡

```
new_entry = vocab_entry_new(text, hash_code, f, val);
if (hash_code != TEXT_HASH) list_of_vocab_with_hash[hash_code] = new_entry;
LOGIF(VOCABULARY, "Word %d <%s> is first vocabulary with hash %d\n",
    no_vocabulary_entries++, text, hash_code);
return new_entry;
```

This code is used in §12.

§**14.** And here, we exhausted the list at entry `n-1`, with the last entry being pointed to by `old_entry`. We add the new word at the end.

⟨My vision is impaired! I cannot see! 14⟩ ≡

```
new_entry = vocab_entry_new(text, hash_code, f, val);
old_entry->next_in_vocab_hash = new_entry;
LOGIF(VOCABULARY, "Word %d <%s> is vocabulary entry no. %d with hash %d\n",
    no_vocabulary_entries++, text, n, hash_code);
return new_entry;
```

This code is used in §12.

Built-In Words 3/words

Purpose

To stock up NI's vocabulary with words which are needed in order to compare the source text against various syntaxes known to NI.

Template interpreter commands

```
1   {-callv:make_reserved_words}
```

Definitions

¶1. If we want to see if a given word in the source is "relation", we want to do so the quick way: by comparing the identities in the vocabulary bank, which involves only a single pointer comparison. All the words in the source have identities: but we have no idea what the pointer for "relation" would be. So when NI begins, it stocks its vocabulary banks by identifying texts of about 550 words it will at one time or another need to compare against. (Usually this is done in the double-square-bracket parsing extension syntaxes, where the `_V` suffixes are dropped).

```
vocabulary_entry *ASTERISK_V;

    eleven_V->flags = NUMBER_MC; eleven_V->literal_number_value = 11;
    twelve_V->flags = NUMBER_MC; twelve_V->literal_number_value = 12;

    not_V->flags = NOT_MC;

    in_V->flags = INORON_MC + PREPOSITION_MC;
    on_V->flags = INORON_MC + PREPOSITION_MC;

    which_V->flags = PREPOSITION_MC;
    who_V->flags = PREPOSITION_MC;
    that_V->flags = PREPOSITION_MC;

    a_V->flags = ARTICLE_MC;
    an_V->flags = ARTICLE_MC;
    the_V->flags = ARTICLE_MC;
    some_V->flags = ARTICLE_MC;
}
```

The function make_reserved_words is invoked by a command in a `.i6t` template file.

§**2.** That completes the assembly of the basic parsing tools we need for dealing with individual source words: we are finally ready to begin attacking the source text on the level of sentences and clauses.

4 Sentences and Extensions

`4/pn`: *Parse Tree.w* To construct a single parse tree with excerpts of text, and in some cases also annotations, at each node.

`4/sent`: *Sentences.w* To break up the stream of words produced by the lexer into English sentences, and join each to the parse tree.

`4/ext`: *Extension Files.w* To keep details of the extensions currently loaded, their authors, titles, versions and rubrics, and to index and credit them suitably.

`4/iext`: *Including Extensions.w* To fulfill requests to include extensions, adding their material to the parse tree as needed, and removing INCLUDE nodes.

`4/eid`: *Extension Identifiers.w* To store, hash code and compare title/author pairs used to identify extensions which, though installed, are not necessarily used in the present source text.

`4/excen`: *Extension Census.w* To conduct a census of all the extensions installed (whether used on this run or not), and keep the documentation index for them up to date.

`4/edict`: *Extension Dictionary.w* To maintain a database of names and constructions in all extensions so far used by this installation of Inform, and spot potential namespace clashes.

`4/edoc`: *Extension Documentation.w* To generate HTML documentation for extensions.

`4/vm`: *Virtual Machines.w* I7 supports a variety of virtual machines as targets. Most source text should be independent of the target VM, but sometimes numbering is needed, and this is where any VM dependencies are decided.

`4/head`: *Headings.w* To keep track of the hierarchy of headings and subheadings found in the source text.

`4/verb`: *Verb Phrases.w* To construct verb-phrase nodes in the parse tree.

`4/noun`: *Noun Phrases.w* To construct noun-phrase subtrees for assertion sentences found in the parse tree.

`4/ofs`: *Of and From.w* To verify that "of" and "from" subtrees in assertion sentence noun phrases are validly used, and reconstruct their sentences without them if they are not.

`4/rtree`: *Rule Subtrees.w* To tidy up `COMMAND_NT` nodes into a list of children under the relevant `ROUTINE_NT` node, and so turn each rule definition into a single subtree.

`4/verif`: *Verify Parse Tree.w* To check that the parse tree has been correctly constructed, in hopes of detecting bugs in the program: this check should never fail.

Parse Tree 4/pn

Purpose

To construct a single parse tree with excerpts of text, and in some cases also annotations, at each node.

Template interpreter commands

```
14  {-callv:plant_parse_tree}
```

Definitions

¶1. Most algorithms for parsing natural language involve the construction of trees, in which the original words appear as leaves at the top of the tree, while the grammatical functions they serve appear as the branches and trunk: thus the word "orange", as an adjective, might be growing from a branch which represents a noun clause ("the orange envelope"), growing in turn from a trunk which in turn might represent a assertion sentence:

> The card is in the orange envelope.

NI is no exception, though nodes seldom go down to the level of individual words. As we shall see, the entire source text is converted to a single but fairly "lightweight" parse tree, containing just enough structure to enable us to see which more sophisticated parsing techniques should be used. The parse tree is more of a navigational aid on the journey to meaning than the destination itself.

Though the parse tree is never going to tell the whole story, its nodes are nonetheless gradually annotated with richer and richer semantic information as NI proceeds. In the above example, for instance, the two noun phrases are both marked as having the definite article, and this has subsumed the usage of the word "the" twice in the original text: neither "the" remains in the parse tree. (Nor does the punctuation, nor the word "is".)

¶2. Node types. Each node in the parse tree has a type, which must be one of the following. The numbers have no significance except that they are all different, and that they must correspond exactly with the sequence of entries in the constant array defined when we verify the parse tree.

```
define ROOT_NT 1                          Only one such node exists: the tree root
define BIBLIOGRAPHIC_NT 2                 For the initial title sentence
define HEADING_NT 3                       "Chapter VIII: Never Turn Your Back On A Shreve"
define INCLUDE_NT 4                       "Include School Rules by Argus Filch"
define BEGINHERE_NT 5                     "The Standard Rules begin here"
define ENDHERE_NT 6                       "The Standard Rules end here"
define SENTENCE_NT 7                      "The Garden is a room"
define ROUTINE_NT 8                       "Instead of taking something, ..."
define INFORM6CODE_NT 9                   "Include (- ... -)
define TABLE_NT 10                        "Table 1 - Counties of England"
define EQUATION_NT 11                     "Equation 2 - Newton's Second Law"
define TRACE_NT 12                        A sentence consisting of a single asterisk, perhaps followed by quoted text
define RELATIONSHIP_NT 13                 "on"
define CALLED_NT 14                       "On the table is a container called the box"
define WITH_NT 15                         "The footstool is a supporter with capacity 2"
```

```
define AND_NT 16                    "whisky and soda"
define KIND_NT 17                   "A woman is a kind of person"
define X_OF_Y_NT 18                 "description of the painting"
define VERB_NT 19                   "is"
define CREATED_NT 20                "a vehicle called Sarah Jane's car"
define NOUNPHRASE_NT 21             "the red handkerchief"
define PROPERTYLIST_NT 22           "capacity 2"
define FROM_NT 23                   "East from the Garden is the Grove"
define COMMAND_NT 24                "change the Marble Door to open"
define ALLOWED_NT 25                "An animal is allowed to have a description"
define EVERY_NT 26                  "every container"
define INSTANCE_NT 27               "a container"
define VALUE_NT 28                  "102"
define ACTION_NT 29                 "taking something closed"
define ADJECTIVE_NT 30              "open"
define PROPERTYNOUN_NT 31           "score for finding"
define PROPERTYCALLED_NT 32         "A man has a number called age"
define TOKEN_NT 33                  Used for tokens in grammar
define HIGHEST_NODE_TYPE 34         Well, actually the highest plus 1
```

¶3. The parse node structure. This is implemented as a basic framework structure to which any number of annotations can be attached, but such that an unannotated node occupies a reasonably small amount of memory. The number of PNs created is typically of the same order as the number of words in the original source text: so perhaps 100,000 for a large work. Since PNs have a `sizeof` of about 36 on a 32-bit CPU, this keeps the storage for the main structural tree down to about 3MB for a large work, which doesn't seem worth reducing.

```
typedef struct parse_node {
    int node_type;                                  One of the list above
    int word_ref1, word_ref2;                       The text
    struct parse_node_annotation *annotations;      Linked list: see below
    struct parse_node *down;                        Pointers to navigate the tree structure
    struct parse_node *next;
    MEMORY_MANAGEMENT
} parse_node;
```

The structure parse_node is private to this section.

¶4. The parse tree annotations are miscellaneous, and many are needed only at a few unusual nodes. Rather than have the structure grow large, we store annotations in the following:

```
typedef struct parse_node_annotation {
    int kind_of_annotation;
    int annotation_integer;
    general_pointer annotation_pointer;
    struct parse_node_annotation *next_annotation;
} parse_node_annotation;
```

The structure parse_node_annotation is private to this section.

¶5. The annotations used are identified by ID numbers, as follows:

define implicit_in_creation_of_ANNOT 1 — world_object: *for assemblies*
define implicitness_count_ANNOT 2 — *int: keeping track of recursive assemblies*
define relationship_ANNOT 3 — binary_predicate: *for RELATIONSHIP nodes*
define property_ANNOT 4 — property_name: *for names of properties*
define resolved_ANNOT 5 — *int: temp storage when resolving NPs*
define full_phrase_evaluation_ANNOT 6 — specification: *temp storage when resolving NPs*
define negated_boolean_ANNOT 7 — *int: set if adjective meant negatively*
define verbal_certainty_ANNOT 8 — *int: a certainty level attached to a sentence*
define slash_class_ANNOT 9 — *int: used when partitioning grammar tokens*
define table_cell_unspecified_ANNOT 10 — *int: used to mark table entries as unset*
define grammar_token_code_ANNOT 11 — *int: used to identify grammar tokens*
define plural_reference_ANNOT 12 — *int: used by NOUNPHRASE nodes for evident plurals*
define heading_level_ANNOT 13 — *int: for HEADING nodes, a hierarchical level, 0 (highest) to 9 (lowest)*
define grammar_token_literal_ANNOT 14 — *int: for grammar tokens which are literal words*
define nounphrase_article_ANNOT 15 — *int: definite or indefinite article: see below*
define sentence_unparsed_ANNOT 16 — *int: set if verbs haven't been sought yet here*
define verb_id_ANNOT 17 — *int: identifying what kind of VERB node*
define relationship_node_type_ANNOT 18 — *int: what kind of inference this assertion makes*
define I6_routine_wn_ANNOT 19 — *int: word number for literal I6 routine name*
define evaluation_ANNOT 20 — specification: *result of evaluating the text*
define refers_to_ANNOT 21 — world_object: *specific object or kind referred to*
define creation_modifier_ANNOT 22 — *int: bitmap of modifiers for kind of value*
define grammar_token_relation_ANNOT 23 — binary_predicate: *for relation tokens*
define table_cell_allocated_ANNOT 24 — *int: table entry already correctly allocated*
define nounphrase_multiplicity_ANNOT 25 — *int: multiplicity of bare number determiner*
define interpretation_of_subject_ANNOT 26 — world_object: *subject, during passes*
define category_of_I6_translation_ANNOT 27 — *int: what sort of "translates into I6" sentence this is*
define suppress_heading_dependencies_ANNOT 28 — *int: ignore extension dependencies on this heading node*
define row_amendable_ANNOT 29 — *int: a candidate row for a table amendment*
define colon_block_command_ANNOT 30 — *int: this COMMAND uses the ":" not begin/end syntax*
define suppress_debug_text_ANNOT 31 — *int: don't print the RULES ALL text for this phrase*
define aph_ANNOT 32 — adjectival_phrase: *which adjective is asserted*
define creation_proposition_ANNOT 33 — pcalc_prop: *proposition which newly created value satisfies*

¶6. A few of the more popular annotations are worth documenting here. First, NOUNPHRASE nodes use the article annotation to record the article used:

define DEF_ART 1 — *the definite article*
define INDEF_ART 2 — *the indefinite article*
define NO_ART 3 — *no article supplied*
define IT_ART 4 — *a special case to handle "it"*

¶7. Second, RELATIONSHIP nodes, which indicate a (usually spatial) relationship, are annotated with a choice of inference type to indicate the particular relationship which seems to be intended: PARTOF_INF, for instance. Such constants are declared in Inferences.

In similar vein, VERB nodes are annotated with a verb type constant, and these are defined in Verb Phrases.

¶8. Where we currently are in the text. NI makes many traverses through the parse tree, often modifying as it goes, and keeps track of its position so that it can make any problem messages correctly refer to the location of the faulty text in the original source files.

During such traverses, `current_sentence` is always the subtree being looked at: it is always a child of the tree root, and is usually a `SENTENCE_NT` node, hence the name.

During the main assertion traverses, we also keep track of whether we are near the start of an extension file or not. (If we are, then a lone string of text is interpreted as the rubric of the extension – an exception to Inform's normal rules.)

```
parse_node *tree_root = NULL;
parse_node *current_sentence = NULL;
int near_start_of_extension = 0;
```

¶9. Two macros are frequently used in NI in order to abstract and abbreviate the traversal process. For instance, we might write:

```
for (TREE_START(p); p; TREE_NEXT(p))
```

and this is expanded using the following macro definitions:

```
define TREE_START(p) p=tree_root->down,current_sentence=p
define TREE_NEXT(p) p=p->next,current_sentence=p
```

---

§**1.** The following routine creates a new parse node. (Here, as for many other NI structures, there is no garbage collection: if we allocate one, and then forget the pointer, it is lost forever and the memory is wasted. This only seldom happens in NI and we are not in pressing need of memory. But we should bear it in mind before coding something which only speculatively grabs new structures.)

```
parse_node *new_node(int type) {
    parse_node *PN = CREATE(parse_node);
    PN->node_type = type;
    PN->word_ref1 = -1; PN->word_ref2 = -1;
    PN->down = NULL; PN->next = NULL;
    PN->annotations = NULL;
    return PN;
}
```

The function new_node is called from 4/sent, 4/verb, 4/noun, 4/rtree, 8/refpt, 8/creat, 8/mass, 8/assem and 9/wo.

§**2.** It's easily overlooked that the single most useful piece of information at each node is its node type, accessed as follows:

```
int pn_get_node_type(parse_node *pn) { return pn->node_type; }
void pn_set_node_type(parse_node *pn, int nt) { pn->node_type = nt; }
```

The function pn_get_node_type is called from 2/prob2, 2/prob3, 3/lwb, 4/iext, 4/head, 4/verb, 4/ofs, 4/rtree, 4/verif, 6/treec, 8/tass, 8/refpt, 8/creat, 8/mass, 8/assem, 8/knowc, 8/knowp, 8/relv, 8/imp, 9/pp, 9/model, 9/map, 10/tab, 10/eqns, 11/act, 11/av, 12/cs, 12/ph, 12/cph, 12/def, 12/rb, 13/tfg and 13/gl.
The function pn_set_node_type is called from 4/sent, 4/noun, 4/ofs, 4/verif, 8/refpt, 8/creat, 8/mass, 8/assem, 8/relv, 9/pp, 10/tab and 13/gtok.

§**3. Annotations.** A blank annotation is like a blank luggage ticket, waiting to be filled out and attached to some suitcase:

```
parse_node_annotation *pna_new(int koa) {
    parse_node_annotation *pna = CREATE(parse_node_annotation);
    pna->kind_of_annotation = koa;
    pna->annotation_integer = 0;
    pna->annotation_pointer = NULL_GENERAL_POINTER;
    pna->next_annotation = NULL;
    return pna;
}
```

§**4.** Annotations are identified by an enumerated range of constants (KOA here stands for "kind of annotation"). Each node is permitted an arbitrary selection of these, storing them as a linked list: it will always be short (worst case about 5), so there is no need for a more efficient algorithm to search this list.

```
int pn_has_annotation(parse_node *PN, int koa) {
    parse_node_annotation *pna;
    for (pna=PN->annotations; pna; pna=pna->next_annotation)
        if (pna->kind_of_annotation == koa)
            return TRUE;
    return FALSE;
}
```

The function pn_has_annotation is called from 8/sob and 8/creat.

§**5.** Reading annotations is similar. We need two variant forms: one for reading integer-valued annotations (which is most of them, as it happens) and the other for reading pointers to structures.

```
int pn_int_annotation(parse_node *PN, int koa) {
    parse_node_annotation *pna;
    for (pna=PN->annotations; pna; pna=pna->next_annotation)
        if (pna->kind_of_annotation == koa)
            return pna->annotation_integer;
    return 0;
}
general_pointer pn_pointer_annotation(parse_node *PN, int koa) {
    parse_node_annotation *pna;
    for (pna=PN->annotations; pna; pna=pna->next_annotation)
        if (pna->kind_of_annotation == koa)
            return pna->annotation_pointer;
    return NULL_GENERAL_POINTER;
}
```

The function pn_int_annotation is called from 2/isn, 2/prob2, 3/lwb, 4/head, 4/verb, 4/ofs, 4/rtree, 6/treec, 8/tass, 8/refpt, 8/creat, 8/mass, 8/assem, 8/relv, 8/imp, 9/scene, 9/model, 9/map, 10/tab, 12/cs, 12/cph, 13/tfg, 13/gl and 13/gtok.

§**6.** Integer-valued annotations are set with the following routine. Note that any second or subsequent annotation with the same KOA as an existing one overwrites it.

```
void pn_annotate_int(parse_node *PN, int koa, int v) {
    parse_node_annotation *newpna, *pna, *final = NULL;
    for (pna=PN->annotations; pna; pna=pna->next_annotation) {
        if (pna->kind_of_annotation == koa) {
            an annotation with this KOA exists already: overwrite it
            pna->annotation_integer = v;
            return;
        }
        if (pna->next_annotation == NULL) final = pna;
    }
    no annotation with this KOA exists: create a new one and add to end of node's list
    newpna = pna_new(koa); newpna->annotation_integer = v;
    if (final) final->next_annotation = newpna; else PN->annotations = newpna;
}
```

The function pn_annotate_int is called from 2/isn, 4/sent, 4/head, 4/verb, 4/noun, 4/ofs, 4/rtree, 8/refpt, 8/mass, 8/assem, 10/tab, 12/cs, 13/gl and 13/gtok.

§**7.** Again, almost identical code handles the case of pointer-valued annotations:

```
void pn_annotate_pointer(parse_node *PN, int koa, general_pointer data) {
    parse_node_annotation *newpna, *pna, *final = NULL;
    for (pna=PN->annotations; pna; pna=pna->next_annotation) {
        if (pna->kind_of_annotation == koa) {
            an annotation with this KOA exists already: overwrite it
            pna->annotation_pointer = data;
            return;
        }
        if (pna->next_annotation == NULL) final = pna;
    }
    no annotation with this KOA exists: create a new one and add to end of node's list
    newpna = pna_new(koa); newpna->annotation_pointer = data;
    if (final) final->next_annotation = newpna; else PN->annotations = newpna;
}
```

§**8.** It turns out to be convenient to access annotations with standard-form get and set functions, for pointers, to avoid difficulties with null pointers (which would throw run-time errors as being invalid if the store and retrieve routines were allowed to work on them). It's also less verbose.

```
define MAKE_ANNOTATION_FUNCTIONS(annotation_name, pointer_type)
void pn_set_##annotation_name(parse_node *pn, pointer_type *bp) {
    pn_annotate_pointer(pn, annotation_name##_ANNOT,
        STORE_POINTER_##pointer_type(bp));
}
pointer_type *pn_get_##annotation_name(parse_node *pn) {
    pointer_type *pt = NULL;
    if (pn_has_annotation(pn, annotation_name##_ANNOT))
        pt = RETRIEVE_POINTER_##pointer_type(
            pn_pointer_annotation(pn, annotation_name##_ANNOT));
    return pt;
}
```

§**9.** So we itemise the pointer-valued annotations below, and the macro expands to provide their get and set functions:

```
MAKE_ANNOTATION_FUNCTIONS(evaluation, specification)
MAKE_ANNOTATION_FUNCTIONS(full_phrase_evaluation, specification)
MAKE_ANNOTATION_FUNCTIONS(property, property_name)
MAKE_ANNOTATION_FUNCTIONS(relationship, binary_predicate)
MAKE_ANNOTATION_FUNCTIONS(refers_to, world_object)
MAKE_ANNOTATION_FUNCTIONS(grammar_token_relation, binary_predicate)
MAKE_ANNOTATION_FUNCTIONS(interpretation_of_subject, world_object)
MAKE_ANNOTATION_FUNCTIONS(implicit_in_creation_of, world_object)
MAKE_ANNOTATION_FUNCTIONS(aph, adjectival_phrase)
MAKE_ANNOTATION_FUNCTIONS(creation_proposition, pcalc_prop)
```

§**10. Copying parse nodes.** If we want to duplicate a parse node, we cannot do so with a shallow bit copy: the node points to a list of its annotations, and the duplicated node would therefore point to the same list. If, subsequently, one of the two nodes were annotated further, then the other would change in synchrony, which would be the source of mysterious bugs. We therefore need to perform a deep copy which duplicates not only the node, but also its annotation list.

```
void pn_copy(parse_node *to, parse_node *from) {
    parse_node_annotation *pna, *latest = NULL;
    *to = *from;
    to->annotations = NULL;
    for (pna=from->annotations; pna; pna=pna->next_annotation) {
        parse_node_annotation *pna_copy = CREATE(parse_node_annotation);
        *pna_copy = *pna; pna_copy->next_annotation = NULL;
        if (to->annotations == NULL) to->annotations = pna_copy;
        else latest->next_annotation = pna_copy;
        latest = pna_copy;
    }
}
```

The function pn_copy is called from 8/refpt, 8/creat and 8/assem.

§**11. Detection of subnodes.** This is needed when producing problem messages: we may need to work up from an arbitrary leaf to the main sentence branch containing it. At any rate, given a node `PN`, we want to know if another node `to_find` lies beneath it. (This will never be called when `PN` is the root, and from all other nodes it will certainly run quickly, since the tree is otherwise neither wide nor deep.)

```
int pn_contains(parse_node *PN, parse_node *to_find) {
    parse_node *to_try;
    if (PN == to_find) return TRUE;
    for (to_try = PN->down; to_try; to_try = to_try->next)
        if (pn_contains(to_try, to_find))
            return TRUE;
    return FALSE;
}
```

The function pn_contains is called from 2/prob2.

§**12. The word range beneath a given node.** Any given node may be the root of a subtree concerning the structure of a given contiguous range of words in the original source text. The "left edge" of a node `PN` is the least-numbered word considered by any node at or below `PN` in the tree; the "right edge" is the highest-numbered word similarly considered.

The left edge is calculated by taking the minimum value of the `word_ref1` for `PN` and the left edges of its children, except that -1 is not counted. (A left edge of -1 means no source text is here.)

```
int left_edge_of(parse_node *PN) {
    parse_node *child;
    int l = PN->word_ref1, lc;
    for (child = PN->down; child; child = child->next) {
        lc = left_edge_of(child);
        if ((lc >= 0) && ((l == -1) || (lc < l))) l = lc;
    }
    return l;
}
```

The function left_edge_of is called from 8/mass.

§**13.** Symmetrically, the right edge is found by taking the maximum of `word_ref2` for `PN` and the right edges of its children.

```
int right_edge_of(parse_node *PN) {
    parse_node *child;
    int r = PN->word_ref2, rc;
    if (PN->word_ref1 < 0) r = -1;
    for (child = PN->down; child; child = child->next) {
        rc = right_edge_of(child);
        if ((rc >= 0) && ((r == -1) || (rc > r))) r = rc;
    }
    return r;
}
```

The function right_edge_of is called from 8/mass.

§**14. Planting and grafting the tree.** Further horticultural metaphors follow: this is where we plant the tree, and graft new branches onto it.

```
void plant_parse_tree(void) {
    tree_root = new_node(ROOT_NT);
}
```

The function plant_parse_tree is invoked by a command in a `.i6t` template file.

§**15.** Every node in the tree is indirectly a child of the root node, which is stored in `tree_root`. The tree tends to be very wide: since each sentence in the original source text is a different child of the root, the root may have 5000 or so children, though the maximum depth of the tree might be only 10.

That means that perpetually scanning through them in order to add another one on the end is inefficient: so we cache the "last sentence" in the tree, meaning, the youngest child of root. (But we must only do this when we are not also performing surgery on the tree at the same time, which is why it is not always allowed.)

```
parse_node *youngest_child_of_root = NULL;                    youngest child of tree root
int allow_last_sentence_cacheing = FALSE;

void enable_last_sentence_cacheing(void) {
    youngest_child_of_root = NULL;                    because this may have changed since last enabled
    allow_last_sentence_cacheing = TRUE;
}

void disable_last_sentence_cacheing(void) {
    allow_last_sentence_cacheing = FALSE;
}
```

The function enable_last_sentence_cacheing is called from 4/sent.
The function disable_last_sentence_cacheing is called from 4/sent.

§**16.** This is where metaphors become mixed. The routine below is called `graft` by analogy with gardening, where the rootstock of one plant is joined to a scion (or cutting) of another, so that a root chosen for strength can be combined with the fruits or blossom of the scion. This is fairly apt for the process of joining one subtree onto a node of another. But since gardening lacks words to describe branches as being eldest or youngest, and so on, for the actual body of the routine we talk about family trees instead.

`graft` returns the node for which `newborn` is the immediate sibling, that is, it returns the previously youngest child of the `parent` (or `NULL` if it previously had no children).

```
parse_node *graft(parse_node *newborn, parse_node *parent) {
    parse_node *elder = NULL;
    if (newborn == NULL) internal_error("newborn is null in tree graft");
    if (parent == NULL) internal_error("parent is null in tree graft");
    is the new node to be the only child of the old?
    if (parent->down == NULL) { parent->down = newborn; return NULL; }
    can last sentence cacheing save us a long search through many children of root?
    if ((parent == tree_root) && (allow_last_sentence_cacheing)) {
        if (youngest_child_of_root) {
            elder = youngest_child_of_root;
            elder->next = newborn;
            youngest_child_of_root = newborn;
            return elder;
        }
        we don't know who's the youngest child now, but we know who soon will be:
        youngest_child_of_root = newborn;
    }
    find youngest child of attach node...
    for (elder = parent->down; elder->next; elder = elder->next) ;
    ...and make the new node its younger sibling
    elder->next = newborn; return elder;
}
```

The function graft is called from 4/sent, 4/iext, 4/verb, 9/pp, 9/model, 10/tab and 13/gtok.

§**17. Logging the parse tree.** For most trees, logging is a fearsome prospect, but here we only mean printing out a textual representation to the debugging log.

We usually want to log recursive pictures of the tree, but not always.

```
void log_single_parse_node_at_current_margin(parse_node *p) {
    log_single_node(p, 1);
}
void log_parse_node_at_current_margin(parse_node *p) {
    log_subtree(p, 1);
}
```

The function log_single_parse_node_at_current_margin is called from 2/dl.
The function log_parse_node_at_current_margin is called from 2/dl.

§**18.** The recursive logger covers the subtree from the current node down, but does not include the siblings of the current node. (If it did, logging any sentence node would produce humungous output, as the sentences are typically among thousands of siblings as children of the root.)

```
void log_subtree(parse_node *p, int indentation) {
    if (p == NULL) { LOG("<null-parse-node>"); return; }
    log_single_node(p, indentation);
    if (p->down) { log_subtree_recursively(p->down, indentation+1); }
}
void log_subtree_recursively(parse_node *p, int indentation) {
    if (p == NULL) { LOG("<null-parse-node>"); return; }
    log_single_node(p, indentation);
    if (p->down) { log_subtree_recursively(p->down, indentation+1); }
    if (p->next) { log_subtree_recursively(p->next, indentation); }
}
```

The function log_subtree is called from 2/prob0, 2/prob3, 4/verif, 8/tass, 8/refpt, 8/mass, 8/assem, 8/knowp and 13/gtok.

§**19.** All of those routines make use of the following, which actually performs the log of a parse node. Note that this always produces exactly one line of text in the debugging log, indented as requested.

```
void log_single_node(parse_node *p, int indentation) {
    int t;
    while (indentation-- > 0) LOG("    ");
    if (p == NULL) { LOG("<null-parse-node>"); return; }
    t = p->node_type;
    if ((t<1) || (t>HIGHEST_NODE_TYPE)) { LOG("<node with bad type %d>\n", t); return; }
    LOG("node:$N ", t);
    if (p->word_ref1 >= 0) {
        int w1 = p->word_ref1, w2 = p->word_ref2;
        if (w2 < 0) w2 = w1;
        LOG(" <$W>", w1, w2);
    }
    ⟨Log annotations of parse tree nodes, depending on the node type 20⟩;
    LOG("\n");
}
```

§**20.** We do not log every annotation: only the few which are most illuminating.

⟨Log annotations of parse tree nodes, depending on the node type 20⟩ ≡

```
int show_eval = FALSE, show_prop = FALSE, show_refers = FALSE;
switch(t) {
    case ADJECTIVE_NT: show_prop = TRUE; show_eval = TRUE; break;
    case HEADING_NT: LOG(" (level %d)", pn_int_annotation(p, heading_level_ANNOT)); break;
    case INSTANCE_NT: show_refers = TRUE; show_eval = TRUE; break;
    case KIND_NT: show_refers = TRUE; break;
    case RELATIONSHIP_NT: LOG(" (type:");
        switch (pn_int_annotation(p, relationship_node_type_ANNOT)) {
            case STANDARD_RELN: LOG("standard"); break;
            case PARENTAGE_HERE_RELN: LOG("here"); break;
            case DIRECTION_RELN: LOG("direction"); break;
        }
        LOG(")"); break;
    case NOUNPHRASE_NT:
        switch (pn_int_annotation(p, nounphrase_article_ANNOT)) {
            case NO_ART: LOG(" (no article)"); break;
            case IT_ART: LOG(" (pronoun)"); break;
            case DEF_ART: LOG(" (definite)"); break;
            case INDEF_ART: LOG(" (indefinite)"); break;
        }
        if (pn_int_annotation(p, plural_reference_ANNOT)) LOG(" (plural)");
        if (pn_int_annotation(p, nounphrase_multiplicity_ANNOT))
            LOG(" (multiplicity %d)", pn_int_annotation(p, nounphrase_multiplicity_ANNOT));
        show_refers = TRUE;
        break;
    case PROPERTYNOUN_NT: show_prop = TRUE; break;
    case VALUE_NT: show_eval = TRUE; break;
    case VERB_NT: LOG(" ($V)", pn_int_annotation(p, verb_id_ANNOT)); break;
    case TOKEN_NT: LOG(" [%d]", pn_int_annotation(p, slash_class_ANNOT)); break;
}
if ((show_refers) && (pn_get_refers_to(p))) LOG(" refers:$O", pn_get_refers_to(p));
if ((show_eval) && (pn_get_evaluation(p))) {
    LOG(" evaluation:$S", pn_get_evaluation(p));
    if (pn_int_annotation(p, creation_modifier_ANNOT) != 0)
        LOG(" (modifier %d)", pn_int_annotation(p, creation_modifier_ANNOT));
    if (pn_get_creation_proposition(p))
        LOG(" (subject to $D)", pn_get_creation_proposition(p));
}
```

This code is used in §19.

§**21. The asterisked tree.** The entire parse tree is a bewilderingly large object to take in at a glance, so NI contains a secret debugging feature: a sentence consisting of a single asterisk only switches tracing on and off. Thus, any text in between two asterisk sentences will be watched in the debugging log: the "asterisked tree" is the subset of the tree which fell between asterisks in this way. For instance:

The Court is a room. *. The Judge is a man in the Court. *.

Here a single sentence is watched: the one about the Judge.

```
void log_asterisked_parts_of_parse_tree(char *desc) {
    parse_node *p; int asterisked = FALSE;
    if (dl_this(ASTERISKED_SYNTAX_DA) == FALSE) return;
    LOG("\n%s (asterisked areas only):\n", desc);
    for (TREE_START(p); p; TREE_NEXT(p))
        if (p->node_type == TRACE_NT) asterisked = 1-asterisked;
        else if (asterisked) log_subtree(p, 1);
}
```

The function log_asterisked_parts_of_parse_tree is called from 8/tass.

Sentences 4/sent

Purpose

To break up the stream of words produced by the lexer into English sentences, and join each to the parse tree.

4/sent.§2-10 Sentence breaking; §11-17 Making sentence nodes; §18-19 Begins and ends here; §20-32 Unskipped material which is not a heading

---

Template interpreter commands

```
{-callv:declare_source_loaded}
{-callv:break_source_into_sentences}
```

---

§**1.** Sentence division can happen either early in NI's run, when the vast bulk of the source text is read, or at intermittent periods later when fresh text is generated internally. New sentences need to be treated slightly differently in these cases, so this seems as good a point as any to define the routine which the `.i6t` interpreter calls when it wants to signal that the source text has now officially been read.

```
void declare_source_loaded(void) {
    text_loaded_from_source = TRUE;
}
```

The function declare_source_loaded is invoked by a command in a `.i6t` template file.

§**2. Sentence breaking.** The `break_into_sentences` routine is used for long stretches of text, normally entire files. The following provides a way for the `.i6t` interpreter to apply it to the whole text as lexed, which provides the original basis for parsing. (This won't be the entire source text, though: extensions, including the Standard Rules, have yet to be read.)

```
void break_source_into_sentences(void) {
    break_into_sentences(0, lexer_wordcount-1, NULL);
}
```

The function break_source_into_sentences is invoked by a command in a `.i6t` template file.

§**3.** What breaks a sentence? In ordinary English, question marks, exclamation marks, in some cases ellipses, but mainly full stops. In Inform source text, only full stops are used outside quoted text; but we do have to recognise the other cases when they occur at the end of quoted matter. Moreover, we actually subdivide a little further, because we also want to break up rule "sentences" into their subordinate clauses. Thus, going on punctuation, we recognise rules as having the following model:

Preamble: phrase 1; phrase 2; ...; phrase N.

It is even, in certain limited circumstances, possible that a comma can divide a sentence:

Instead of eating, say "You really aren't hungry just now."

This means that context is important even here, where it might have been expected that all we needed to do was to spot the punctuation marks. So we carry out the sentence breaking with a simple finite state machine – the last sentence having been a rule preamble tells us that the current one is probably a phrase, and so on – and the following is its state.

```
source_file *sfsm_source_file = NULL;
int sfsm_inside_rule_mode = FALSE;
int sfsm_skipping_material_at_level = -1;
int sfsm_in_table_mode = FALSE;
extension_file *sfsm_extension = NULL;
int sfsm_extension_position = 0;    0: not an extension; 1: before "begins here"; 2: before "ends here"; 3: after
```

§**4.** Now for the routine itself. `w1` is the first word the lexer read, `w2` is the last. We break into bite-sized chunks, each of which is despatched to the `make_sentence_node` routine with a note of the punctuation which was used to end it. Each call to this routine represents one cycle of our finite state machine.

```
void break_into_sentences(int w1, int w2, extension_file *from_extension) {
    int position, sentence_start = w1;
    enable_last_sentence_cacheing();
    ⟨Reset the sentence finite state machine 5⟩;
    ⟨Go into table sentence mode if necessary 6⟩;
    for (position=w1; position<=w2; position++)
        if (sentence_start < position) {
            int no_stop_words, back_up_one_word;
            char stop_character;
            ⟨Look for a sentence break, finding the number of stop words and the stop character 8⟩;
            if (no_stop_words > 0) {
                make_sentence_node(sentence_start, position-1, stop_character);
                position = position + no_stop_words - 1;
                if (back_up_one_word) sentence_start = position;
                else sentence_start = position + 1;
                ⟨Go into table sentence mode if necessary 6⟩;
            }
        }
    if ((sentence_start < w2) ||
        ((sentence_start == w2) && (![[word w2 == STROKE]])))
        make_sentence_node(sentence_start, w2, '.');
    disable_last_sentence_cacheing();
    if (from_extension)
        ⟨Issue a problem message if we are missing the begin and end here sentences 19⟩;
}
```

The function break_into_sentences is called from 4/iext.

§**5.** Each call to `break_into_sentences` starts afresh, with no residual state left over from previous calls. (The same cannot be said for `make_sentence_node`, which constructs individual sentences and is repeatedly called by us, and that is why these are global variables rather than locals in `break_into_sentences`.)

⟨Reset the sentence finite state machine 5⟩ ≡

```
sfsm_source_file = NULL;
sfsm_inside_rule_mode = FALSE;
sfsm_skipping_material_at_level = -1;
sfsm_extension = from_extension;
if (from_extension) sfsm_extension_position = 1;
else sfsm_extension_position = 0;
```

This code is used in §4.

§**6.** A table is any sentence beginning with the word "Table". (Bad news for anyone writing "Table Mountain is a room.", of course, but there are other ways to do that, and it seems wise to keep the syntax for tables clear, since their entries are governed by different lexical and semantic rules even at the lowest levels of NI.)

⟨Go into table sentence mode if necessary 6⟩ ≡

```
if [[sentence_start, w2 == table ...]] sfsm_in_table_mode = TRUE;
else sfsm_in_table_mode = FALSE;
```

This code is used in §4.

§**7.** We now come to the definition of a sentence break, which is more complicated than might have been expected.

For one thing, a run of sentence divisions is treated as a single division, only the last of which is the one which counts. This looks odd at first sight, because it means that Inform considers

> The cat is on the table;.

to be a valid sentence, equivalent to

> The cat is on the table.

But it has the advantage that it enables us to avoid being pointlessly strict over the punctuation which precedes a paragraph break. Some people like to write paragraphs like this:

```
Before going north:
    say "Northward ho!";
    now the compass points north;
```

And properly speaking that ends with a semicolon then a paragraph break, which is a doubled sentence division. But we forgive it as harmless, and that forgiveness is provided by the loop arrangement below.

We also avoid the need for empty sentences, because it is not possible for the code below to detect them: thus

> say "Look behind you!";;;;; now the Wug is in the Cave

is broken as two sentences, not six sentences of which four are empty. Perhaps we ought to be stricter, and reject more of these dubious forms, but at this point we have too little understanding of the semantics of the text to risk annoying the user with problem messages.

§**8.** Full stops, semicolons and paragraph breaks (all rendered by the lexer as individual words: the stroke word in the case of the latter) are always sentence divisions. The other cases are more complicated: see below.

⟨Look for a sentence break, finding the number of stop words and the stop character 8⟩ ≡

```
int at = position;
no_stop_words = 0; stop_character = '?'; back_up_one_word = FALSE;
while (at < w2) {
    int stopped = FALSE;
    if [[word at == STROKE]] { stop_character = '|'; stopped = TRUE; }
    if [[word at == FULLSTOP]] { stop_character = '.'; stopped = TRUE; }
    if [[word at == SEMICOLON]] { stop_character = ';'; stopped = TRUE; }
    ⟨Consider if a colon divides a sentence 9⟩;
    ⟨Consider if punctuation within a preceding quoted text divides a sentence, making an X break 10⟩;
    if (stopped == FALSE) break;
    no_stop_words++; at++;
}
if (stop_character == 'X') {            X breaks are like full stops, but there is no stop word to skip over
    stop_character = '.'; back_up_one_word = TRUE;
}
if (no_stop_words > 0)
    LOGIF(LEXER, "Stop character '%c', no_stop_words %d, sentence_break %d, position %d\n",
        stop_character, no_stop_words, sentence_start, position);
```

This code is used in §4.

§**9.** Colons are normally dividers, too, but an exception is made if they come between two apparently numerical constructions, because this suggests that the colon is being used not as punctuation but within a literal pattern. (For instance, "He went out at 1:34 PM." is a sentence with just one clause, not two clauses divided by the colon; but "He went out at 1 PM: the snow was still falling." is indeed divided. Our rule here correctly distinguishes these cases, and although it can be fooled by really contrived sentences – "He went out at 1: 22 Company, the Parachute Regiment, was marching." – it's robust enough in practice.)

Note that here we are at a word position which is strictly within the word range being sentence-broken, so that it is safe to examine both the word before and the word after the current position.

⟨Consider if a colon divides a sentence 9⟩ ≡

```
if ([[word at == COLON]] &&
    ((isdigit(*(lw_array[at-1].lw_rawtext)) == FALSE) ||
        (isdigit(*(lw_array[at+1].lw_rawtext))) == FALSE)) {
    stop_character = ':'; stopped = TRUE;
}
```

This code is used in §8.

§**10.** Inform authors habitually use the punctuation in quoted text to end sentences, just as other writers of English do. The text

"Look out!" The explosion shattered the calm of the hillside.

is certainly intended as two sentences, not one.

An exception is made for table declarations, because a table needs to be formed as one long sentence, and it clearly does not abide by the ordinary punctuation rules of English. The point is that in the random line of table entries...

"Of cabbages and kings." Walrus "Carroll"

...the full stop after "kings" has no significance: the semantics of the table would be no different if it were not there.

⟨Consider if punctuation within a preceding quoted text divides a sentence, making an X break 10⟩ ≡

```
if ((stopped == FALSE) &&                                   only look if we are not already at a division
    (no_stop_words == 0) &&                                 be sure not to elide two such texts in a row
    (sfsm_in_table_mode == FALSE) &&                        check that we are not scanning the body of a table
    (isupper(*(lw_array[at].lw_rawtext))) &&                and the current word begins with a capital letter
    (text_ending_sentence(at-1))) {                         and the preceding one was quoted text ending in punctuation
    stop_character = 'X'; stopped = TRUE;
}
```

This code is used in §8.

§**11. Making sentence nodes.** At this point we have established that `make_sentence_node` is called sequentially for every divided-off sentence in the original source text. But we need a little machinery to skip past sentences which are being excluded for one reason or another.

The design of Inform deliberately excludes conditional compilation in the traditional C sense of `#ifdef` and `#endif`. This takes us too far from what natural language would do, faced with the same basic issue. A book, or a government form, would more naturally have a heading making clear that the section beneath it is not universal in application. This is what Inform does, too: it parses a heading to decide whether to skip the material, and if so, the state `sfsm_skipping_material_at_level` is set to the level of the heading in question. We then skip all subsequent sentences until reaching the next heading of the same or higher status, or until reaching the "... ends here." sentence (if we are reading an extension), or until reaching the end of the text: whichever comes first.

```
int no_sentences_read = 0;

void make_sentence_node(int w1, int w2, char stop_character) {
    int heading_level = 0, start_of_paragraph = FALSE, begins_or_ends = 0;
    parse_node *new;

    no_sentences_read++;
    LOGIF(LEXER, "MSN(%d): %d,%d='$W' stop_character <%c>\n",
            no_sentences_read, w1, w2, w1, w2, stop_character);

    if (w2<w1) internal_error("empty sentence generated");
    vocab_identify_word_range(w1, w2);                      a precaution to catch any late unidentified text

    if ((w1 == 0) || (compare_word(w1-1, STROKE_V))) start_of_paragraph = TRUE;

    ⟨Detect a change of source file, and declare it as an implicit heading 12⟩;
    if (start_of_paragraph) ⟨Detect any explicit heading and set heading level 13⟩;
    ⟨Detect a begins here or ends here sentence 18⟩;

    if ((begins_or_ends == -1) ||
        ((heading_level > 0) && (heading_level <= sfsm_skipping_material_at_level)))
        sfsm_skipping_material_at_level = -1;
```

```
    if (sfsm_skipping_material_at_level >= 0) return;
    if (heading_level > 0) {
        ⟨Issue a problem message if the heading incorporates a line break 14⟩;
        ⟨Issue a problem message if the heading does not end with a line break 15⟩;
        ⟨Make a new HEADING node, possibly beginning to skip material 16⟩;
        return;
    }
    ⟨If this is the top of the source text and starts with quoted matter, make a BIBLIOGRAPHIC node and return 17⟩;
    ⟨Accept the new sentence as one or more nodes in the parse tree 21⟩;
}
```

The function make_sentence_node is called from 5/litp, 7/dti, 9/scene and 9/madj.

§**12.** For reasons gone into in the section on Headings below, a change of source file (e.g., when one extension has been read in and another begins) is declared as if it were a super-heading in the text.

⟨Detect a change of source file, and declare it as an implicit heading 12⟩ ≡

```
    if (lw_array[w1].lw_source.file_of_origin != sfsm_source_file) {
        parse_node *implicit_heading = new_node(HEADING_NT);
        implicit_heading->word_ref1 = w1;
        implicit_heading->word_ref2 = w2;
        graft(implicit_heading, tree_root);
        pn_annotate_int(implicit_heading, sentence_unparsed_ANNOT, FALSE);
        pn_annotate_int(implicit_heading, heading_level_ANNOT, 0);
        declare_heading(implicit_heading);
        sfsm_skipping_material_at_level = -1;
    }
    sfsm_source_file = lw_array[w1].lw_source.file_of_origin;
```

This code is used in §11.

§**13.** Sentences beginning with “book”, “volume”, “part”, “chapter” or “section”, which occur at the start of the source text or the start of a paragraph, and which do not contain line breaks, are construed as headings.

⟨Detect any explicit heading and set heading level 13⟩ ≡

```
    heading_level = 0;
    if [[w1, w2 == volume ...]]  heading_level = 1;
    if [[w1, w2 == book ...]]    heading_level = 2;
    if [[w1, w2 == part ...]]    heading_level = 3;
    if [[w1, w2 == chapter ...]] heading_level = 4;
    if [[w1, w2 == section ...]] heading_level = 5;
```

This code is used in §11.

§**14.** We have already looked to see if the sentence could be a heading, and set the variable `heading_level` to be its ranking in the hierarchy (with 1, for "volume", the highest). But we also want to check that the heading does not have a line break in, because this is almost certainly a mistake by the designer, and likely to be a difficult one to understand: so we should help out if we can. Such a problem is best recovered from by continuing regardless.

⟨Issue a problem message if the heading incorporates a line break 14⟩ ≡

```
int k;
for (k=w1+1; k<=w2; k++)
    if ((lw_array[k].lw_break == '\n') || (isdigit(lw_array[k].lw_break))){
        quote_source(1, new_nounphrase_raw(w1, w2));
        quote_source(2, new_nounphrase_raw(w1, k-1));
        quote_source(3, new_nounphrase_raw(k, w2));
        handmade_problem(_P_(C4HeadingOverLine));
        issue_problem_segment(
            "The text %1 seems to be a heading, but contains a "
            "line break, which is not allowed: so I am reading it "
            "as just %2 and ignoring the continuation %3. The rule "
            "is that a heading must be a single line which is the "
            "only sentence in its paragraph, so there must be a "
            "skipped line above and below.");
        issue_problem_end();
        break;
    }
```

This code is used in §11.

§**15.** And similarly... Here we take the liberty of looking a little ahead of the current word range in order to make the problem message more helpful: we check that we are still looking at valid words in the lexer, just to be on the safe side, but in fact we cannot run on past the end of the lexer feed which fed the malformed heading, because of all of the run-off newlines automatically added at the end of the feed of any source file.

⟨Issue a problem message if the heading does not end with a line break 15⟩ ≡

```
if (lw_array[w2+1].lw_break != '\n') {
    int k;
    for (k = w2+1;
        (k<=w2+8) && (k<lexer_wordcount) && (lw_array[k].lw_break != '\n');
        k++) ;
    quote_source(1, new_nounphrase_raw(w1, w2));
    quote_source(2, new_nounphrase_raw(w2+1, k-1));
    handmade_problem(_P_(C4HeadingStopsBeforeEndOfLine));
    issue_problem_segment(
        "The text %1 seems to be a heading, but does not occupy "
        "the whole of its line of source text, which continues %2. "
        "The rule is that a heading must occupy a whole single line "
        "which is the only sentence in its paragraph, so there "
        "must be a skipped line above and below, and it must not "
        "contain any full stop characters '.', even if they occur "
        "in an ellipsis '...' or a number '2.3.13'. (I mention this "
        "because sometimes this problem arises when a decimal point is "
        "misread as a full stop.)");
    issue_problem_end();
}
```

This code is used in §11.

§**16.** We now have a genuine heading, and can declare it, calling a routine in Headings to determine whether we should include the material.

⟨Make a new HEADING node, possibly beginning to skip material 16⟩ ≡

```
heading *h;
new = new_node(HEADING_NT);
new->word_ref1 = w1;
new->word_ref2 = w2;
graft(new, tree_root);
pn_annotate_int(new, sentence_unparsed_ANNOT, FALSE);
pn_annotate_int(new, heading_level_ANNOT, heading_level);
h = declare_heading(new);
if (hd_include_material(h) == FALSE)
    sfsm_skipping_material_at_level = heading_level;
return;
```

This code is used in §11.

§**17.** The second sentence in the source text is construed as containing bibliographic data if it begins with a quoted piece of text, perhaps with substitutions. For instance,

"A Dream of Fair to Middling Women" by Samuel Beckett

might be a `BIBLIOGRAPHIC_NT` sentence. (The reason this is the second sentence read, not the first, is that all source texts read by NI implicitly begin with an inclusion of the Standard Rules.)

⟨If this is the top of the source text and starts with quoted matter, make a BIBLIOGRAPHIC node and return 17⟩ ≡

```
if ((no_sentences_read == 2) && (vocab_test_flags(w1, TEXT_MC+TEXTWITHSUBS_MC))) {
    new = new_node(BIBLIOGRAPHIC_NT);
    new->word_ref1 = w1; new->word_ref2 = w2;
    pn_annotate_int(new, sentence_unparsed_ANNOT, FALSE);
    graft(new, tree_root);
    return;
}
```

This code is used in §11.

§**18. Begins and ends here.** The final kind of pseudo-heading we shall consider are the sentences ending "begins here" or "ends here" in an extension, and which mark its start and end.

⟨Detect a begins here or ends here sentence 18⟩ ≡

```
begins_or_ends = 0;
if (sfsm_extension_position > 0) {                    i.e., if this is an extension at all
    if [[w1, w2 == ... begin/begins here]] {
        switch (sfsm_extension_position) {
            case 1: sfsm_extension_position++; break;
            case 2: extension_problem(_P_(C4ExtMultipleBeginsHere),
                sfsm_extension, "has more than one 'begins here' sentence"); break;
            case 3: extension_problem(_P_(C4ExtBeginsAfterEndsHere),
                sfsm_extension, "has a further 'begins here' after an 'ends here'"); break;
        }
        begins_or_ends = 1;
    }
    if [[w1, w2 == ... end/ends here]] {
        switch (sfsm_extension_position) {
            case 1: extension_problem(_P_(C4ExtEndsWithoutBegins),
                sfsm_extension, "has an 'ends here' with nothing having begun"); break;
            case 2: sfsm_extension_position++; break;
            case 3: extension_problem(_P_(C4ExtMultipleEndsHere),
                sfsm_extension, "has more than one 'ends here' sentence"); break;
        }
        begins_or_ends = -1;
    }
}
```

This code is used in §11.

§**19.** When we finish scanning all the sentences in a given batch, and if they came from an extension, we need to make sure we saw both beginning and end:

⟨Issue a problem message if we are missing the begin and end here sentences 19⟩ ≡

```
switch (sfsm_extension_position) {
    case 1: extension_problem(_P_(C4ExtNoBeginsHere),
        sfsm_extension, "has no 'begins here' sentence"); break;
    case 2: extension_problem(_P_(C4ExtNoEndsHere),
        sfsm_extension, "has no 'ends here' sentence"); break;
    case 3: break;
}
```

This code is used in §4.

§**20. Unskipped material which is not a heading.** Each of the sentences which are to be included is given its own node on the parse tree, which for the time being is a direct child of the root. Sentences are classified by their node types, the main identification attached to each unit in the tree, and one purpose of this code is to sort them into three broad categories:

(a) **Sentences with primary verbs**, which will be subject to further parsing work later: these have node type `SENTENCE_NT`. Anything we cannot place into categories (b) or (c) below will go here.

(b) **Sentences making up rules**. These are sequences of sentences in which a preamble (ending with a colon, or in certain cases a comma) of node type `ROUTINE_NT` is followed by a sequence of phrases (ending with semicolons until the last, which ends with a full stop or paragraph break), each of node type `COMMAND_NT`. For instance, the following produces three nodes:

To look upwards: say "Look out!"; something else.

(c) **Structural sentences**. These demarcate the text, call for other text or unusual matter to be included, etc.: the types in question are `TRACE_NT`, `HEADING_NT`, `INCLUDE_NT`, `INFORM6CODE_NT`, `BEGINHERE_NT`, `ENDHERE_NT`, `TABLE_NT`, `EQUATION_NT` and `BIBLIOGRAPHIC_NT`.

§**21.** And here is how we handle each new sentence to be added. If we do end up with a SENTENCE, which is how a typical assertion ends up, then it will initially not have its primary verb identified. If we are still in the early stages of NI's run, we simply mark it as unparsed for later. But if we have already passed the stage at which the identification of primary verbs normally happens, then we cannot defer the point: we must look for the verb straight away.

```
⟨Accept the new sentence as one or more nodes in the parse tree 21⟩ ≡
    ⟨Convert comma-divided rule into two sentences, if this is allowed 22⟩;
    ⟨Otherwise, make a SENTENCE node 24⟩;
    ⟨Convert a rule preamble to a ROUTINE node and enter rule mode 25⟩;
    if (sfsm_inside_rule_mode)
        ⟨Convert to a COMMAND node and exit rule mode unless a semicolon implies further commands 26⟩;
    at this point we are certainly in assertion mode, not rule mode
    ⟨Convert an asterisk sentence to a TRACE node and return 27⟩;
    if (start_of_paragraph) {
        ⟨Convert a Table paragraph to a TABLE node and return 28⟩;
        ⟨Convert an Equation paragraph to an EQUATION node and return 29⟩;
    }
    ⟨Convert an extension Include sentence to an INCLUDE node and return 30⟩;
    ⟨Convert a verbatim I6 Include sentence to an INFORM6CODE node and return 31⟩;
    ⟨Convert a begins here or ends here sentence to a BEGINHERE or ENDHERE node and return 32⟩;
    none of that happened, so we have a SENTENCE node for certain
    if (text_loaded_from_source) look_for_verb_phrase(new);
    else pn_annotate_int(new, sentence_unparsed_ANNOT, TRUE);
```

This code is used in §11.

§**22.** Rules are ordinarily noticed by the colon, which divides the header from the rest: colons are not otherwise legal in NI. However, we allow five exceptions, provided that we are outside a rule at the moment. (If we were inside a rule, the stop character would be a semicolon or colon.)

⟨Convert comma-divided rule into two sentences, if this is allowed 22⟩ ≡

```
if ((sfsm_inside_rule_mode == FALSE)
    && ((stop_character == '.') || (stop_character == '|'))
    && ([[w1, w2 == instead of ...]] ||
        [[w1, w2 == every turn ...]] ||
        [[w1, w2 == before ...]] ||
        [[w1, w2 == after ...]] ||
        [[w1, w2 == when ...]]))
    ⟨Look for a comma and split the sentence at it, unless in serial list 23⟩;
```

This code is used in §21.

§**23.** In such sentences a comma is read as if it were a colon. (The text up to the comma will then be given a `ROUTINE_NT` node and the text beyond the comma will make a `COMMAND_NT` node.)

Note that we make an exception for the serial comma used in a list of alternatives: thus the comma in "Aeschylus, Sophocles, or Euripides" does not trigger this rule. We need this exception because such lists of alternatives often occur in rule preambles, where it's the third comma which divides rule from preamble:

Instead of pushing, dropping, or taking the talisman, say "It is cursed."

⟨Look for a comma and split the sentence at it, unless in serial list 23⟩ ≡

```
int comma_pos, earliest_comma_position = is_word_intermediate(or_V, w1, w2);
if (earliest_comma_position < 0) earliest_comma_position = w1;
comma_pos = is_word_intermediate(COMMA_V, earliest_comma_position, w2);
if (comma_pos >= 0) {
    make_sentence_node(w1, comma_pos-1, ':');                    rule preamble stopped with a colon
    make_sentence_node(comma_pos+1, w2, '.');          rule body with one sentence, stopped with a stop
    return;
}
```

This code is used in §22.

§**24.** At this point we know that the text `w1` to `w2` will make one and only one sentence node in the parse tree, so we may as well create and graft it now. There are a number of special cases with variant node types, but the commonest outcome is a SENTENCE node, so that's what we shall assume for now.

⟨Otherwise, make a SENTENCE node 24⟩ ≡

```
new = new_node(SENTENCE_NT);
new->word_ref1 = w1;
new->word_ref2 = w2;
pn_annotate_int(new, sentence_unparsed_ANNOT, FALSE);
graft(new, tree_root);
```

This code is used in §21.

§**25.** Rules are sequences of phrases with a preamble in front, which we detect by its terminating colon. For instance:

To look upwards: say "Look out!"; something else.

(which arrives at this routine as three separate "sentences") will produce nodes with type `ROUTINE_NT`, `COMMAND_NT` and `COMMAND_NT` respectively.

This paragraph of code might look as if it should only be used in assertion mode, not in rule mode, because how can a rule preamble legally occur in the middle of another rule? But in fact it can, in two ways. One is the officially sanctioned way to make a definition with a complex phrase:

Definition: a supporter is wobbly: if the player is on it, decide yes; decide no.

This produces four nodes: `ROUTINE_NT`, `ROUTINE_NT`, `COMMAND_NT` and `COMMAND_NT` respectively.

The other arises somewhat less officially when people treat phrases as if they were C (or Inform 6) statements, always to be terminated with semicolons, and also run two rules together with no skipped paragraph between:

```
To do one thing: something here;
To do another thing: something else here;
```

A strict reading of our rules would oblige us to consider "To do another thing:" as a phrase within the definition of "To do one thing", and we would then have to issue a problem message. But this would be pettifogging. (People who habitually shuffle phrases about in their editors tend not to want to fuss about changing the punctuation of the last to a full stop instead of a semicolon. We may lament this, but it is so.)

⟨Convert a rule preamble to a ROUTINE node and enter rule mode 25⟩ ≡

```
if (stop_character == ':') {
    if ((sfsm_inside_rule_mode) && (detect_control_structure(w1, w2))) {
        pn_set_node_type(new, COMMAND_NT);
        pn_annotate_int(new, colon_block_command_ANNOT, TRUE);
        sfsm_inside_rule_mode = TRUE;
        return;
    } else {
        pn_set_node_type(new, ROUTINE_NT);
        sfsm_inside_rule_mode = TRUE;
        return;
    }
}
```

This code is used in §21.

§**26.** Subsequent commands are divided by semicolons, and any failure of a semicolon to appear indicates an end of the rule.

⟨Convert to a COMMAND node and exit rule mode unless a semicolon implies further commands 26⟩ ≡

```
pn_set_node_type(new, COMMAND_NT);
if (stop_character != ';') sfsm_inside_rule_mode = FALSE;
return;
```

This code is used in §21.

§**27.** A sentence consisting only of a single asterisk toggles whether sentences should be traced to the special sentence tracing file: such a node has type `TRACE_NT` and is otherwise ignored. A sentence of an asterisk followed by a double-quoted text is a note for the benefit of the telemetry file (again, a convenience for testing Inform).

⟨Convert an asterisk sentence to a TRACE node and return 27⟩ ≡
```
if ([[w1, w2 == ASTERISK]] ||
    ([[w1, w2 == ASTERISK ###]] && (vocab_test_flags(w2, TEXT_MC)))) {
    pn_set_node_type(new, TRACE_NT); return;
}
```

This code is used in §21.

§**28.** Sentences beginning with "table" which occur at the start of the source text or the start of a paragraph are construed as table declarations, and given type `TABLE_NT`.

⟨Convert a Table paragraph to a TABLE node and return 28⟩ ≡
```
if [[w1, w2 == table ...]] {
    pn_set_node_type(new, TABLE_NT); return;
}
```

This code is used in §21.

§**29.** Sentences beginning with "equation" which occur at the start of the source text or the start of a paragraph are similarly given type `EQUATION_NT`.

⟨Convert an Equation paragraph to an EQUATION node and return 29⟩ ≡
```
if [[w1, w2 == equation ...]] {
    pn_set_node_type(new, EQUATION_NT); return;
}
```

This code is used in §21.

§**30.** Sentences in the form "include ... by ..." are construed as requiring extensions to be loaded, and typed `INCLUDE_NT`.

⟨Convert an extension Include sentence to an INCLUDE node and return 30⟩ ≡
```
if [[w1, w2 == include ... by ...]] {
    pn_set_node_type(new, INCLUDE_NT); return;
}
```

This code is used in §21.

§**31.** Sentences in the form "Include (- ..." are construed as verbatim I6 code inclusions, and typed `INFORM6CODE_NT`.

⟨Convert a verbatim I6 Include sentence to an INFORM6CODE node and return 31⟩ ≡
```
if [[w1, w2 == include OPENI6 ...]] {
    pn_set_node_type(new, INFORM6CODE_NT); return;
}
```

This code is used in §21.

§**32.** Finally, we must tidy away the previously detected "begins here" and "ends here" sentences into nodes on the tree.

⟨Convert a begins here or ends here sentence to a BEGINHERE or ENDHERE node and return 32⟩ ≡

```
if (begins_or_ends == 1) {
    pn_set_node_type(new, BEGINHERE_NT);
    new->word_ref1 = w1;
    new->word_ref2 = w2 - 2;
    check_extension_begins_here(new, sfsm_extension);
    return;
}
if (begins_or_ends == -1) {
    new->word_ref1 = w1;
    new->word_ref2 = w2 - 2;
    pn_set_node_type(new, ENDHERE_NT);
    check_extension_ends_here(new, sfsm_extension);
    return;
}
```

This code is used in §21.

Extension Files 4/ext

Purpose

To keep details of the extensions currently loaded, their authors, titles, versions and rubrics, and to index and credit them suitably.

Template interpreter commands

```
{-callv:check_extension_versions}
{-routine:ShowExtensionVersions}
{-callv:index_extensions}
{-callv:handle_census_mode}
{-callv:update_census_of_extensions}
```

Definitions

¶1. Extensions are files of source text, normally combined with an appendix of documentation, provided by third parties for users to include with the source text of their own projects. Extensions are intended to provide general solutions to typical needs, and an archive of extensions for download is provided by the Inform website: those are licenced by their authors with a Creative Commons Attribution licence, and because of that, Inform behaves as if all extensions it sees require attribution (unless the author requests anonymity). A user of Inform 7 will certainly have nine or ten extensions available to him, because that many are built into the standard distribution: as of 2007 it is typical for users to have installed 50 to 90 others, and the total is steadily rising. Our routines here therefore need to be scalable.

Extensions are stored in two places: a built-in area, inside the Inform 7 application, and an external area. NI knows the location of the former because the application passes this as `-rules` on the command line, and it knows the location of the latter because this is standard and fixed for each platform: see Platform-Specific Definitions.

¶2. An extension has a title and an author name, each of which is limited in length to one character less than the following constants:

```
define MAX_EXTENSION_TITLE_LENGTH 51
define MAX_EXTENSION_AUTHOR_LENGTH 51
```

¶3. How the application should install extensions. When the Inform 7 application looks at a file chosen by the user to be installed, it should look at the first line. (Note that this might have any of `0a`, `0d`, `0a0d`, `0d0a`, or Unicode line division as its line ending: and that the file might, or might not, begin with a Unicode BOM, "byte order marker", code. Characters within the line will be encoded as UTF-8, though – except possibly for some exotic forms of space – they will all be found in the ISO Latin-1 set.) The first line is required to have one of the following forms, possibly with white space before or after, but definitely without line breaks before:

Locksmith Extra by Emily Short begins here.

Version 2 of Locksmith Extra by Emily Short begins here.

Version 060430 of Locksmith Extra by Emily Short begins here.

Version 2/060430 of Locksmith Extra by Emily Short begins here.

If the name of the extension finishes with a bracketed clause, that should be disregarded. Such clauses are used to specify virtual machine requirements, at present, and could conceivably be used for other purposes later, so let's reserve them now.

Version 2 of Glulx Text Effects (for Glulx only) by Emily Short begins here.

The application should reject (that is, politely refuse to install) any purported extension file whose first line does not conform to the above.

Ignoring any version number given, the Inform application should then store the file in the external extensions area. For instance,

`~/Library/Inform/Extensions/Emily Short/Glulx Text Effects` (OS X)
`My Documents\Inform\Extensions\Emily Short\Glulx Text Effects` (Windows)

Note that the file will probably not have the right name initially, and will need to be renamed as well as moved. (Note the lack of a file extension.) The subfolders `Inform`, `Extensions` and `Emily Short` must be created if not already present.

If to install such an extension would result in over-writing an extension already present at that filename, the user should be given a warning and asked if he wants to proceed.

However, note that it is *not* an error to install an extension with the same name and author as one in the built-in extensions folder. This does not result in overwriting, since the newly installed version will live in the external area, not the built-in area.

An extension may be uninstalled simply by deleting the file: but the application must not allow the user to uninstall any extension from the built-in area. We must assume that the latter could be on a read-only disc, or could be part of a cryptographically signed application bundle.

¶4. The extension census. The Inform application should run NI in "census mode" in order to keep extension documentation up to date. NI should be run in census mode on three occasions:

(a) when the Inform application starts up;
(b) when the Inform application installs a new extension;
(c) when the Inform application uninstalls an extension.

When NI is run in "census mode", it should be run with the command

```
ni -rules (...) -census
```

where the argument for `-rules` is the same as for any other run. All output from NI should be ignored, including its return code: ideally, not even a fatal error should provoke a reaction from the application. If the census doesn't work for some file-system reason, never mind – it's not mission-critical.

¶5. What happens in census mode. The census has two purposes: first, to create provisional documentation where needed for new and unused extensions; and second, to create the following index files in the external documentation area (*not* in the external extension area):

`.../Extensions.html` (basically a contents page)
`.../ExtIndex.html` (basically an index)

Documentation for any individual extension is stored at, e.g.,

`.../Extensions/Victoria Saxe-Coburg-Gotha/Werewolves.html`

NI can generate such a file, for an individual extension, in two ways: (a) provisionally, with much less detail, and (b) fully. Whenever it successfully compiles a work using extension X, it rewrites the documentation for X fully, and updates both the two indexing pages.

When NI runs in `-census` mode, what it does is to scan for all extensions. If NI finds a valid extension with no documentation page, it writes a provisional one; and again, it updates both the two indexing pages.

(NI in fact runs a census on every compilation, as well, so `-census` runs do nothing "extra" that a normal run of NI does not also do. On every census, NI automatically checks for misfiled or broken extensions, and places a descriptive report of what's wrong on the `Extensions.html` index page – if people move around or edit extensions by hand, they may run into these errors.)

¶6. With that general discussion out of the way, we can get on with implementation. A modest structure is used to store details of extension files loaded into NI: or rather, to store requests to include them, and then to keep track of the results.

The rubric of an extension is text found near its opening, describing its purpose. This is truncated to the following length, which must remain strictly less than `MAX_STRING_LENGTH`:

```
define MAX_RUBRIC_LENGTH 500

typedef struct extension_file {
    struct extension_identifier ef_id;                    Texts of title and author with hash code
    int author_w1, author_w2;                                          Author's name
    int name_w1, name_w2;                                              Extension name
    int body_w1, body_w2;                          Body of source text supplied in extension, if any
    int body_text_unbroken;                   Does this contain text waiting to be sentence-broken?
    int doc_w1, doc_w2;                            Documentation supplied in extension, if any
    int VM_restriction_w1, VM_restriction_w2;                  Restricting use to certain VMs
    int min_version_needed;                                    As stipulated by source
    int version_loaded;                                        As actually loaded
    int footnote_number;                          In the index, which footnote refers to this
    int loaded_from_built_in_area;                             Located within Inform application
    int authorial_modesty;                                     Do not credit in the compiled game
    struct parse_node *inclusion_sentence;                     Where the source called for this
    struct source_file *read_into_file;                        Which source file loaded this
    char rubric_as_lexed[MAX_RUBRIC_LENGTH+1];
    char extra_credit_as_lexed[MAX_RUBRIC_LENGTH+1];
    MEMORY_MANAGEMENT
} extension_file;

extension_file *standard_rules_extension;              the Standard Rules by Graham Nelson
```

The structure extension_file is shared with 4/iext, 4/edict and 4/edoc.

§**1.** We begin with some housekeeping, really: the code required to create new extension file structures, and to manage existing ones.

```
extension_file *new_extension_file(int author_w1, int author_w2,
    int nw1, int nw2, int vm1, int vm2, int version_word) {
    char violation[160];                                          enough for two lines of type
    violation[0] = 0;
    extension_file *ef = CREATE(extension_file);
    ef->author_w1 = author_w1; ef->author_w2 = author_w2;
    ef->name_w1 = nw1; ef->name_w2 = nw2;
    ⟨Create EID for new extension file 2⟩;
    ef->min_version_needed = version_word;
    ef->inclusion_sentence = current_sentence;
    ef->VM_restriction_w1 = vm1; ef->VM_restriction_w2 = vm2;
    ef->body_w1 = -1; ef->body_w2 = -1;
    ef->body_text_unbroken = FALSE;
    ef->doc_w1 = -1; ef->doc_w2 = -1;
    ef->version_loaded = -1;
    ef->loaded_from_built_in_area = FALSE;
    ef->authorial_modesty = FALSE;
    ef->rubric_as_lexed[0] = 0;
    ef->extra_credit_as_lexed[0] = 0;
    if (violation[0]) extension_problem(_P_(Untestable), ef, violation);          see below
    return ef;
}
```

The function new_extension_file is called from 4/iext.

§**2.** We protect ourselves a little against absurdly long requested author or title names, and then produce problem messages in the event of only longish ones, unless the census is going on: in which case it's better to leave the matter to the census errors system elsewhere.

⟨Create EID for new extension file 2⟩ ≡

```
    char exft[MAX_FILENAME_LENGTH], exfa[MAX_FILENAME_LENGTH];
    print_raw_text_to_string_truncated(ef->author_w1, ef->author_w2, exfa, MAX_FILENAME_LENGTH);
    print_raw_text_to_string_truncated(ef->name_w1, ef->name_w2, exft, MAX_FILENAME_LENGTH);
    if (currently_recording_census_errors() == FALSE) {
        if (strlen(exfa) >= MAX_EXTENSION_AUTHOR_LENGTH)                  intest cannot easily test this
            sprintf(violation,
                "has an author's name which is too long, exceeding the maximum "
                "allowed (%d characters) by %d",
                MAX_EXTENSION_AUTHOR_LENGTH-1,
                (int) (1+strlen(exfa)-MAX_EXTENSION_AUTHOR_LENGTH));
        if (strlen(exft) >= MAX_EXTENSION_AUTHOR_LENGTH)                  intest cannot easily test this
            sprintf(violation,
                "has a title which is too long, exceeding the maximum allowed "
                "(%d characters) by %d",
                MAX_EXTENSION_TITLE_LENGTH-1,
                (int) (1+strlen(exft)-MAX_EXTENSION_TITLE_LENGTH));
    }
    eid_new(&(ef->ef_id), exfa, exft, LOADED_EIDBC);
    if (eid_is_standard_rules(&(ef->ef_id))) standard_rules_extension = ef;
```

This code is used in §1.

§**3.** Three pieces of information (not available when the EF is created) will be set later on, by other parts of NI calling the routines below.

The rubric text for an extension, which is double-quoted matter just below its "begins here" line, is parsed as a sentence and will be read as an assertion in the usual way when the material from this extension is being worked through (quite a long time after the EF structure was created). When that happens, the following routine will be called to set the rubric; and the one after for the optional extra credit line, used to acknowledge I6 sources, collaborators, translators and so on.

```
void ef_set_rubric(extension_file *ef, char *text) {
    truncated_strcpy(ef->rubric_as_lexed, text, MAX_RUBRIC_LENGTH);
    LOGIF(EXTCENSUS, "Extension rubric: %s\n", ef->rubric_as_lexed);
}
void ef_set_extra_credit(extension_file *ef, char *text) {
    truncated_strcpy(ef->extra_credit_as_lexed, text, MAX_RUBRIC_LENGTH);
    LOGIF(EXTCENSUS, "Extension extra credit: %s\n", ef->extra_credit_as_lexed);
}
```

The function ef_set_rubric is called from 8/sob.
The function ef_set_extra_credit is called from 8/sob.

§**4.** Once we start reading text from the file (if it can successfully be found: when the EF structure is created, we don't know that yet), we need to tally it up with the corresponding source file structure.

```
void ef_set_corresponding_source_file(extension_file *ef, source_file *sf) {
    ef->read_into_file = sf;
}
```

The function ef_set_corresponding_source_file is called from 3/read.

§**5.** When headings cross-refer to extensions, they need to read extension IDs, so:

```
extension_identifier *ef_get_eid(extension_file *ef) {
    return &(ef->ef_id);
}
```

The function ef_get_eid is called from 2/index, 2/prob1, 4/head and 12/rb.

§**6.** The use option "authorial modesty" is unusual in applying to the extension it is found in, not the whole source text. When we read it, we call one of the following routines, depending on whether it was in an extension or in the main source text:

```
int general_authorial_modesty = FALSE;
void ef_set_authorial_modesty(extension_file *ef) { ef->authorial_modesty = TRUE; }
void set_general_authorial_modesty(void) { general_authorial_modesty = TRUE; }
```

The function ef_set_authorial_modesty is called from 10/isin.
The function set_general_authorial_modesty is called from 10/isin.

§**7. Index footnotes.** These are used only in indexing, to show that a given meaning is defined by an extension rather than by the source text.

Before compiling each index, we clear the current footnote numbers:

```
int no_extensions_footnoted_in_current_index = 0;
int ef_no_of_footnoted_extensions(void) {
    return no_extensions_footnoted_in_current_index;
}
void ef_clear_extension_footnotes(void) {
    extension_file *ef;
    no_extensions_footnoted_in_current_index = 0;
    LOOP_OVER(ef, extension_file) ef->footnote_number = 0;
}
```

The function ef_no_of_footnoted_extensions is called from 2/index.

The function ef_clear_extension_footnotes is called from 2/index.

§**8.** When and as needed, each EF is allocated the next available positive integer as its footnote number. Thus the first to be footnoted on a given index page becomes footnote 1, and so on.

```
int ef_get_footnote(extension_file *ef) {
    if (ef->footnote_number == 0)
        ef->footnote_number = ++no_extensions_footnoted_in_current_index;
    return ef->footnote_number;
}
```

The function ef_get_footnote is called from 2/index.

§**9.** Lastly, we recover the EF corresponding to a given footnote number thus. The routine returns `NULL` if the EF is not footnoted on the current index page so far.

```
extension_file *ef_by_footnote(int n) {
    extension_file *ef;
    LOOP_OVER(ef, extension_file)
        if (ef->footnote_number == n) return ef;
    return NULL;
}
```

The function ef_by_footnote is called from 2/index.

§**10. Printing names of extensions.** We can print the name of the extension in a variety of ways and to a variety of destinations, but it all comes down to the same thing in the end. First, printing the name to an arbitrary UTF-8 file:

```
void ef_write_name_to_file(extension_file *ef, OUTPUT_STREAM) {
    print_raw_text_to_file(ef->name_w1, ef->name_w2, OUT);
}
void ef_write_author_to_file(extension_file *ef, OUTPUT_STREAM) {
    print_raw_text_to_file(ef->author_w1, ef->author_w2, OUT);
}
void ef_write_full_title_to_file(extension_file *ef, OUTPUT_STREAM) {
    ef_write_name_to_file(ef, OUT);
    INDEX(" by ");
    ef_write_author_to_file(ef, OUT);
}
```

The function ef_write_name_to_file is called from 11/act and 12/phin.
The function ef_write_author_to_file is called from 11/act and 12/phin.
The function ef_write_full_title_to_file is called from 2/index.

§**11.** Next, the debugging log:

```
void log_extension_file(extension_file *ef) {
    if (ef == NULL) { LOG("<null-extension-file>"); return; }
    LOG("$W by $W", ef->name_w1, ef->name_w2, ef->author_w1, ef->author_w2);
}
```

The function log_extension_file is called from 2/dl.

§**12.** Next, printing the name in the form of a comment in an (ISO Latin-1) Inform 6 source file:

```
void ef_write_I6_comment_describing(extension_file *ef, OUTPUT_STREAM) {
    if (ef == standard_rules_extension) {
        WRITE("! From the Standard Rules\n");
    } else {
        WRITE("! From \"");
        print_raw_text_within_i6_literal(OUT, ef->name_w1, ef->name_w2);
        WRITE("\" by ");
        print_raw_text_within_i6_literal(OUT, ef->author_w1, ef->author_w2);
        WRITE("\n");
    }
}
```

The function ef_write_I6_comment_describing is called from 12/cph.

§**13.** And finally printing the name to a C string:

```
void ef_write_full_title_to_string(extension_file *ef, char *p) {
    print_raw_text_to_string(ef->name_w1, ef->name_w2, p);
    sprintf(p + strlen(p), " by ");
    print_raw_text_to_string(ef->author_w1, ef->author_w2, p + strlen(p));
}
```

The function ef_write_full_title_to_string is called from 2/prob2.

§14. Checking version numbers. It's only at the end of semantic analysis, when all extensions have been loaded, that we check that all the version numbers are sufficient to meet the requests made. The reason we don't do this one at a time, as we load them in, is that we might load E at a time when version V is required, and find that it matches; but then an extension loaded later might turn out to require E version $V + 1$. So it is only when all extensions have been loaded that we know the full set of requirements, and only then do we check that they have been met.

```
void check_extension_versions(void) {
    extension_file *ef;
    LOOP_OVER(ef, extension_file) {
        int have = parse_version_number(ef->version_loaded),
            need = parse_version_number(ef->min_version_needed);
        if (need > have) {
            LOG("Need %d, have %d\n", need, have);
            current_sentence = ef->inclusion_sentence;
            quote_source(1, current_sentence);
            quote_extension(2, ef);
            if (ef->version_loaded >= 0) {
                quote_words(3, ef->version_loaded, ef->version_loaded);
                handmade_problem(_P_(C4ExtVersionTooLow));
                issue_problem_segment(
                    "You wrote %1: but my copy of %2 is only version %3.");
                issue_problem_end();
            } else {
                handmade_problem(_P_(C4ExtNoVersion));
                issue_problem_segment(
                    "You wrote %1: but my copy of %2 contains no version "
                    "number, and is therefore considered to be earlier than "
                    "all numbered versions.");
                issue_problem_end();
            }
        }
    }
}
```

The function check_extension_versions is invoked by a command in a `.i6t` template file.

§15. Credit for extensions. Here we compile an I6 routine to print out credits for all the extensions present in the compiled work. This is important because the extensions published at the Inform website are available under a Creative Commons license which requires users to give credit to the authors: Inform ensures that this happens automatically.

Use of authorial modesty (see above) will suppress a credit in the `ShowExtensionVersions` routine, but the system is set up so that one can only be modest about one's own extensions: this would otherwise violate a CC license of somebody else. General authorial modesty thus suppresses credits for all extensions used which are by the user himself. On the other hand, if an extension contains an authorial modesty disclaimer in its own text, then that must have been the wish of its author, so we can suppress the credit whoever that author was.

In `I7FullExtensionVersions` all extensions are credited whatever anyone's feelings of modesty.

```
void compile_ShowExtensionVersions_routine(OUTPUT_STREAM) {
    extension_file *ef;
    WRITE("[ ShowExtensionVersions;\n"); INDENT;
    LOOP_OVER(ef, extension_file) {
```

```
        char the_author_name[512];
        print_raw_text_to_string(ef->author_w1, ef->author_w2, the_author_name);
        if ((ef->authorial_modesty == FALSE) &&                    if (1) extension doesn't ask to be modest
            ((general_authorial_modesty == FALSE) ||          and (2) author doesn't ask to be modest, or...
            (story_author_is(the_author_name) == FALSE)))                    ...didn't write this extension
                credit_ef(OUT, ef);                                                then we award a credit
    }
    OUTDENT; WRITE("];\n");
    WRITE("[ ShowFullExtensionVersions;\n"); INDENT;
    LOOP_OVER(ef, extension_file) credit_ef(OUT, ef);
    OUTDENT; WRITE("];\n");
}
```

The function compile_ShowExtensionVersions_routine is invoked by a command in a `.i6t` template file.

§**16.** The actual credit consists of a single line, with name, version number and author. These are printed as I6 strings, hence the ISO encoding.

```
void credit_ef(OUTPUT_STREAM, extension_file *ef) {
    WRITE("print \"%s", ef->ef_id.raw_title);
    if (ef->version_loaded >= 0) {
        WRITE(" version ");
        print_raw_text_to_file(ef->version_loaded, ef->version_loaded, OUT);
    }
    WRITE(" by %s", ef->ef_id.raw_author_name);
    if (ef->extra_credit_as_lexed[0]) WRITE(" (%s)", ef->extra_credit_as_lexed);
    WRITE("^\";\n");
}
```

§**17. Indexing extensions in the Contents index.** The routine below places a list of extensions used in the Contents index, giving only minimal entries about them.

```
void index_extensions(void) {
    extension_file *ef;
    index_anchor("EXTLIST");
    INDEX("<p><b>List of extensions included</b> <i>(About these ");
    index_doc_link("EXTENSIONS");
    INDEX(")</i><p>\n");
    LOOP_OVER(ef, extension_file) {
        print_raw_text_to_file(ef->name_w1, ef->name_w2, ifl);
        if (ef != standard_rules_extension) {              give author and inclusion links, but not for SR
            INDEX(" by ");
            print_raw_text_to_file(ef->author_w1, ef->author_w2, ifl);
            index_link(lw_array[ef->inclusion_sentence->word_ref1].lw_source);
        } else index_doc_link("SRULES");
        if (ef->version_loaded >= 0) {
            INDEX(" version ");
            print_raw_text_to_file(ef->version_loaded, ef->version_loaded, ifl);
        }
        if (ef->extra_credit_as_lexed[0]) {
            INDEX(" (");
            print_literal_string_to_file(ifl, ef->extra_credit_as_lexed);
            INDEX(")");
```

```
        }
        INDEX("<br>\n");
    }
}
```

The function index_extensions is invoked by a command in a `.i6t` template file.

§**18. Updating the documentation.** This is done in the course of taking an extension census, which is called for in one of two circumstances: when NI is being run in "census mode" to notify it that extensions have been installed or uninstalled; or when NI has completed the successful compilation of a source text. In the latter case, it knows quite a lot about the extensions actually used in that compilation, and so can write detailed versions of their documentation: since it is updating extension documentation anyway, it conducts a census as well. (In both cases the extension dictionary is also worked upon.) The two alternatives are expressed here:

```
void handle_census_mode(void) {
    if (census_mode) {
        load_extension_dictionary();
        extension_census();
        write_top_level_of_extensions_documentation();
        write_sketchy_documentation_for_extensions_found();
        abort_I6T_interpreter = TRUE;                our work is done: exit at the next graceful opportunity
    }
}

void update_census_of_extensions(void) {
    extension_file *ef;
    load_extension_dictionary();
    extension_census();
    write_top_level_of_extensions_documentation();
    LOOP_OVER(ef, extension_file) write_detailed_extension_documentation(ef);
    write_sketchy_documentation_for_extensions_found();
    write_dictionary_back();
    if (dl_this(EXTCENSUS_DA)) log_EID_hash_table();
}
```

The function handle_census_mode is invoked by a command in a `.i6t` template file.
The function update_census_of_extensions is invoked by a command in a `.i6t` template file.

§**19.** Documenting extensions seen but not used: we run through the census results in no particular order and create a sketchy page of documentation, if there's no better one already.

```
void write_sketchy_documentation_for_extensions_found(void) {
    extension_census_datum *ecd;
    LOOP_OVER(ecd, extension_census_datum)
        write_sketchy_extension_documentation(ecd);
}
```

§**20. Writing the extensions home pages.** Extensions documentation forms a mini-website within the Inform documentation. There is a top level consisting of two home pages: a directory of all installed extensions, and an index to the terms defined in those extensions. A cross-link switches between them. Each of these links down to the bottom level, where there is a page for every installed extension (wherever it is installed). The picture is therefore something like this:

```
(Main documentation contents page)
        |
Extensions.html--ExtIndex.html
        |      \/      |
        |      /\      |
Nigel Toad/Eggs  Barnabas Dundritch/Neopolitan Iced Cream   ...
```

§**21.** These pages are stored at the relative pathnames

```
Extensions/Documentation/Extensions.html
Extensions/Documentation/ExtIndex.html
```

They are made by inserting content in place of the material between the HTML anchors `on` and `off` in a template version of the page kept in the `Reserved` subfolder of the built-in extensions area (and therefore within the application), with a leafname which varies from platform to platform, for reasons as always to do with the vagaries of Internet Explorer 7 for Windows.

```
void write_top_level_of_extensions_documentation(void) {
    write_top_level_extensions_page("Extensions",
        "As extensions are installed, documentation on them is added to this "
        "page. Click on the name of an extension for more. See also the "
        "<a href=ExtIndex.html STYLE=\"text-decoration: none\"><font color=\"#4040FF\">"
        "index of extension definitions</font></a>.",
        1);
    write_top_level_extensions_page("ExtIndex",
        "Whenever an extension is used, its definitions are entered into the "
        "following index. (Thus, a newly installed but never-used extension "
        "is not indexed yet.) See also the "
        "<a href=Extensions.html STYLE=\"text-decoration: none\"><font color=\"#4040FF\">"
        "directory of installed extensions</font></a>.",
        2);
}
```

§**22.**

```
void write_top_level_extensions_page(char *leafname, char *explanatory_heading,
    int content) {
    STREAM HOMEPAGE_struct;
    STREAM *HOMEPAGE = &HOMEPAGE_struct;
    FILE *TEMPLATE;
    char path_to_census[MAX_FILENAME_LENGTH];
    char path_to_model[MAX_FILENAME_LENGTH];
    sprintf(path_to_census, "%s%c%s.html", pathname_of_extension_docs, FOLDER_SEPARATOR,
        leafname);
    if (STREAM_OPEN_TO_FILE(HOMEPAGE, path_to_census, UTF8_ENC) == FALSE)
        fatal_error2("Unable to open extensions documentation index for writing",
            path_to_census);
    sprintf(path_to_model, "%s%cReserved%c%s",
        pathname_of_built_in_extensions, FOLDER_SEPARATOR, FOLDER_SEPARATOR,
        EXTENSIONS_MODEL_HTML);
    TEMPLATE = iso_fopen(path_to_model, "r");
    if (TEMPLATE == NULL)
        fatal_error("Unable to open model extensions documentation for reading");
    ⟨Copy the template, inserting the census results at the appropriate place 23⟩;
    STREAM_CLOSE(HOMEPAGE);
    fclose(TEMPLATE);
}
```

§**23.** The template must be a valid HTML page encoded as UTF-8 whose lines are divided with Unix line endings and in which every line is shorter than the following number of characters in length:

```
define LONGEST_LINE_IN_EX_TEMPLATE 1024
define LINE_MARKING_START_OF_CENSUS "<a name=on>"
define LINE_MARKING_END_OF_CENSUS "<a name=off>"
```

⟨Copy the template, inserting the census results at the appropriate place 23⟩ ≡

```
    char line_of_template[LONGEST_LINE_IN_EX_TEMPLATE];
    int skipping_between_markers = FALSE;
    while (!(feof(TEMPLATE))) {
        int n = truncated_iso_fgets(TEMPLATE, line_of_template, LONGEST_LINE_IN_EX_TEMPLATE);
        if (n == -1) break;                                    file I/O error, or end of file
        if (strcmp(line_of_template, LINE_MARKING_START_OF_CENSUS) == 0) {
            STREAM_WRITE(HOMEPAGE, "<p>%s<p>", explanatory_heading);
            switch (content) {
                case 1: write_extensions_census_to_HTML_file(HOMEPAGE); break;
                case 2: write_extension_dictionary_to_HTML_file(HOMEPAGE); break;
            }
            skipping_between_markers = TRUE;
        }
        if (skipping_between_markers == FALSE) STREAM_WRITE(HOMEPAGE, "%s", line_of_template);
        if (strcmp(line_of_template, LINE_MARKING_END_OF_CENSUS) == 0)
            skipping_between_markers = FALSE;
    }
```

This code is used in §22.

§**24.** Note the cross-link to the extension dictionary, which is reciprocated from there.

⟨Print the headnote explaining what the census is 24⟩ ≡

```
STREAM_WRITE(HOMEPAGE,
    "<p>As extensions are installed, documentation on them is added to this "
    "page. Click on the name of an extension for more. See also the "
    "<a href=ExtIndex.html STYLE=\"text-decoration: none\"><font color=\"#4040FF\">"
    "index of extension definitions</font></a>.<p>");
```

This code is used in §.

Including Extensions 4/iext

Purpose

To fulfill requests to include extensions, adding their material to the parse tree as needed, and removing INCLUDE nodes.

4/iext.§6-10 Extension loading; §11-12 Parsing extension version numbers; §13-20 Checking the begins here and ends here sentences; §21 Sentence handlers for begins here and ends here

---

Template interpreter commands

```
1   {-callv:traverse_for_extensions}
```

---

§**1.** At this point in the narrative of a typical run of NI, we have read in the source text supplied by the user. The lexer automatically prefaced this with "Include Standard Rules by Graham Nelson", and the sentence-breaker converted all such sentences to nodes of type `INCLUDE_NT` which are children of the parse tree root. (The eldest child, therefore, is the Standard Rules inclusion.)

We now look through the parse tree in sentence order – something we shall do many times, and which we call a "traverse" – and look for INCLUDE nodes. Each is replaced with a mass of further nodes for the material in whatever new extensions were required. This process is repeated until there are no "Include" sentences left. In principle this could go on forever if A includes B which includes A, or some such, but we log each extension read in to ensure that nothing is read twice.

At the end of this routine, provided no Problems have been issued, there are guaranteed to be no INCLUDE nodes remaining in the parse tree.

```
void traverse_for_extensions(void) {
    int includes_cleared;
    do {
        parse_node *pn, *elder;
        includes_cleared = TRUE;
        if (problem_count > 0) return;
        for (elder=NULL, TREE_START(pn); pn; TREE_NEXT(pn)) {
            current_sentence = pn;                          to report problems at the right place
            if (pn_get_node_type(pn) == INCLUDE_NT) {
                ⟨Replace INCLUDE node with sentence nodes for any extensions required 2⟩;
                includes_cleared = FALSE;
                continue;
            }
            elder = pn;
        }
    } while (includes_cleared == FALSE);
}
```

The function traverse_for_extensions is invoked by a command in a `.i6t` template file.

§**2.** We slice out the INCLUDE node and everything after it, which we call the tail: that gives us a clean branch from which new included matter can grow. We then graft the tail back again. The net effect is that the INCLUDE node disappears, since it is never regrafted, while any new matter now appears where the INCLUDE node used to be. (It's possible for that new matter to be empty, if the inclusion request was for an extension which has already been included. If so then the process simply excises the INCLUDE and leaves the tree otherwise unchanged.)

⟨Replace INCLUDE node with sentence nodes for any extensions required 2⟩ ≡

```
    if (elder == NULL) tree_root->down = NULL; else elder->next = NULL;          trim off pn and the tail
    fulfill_request_to_include_extension(pn, pn->word_ref1+1, pn->word_ref2);       which may add new
nodes
    if (pn->next) elder = graft(pn->next, tree_root);          put the tail (not pn) back after the new nodes
```

This code is used in §1.

§**3.** Here we parse requests to include one or more extensions. People mostly don't avail themselves of the opportunity, but it is legal to include several at once, with a line like:

> Include Carrots by Peter Rabbit and Green Lettuce by Flopsy Bunny.

The problem message here can only be seen if the author tries to include multiple extensions in the same sentence, one of which has an author but another of which does not, since the presence of the word "by" is an essential marker in detecting an inclusion sentence. So the test case to provoke this problem is a little bit of a stretch.

A consequence of this convention is that "and" is not permitted in the name of an extension. We might change this some day.

```
void fulfill_request_to_include_extension(parse_node *incl, int w1, int w2) {
    int i, aw1, aw2;
    if ([[w1, w2 == ... by ... : i]] &&
        (is_list_divided(i, w2, LOOK_FOR_AND))) {
        int lw1 = w1, lw2 = left_w2, rw1 = right_w1, rw2 = right_w2;
        fulfill_request_to_include_extension(incl, lw1, lw2);
        fulfill_request_to_include_extension(incl, rw1, rw2);
        return;
    }
    if ([[w1, w2 == ... by ... : i --> w1, w2 ... aw1, aw2]] == FALSE) {
        current_sentence = incl;
        sentence_problem(_P_(C4IncludeExtWithoutBy),
            "the name of an included extension should have the form 'General "
            "Relativity by Albert Einstein'",
            "though real examples are usually more weighty. (The problem here "
            "is that you do not say who the extension is 'by'.)");
        return;
    }
    ⟨Fulfill request to include a single extension 4⟩;
}
```

§**4.** A request consists of author, name and version, the latter being optional. We obtain the extension file structure corresponding to this: it may have no text at all (for instance if NI could not open the file), or it may be one we have seen before, thanks to an earlier inclusion. Only when it provided genuinely new text will its `body_text_unbroken` flag be set, and then we call the sentence-breaker to graft the new material on to the parse tree.

⟨Fulfill request to include a single extension 4⟩ ≡

```
int version_word = -1;
extension_file *requested_extension;
if [[w1, w2 == version ### of ...]] {
    version_word = w1+1;
    parse_version_number(version_word);                this checks the formatting of the version number
    w1 += 3;
}
[[w1, w2 == the ... --> w1, w2]];
⟨Issue problem message if the extension title is written in double quotes 5⟩;
requested_extension = load_extension(aw1, aw2, w1, w2, version_word);
if (requested_extension->body_text_unbroken) {
    break_into_sentences(requested_extension->body_w1, requested_extension->body_w2,
        requested_extension);
    requested_extension->body_text_unbroken = FALSE;
}
```

This code is used in §3.

§**5.** Quite a popular mistake, this:

⟨Issue problem message if the extension title is written in double quotes 5⟩ ≡

```
if (is_kova(is_a_literal(w1, w2), TEXT_TY)) {
    sentence_problem(_P_(C4IncludeExtQuoted),
        "the name of an included extension should be given without double "
        "quotes in an Include sentence",
        "so for instance 'Include Oh My God by Janice Bing.' rather than "
        "'Include \"Oh My God\" by Janice Bing.')");
    return;
}
```

This code is used in §4.

§**6. Extension loading.** Extensions are loaded here.

```
extension_file *load_extension(int author_w1, int author_w2,
    int name_w1, int name_w2, int version_word) {
    int i, vm1 = -1, vm2 = -1;
    extension_file *ef;
    [[name_w1, name_w2 == ... OPENBRACKET ... CLOSEBRACKET : i --> name_w1, name_w2 ... vm1, vm2]];
    LOOP_OVER(ef, extension_file)
        if ((compare_word_range(ef->author_w1, ef->author_w2, author_w1, author_w2))
            && (compare_word_range(ef->name_w1, ef->name_w2, name_w1, name_w2)))
            ⟨This is an extension already loaded, so note any version number hike and return 7⟩;
    ef = new_extension_file(author_w1, author_w2, name_w1, name_w2, vm1, vm2, version_word);
    ⟨Read the extension file into the lexer, and break it into body and documentation 8⟩;
    return ef;
}
```

The function load_extension is called from 4/edoc.

§**7.** Note that we ignore a request for an extension which has already been loaded, except if the new request ups the ante in terms of the minimum version permitted: in which case we need to record that the requirement has been tightened. That is, if we previously wanted version 2 of Pantomime Sausages by Mr Punch, and loaded it, but then read the sentence

> Include version 3 of Pantomime Sausages by Mr Punch.

then we need to note that the version requirement on PS has been raised to 3. (This is why version numbers are not checked at load time: in general, we can't know at load time what we will ultimately require.)

⟨This is an extension already loaded, so note any version number hike and return 7⟩ ≡

```
    if (parse_version_number(ef->min_version_needed) < parse_version_number(version_word)) {
        ef->min_version_needed = version_word;
        ef->inclusion_sentence = current_sentence;
    }
    return ef;
```

This code is used in §6.

§**8.** We finally make our call out of the Extensions section, down through the trap-door into Read Source Text, to seek and open the file.

⟨Read the extension file into the lexer, and break it into body and documentation 8⟩ ≡

```
    char partial_pathname[MAX_FILENAME_LENGTH];
    char synopsis[MAX_FILENAME_LENGTH];
    int start_wn, end_wn;
    ⟨Concoct a partial pathname and synopsis for the extension to be read 9⟩;
    start_wn = lexer_wordcount;
    switch (read_extension_source_text(ef, partial_pathname, synopsis, census_mode)) {
        case ORIGIN_WAS_USER_EXTENSIONS_AREA:
            ef->loaded_from_built_in_area = FALSE; break;
        case ORIGIN_WAS_BUILT_IN_EXTENSIONS_AREA:
            ef->loaded_from_built_in_area = TRUE; break;
        default:                                    which can happen if the extension file cannot be found
            ef->loaded_from_built_in_area = FALSE; break;
    }
    end_wn = lexer_wordcount-1;
    if (end_wn >= start_wn) ⟨Break the extension's text into body and documentation 10⟩;
```

This code is used in §6.

§**9.** We need to concoct the specific part of the pathname for the file to read:

```
Mr Punch/Pantomime Sausages
```

but we do so without specifying where the `Mr Punch` directory is, because it could be in either the built-in or the external area: a detail which we delegate to `read_extension_source_text` to sort out for us. We also concoct a textual synopsis in the form

```
"Pantomime Sausages by Mr Punch"
```

to be used by `read_extension_source_text` for printing to `stdout`. Since we dare not assume `stdout` can manage characters outside the basic ASCII range, we flatten them from general ISO to plain ASCII.

⟨Concoct a partial pathname and synopsis for the extension to be read 9⟩ ≡

```
int i;
print_text_to_string(author_w1, author_w2, partial_pathname);
sprintf(partial_pathname+strlen(partial_pathname), "%c", FOLDER_SEPARATOR);
print_text_to_string(name_w1, name_w2, partial_pathname+strlen(partial_pathname));
print_raw_text_to_string(name_w1, name_w2, synopsis);
sprintf(synopsis+strlen(synopsis), " by ");
print_raw_text_to_string(author_w1, author_w2, synopsis+strlen(synopsis));
for (i=0; synopsis[i]; i++) synopsis[i] = iso_remove_accents(synopsis[i]);
```

This code is used in §8.

§**10.** If an extension file contains the special text (outside literal mode) of

```
---- Documentation ----
```

then this is taken as the end of the NI source, and the beginning of a snippet of documentation about the extension; text from that point on is saved until later, but not broken into sentences for the parse tree, and it is therefore invisible to the rest of NI. If this division line is not present then the extension contains only body source and no documentation.

⟨Break the extension's text into body and documentation 10⟩ ≡

```
int i;
ef->body_w1 = start_wn; ef->body_w2 = end_wn;
for (i=start_wn; i<=end_wn; i++)
    if [[i, end_wn == FOURDASHES DOCUMENTATION FOURDASHES ...]] {
        ef->body_w1 = start_wn; ef->body_w2 = i-1;
        ef->doc_w1 = i+3; ef->doc_w2 = end_wn;
        break;
    }
ef->body_text_unbroken = TRUE;                    mark this to be sentence-broken
```

This code is used in §8.

§11. Parsing extension version numbers. Extensions can have versions in the form N/DDDDDD, a format which was chosen for sentimental reasons: IF enthusiasts know it well from the banner text of the Infocom titles of the 1980s. This story file, for instance, was compiled at the time of the Reykjavik summit between Presidents Gorbachev and Reagan:

```
Moonmist
Infocom interactive fiction - a mystery story
Copyright (c) 1986 by Infocom, Inc. All rights reserved.
Moonmist is a trademark of Infocom, Inc.
Release number 9 / Serial number 861022
```

Story file collectors customarily abbreviate this in catalogues to `9/861022`.

In our scheme, DDDDDD can be omitted (in which case so must the slash be). Spacing is not allowed around the slash (if present), so the version number always occupies a single lexical word.

The following routine parses the version number at word `vwn` to give an non-negative integer – in fact it really just construes the whole thing, with the slash removed, as a 7-digit number – in such a way that an earlier version always has a lower integer than a later one. It is legal for `vwn` to be −1, which means "no version number quoted", and evaluates as 0 – corresponding to `0/000000`, lower than the lowest version number it is legal to quote explicitly, which is `1`. (It follows that requiring no version in particular is equivalent to requiring `0/000000` or better, since every extension passes that test.)

In order that the numerical form of a version number should be a signed 32-bit integer which does not overflow, we require that the release number `N` be at most 999. It could in fact rise to 2146 without incident, but it seems cleaner to constrain the number of digits than the value.

define `MAX_VERSION_NUMBER_LENGTH 10` *for* `999/991231`

```
int parse_version_number(int vwn) {
    int i, rv, slashes = 0, digits = 0, slash_at = 0;
    char *p, *q;
    if (vwn == -1) return 0;                                    an unspecified version equates to 0/000000
    p = lw_array[vwn].lw_text; q = p;
    for (i=0; p[i] != 0; i++)
        if (p[i] == '/') {
            slashes++; if ((i == 0) || (slashes > 1)) goto Malformed;
            slash_at = i; q = p+i+1;
        } else {
            if (!(isdigit(p[i]))) goto Malformed;
            digits++;
        }
    if ((p[0] == '0') || (digits == 0)) goto Malformed;
    if ((slashes == 0) && (digits <= 3))                    so that p points to 1 to 3 digits, not starting with 0
        return atoi(p)*1000000;
    p[slash_at] = 0;                temporarily replace the slash with a null, making p and q distinct C strings
    if (strlen(p) > 3) goto Malformed;                        now p points to 1 to 3 digits, not starting with 0
    if (strlen(q) != 6) goto Malformed;
    while (*q == '0') q++;                                    now q points to 0 to 6 digits, not starting with 0
    if (q[0] == 0) q--;                                     if it was 0 digits, backspace to make it a single digit 0
    rv = (atoi(p)*1000000) + atoi(q);
    p[slash_at] = '/';                        put the slash back over the null byte temporarily dividing the string
    return rv;
    Malformed: ⟨Issue a problem message for a malformed version number 12⟩;
}
```

The function parse_version_number is called from 4/ext.

§**12.** Because we tend to call `parse_version_number` repeatedly on the same word, we want to recover tidily from this problem, and not report it over and over. We do this by altering the text to `1`, the lowest well-formed version number text.

⟨Issue a problem message for a malformed version number 12⟩ ≡

```
LOG("Offending word number %d <%s>\n", vwn, lw_array[vwn].lw_text);
sentence_problem(_P_(C4ExtVersionMalformed),
    "a version number must have the form N/DDDDDD",
    "as in the example '2/040426' for release 2 made on 26 April 2004. "
    "(The DDDDDD part is optional, so '3' is a legal version number too. "
    "N must be between 1 and 999: in particular, there is no version 0.)");
change_text_of_word(vwn, "1");
return 1000000;                                    which equates to 1/000000
```

This code is used in §11.

§13. Checking the begins here and ends here sentences. When a newly loaded extension is being sentence-broken, problem messages will be turned up unless it contains the matching pair of "begins here" and "ends here" sentences. Assuming it does, the sentence breaker has no objection, but it also calls the two routines below to verify that these sentences have the correct format. (The point of this is to catch a malformed extension at the earliest possible moment after loading it: it's easy to mis-install extensions, especially if doing so by hand, and the resulting problem messages could be quite inscrutable if one extension was wrongly identified as another.)

First, we check the "begins here" sentence. We also identify where the version number is given (if it is), and check that we are not trying to use an extension which is marked as not working on the current VM.

```
void check_extension_begins_here(parse_node *PN, extension_file *ef) {
    int i, w1, w2, aw1, aw2, vm1, vm2;
    current_sentence = PN;                                  in case problem messages need to be issued
    [[w1, w2 <-- PN]];
    ef->version_loaded = -1;
    if [[w1, w2 == version ### of ...]] {
        ef->version_loaded = w1+1; w1 += 3;
        ⟨Check that the extension's version number is well-formed 14⟩;
    }
    [[w1, w2 == the ... --> w1, w2]];
    if ([[w1, w2 == ... by ... : i --> w1, w2 ... aw1, aw2]] == FALSE)
        ⟨Issue a problem message pointing out that the author is unspecified 16⟩;
    ef->VM_restriction_w1 = -1; ef->VM_restriction_w2 = -1;
    if [[w1, w2 == ... OPENBRACKET ... CLOSEBRACKET : i --> w1, w2 ... vm1, vm2]] {
        ef->VM_restriction_w1 = vm1; ef->VM_restriction_w2 = vm2;
        ⟨Check that the extension's stipulation about the virtual machine can be met 15⟩;
    }
    if ((compare_word_range(ef->name_w1, ef->name_w2, w1, w2) == FALSE) ||
        (compare_word_range(ef->author_w1, ef->author_w2, aw1, aw2) == FALSE))
        ⟨Issue a problem message pointing out that name and author do not agree with filename 17⟩;
}
```

The function check_extension_begins_here is called from 4/sent.

§14. It is sufficient to try parsing the version number in order to check it: we throw away the answer, as we can't use it yet, but this will provoke problem messages if it is malformed.

⟨Check that the extension's version number is well-formed 14⟩ ≡

```
    parse_version_number(ef->version_loaded);
```

This code is used in §13.

§**15.** On the other hand, we do already know what virtual machine we are compiling for, so we can immediately object if the loaded extension cannot be used with our VM de jour.

⟨Check that the extension's stipulation about the virtual machine can be met 15⟩ ≡

```
switch (current_VM_matches_text(ef->VM_restriction_w1, ef->VM_restriction_w2)) {
    case TRUE: break;
    case FALSE:
        ⟨Issue a problem message saying that the VM does not meet requirements 19⟩;
        break;
    case NOT_APPLICABLE:
        ⟨Issue a problem message saying that the VM requirements are malformed 18⟩;
        break;
    default: internal_error("improper response from current_VM_matches_text");
}
```

This code is used in §13.

§**16.** The extension has to identify its author, or we come here:

⟨Issue a problem message pointing out that the author is unspecified 16⟩ ≡

```
quote_extension(1, ef);
quote_words(2, PN->word_ref1, PN->word_ref2);
handmade_problem(_P_(C4ExtMiswordedBeginsHere));
issue_problem_segment(
    "has a misworded 'begins here' sentence ('%2'), which contains "
    "no 'by'. Recall that every extension should begin with a "
    "sentence such as 'Quantum Mechanics by Max Planck begins "
    "here.', and end with a matching 'Quantum Mechanics ends "
    "here.', perhaps with documentation to follow.");
issue_problem_end();
return;
```

This code is used in §13.

§**17.** Suppose we wanted Onion Cookery by Delia Smith. We loaded the extension file called Onion Cookery in the Delia Smith folder of the (probably external) extensions area: but suppose that file turns out instead to be French Cuisine by Elizabeth David, according to its "begins here" sentence? Then the following problem message is produced:

⟨Issue a problem message pointing out that name and author do not agree with filename 17⟩ ≡

```
quote_extension(1, ef);
quote_words(2, PN->word_ref1, PN->word_ref2);
handmade_problem(_P_(C4ExtMisidentified));
issue_problem_segment(
    "The extension %1, which your source text makes use of, seems to be "
    "misidentified: its 'begins here' sentence declares it as '%2'. "
    "(Perhaps it was wrongly installed?)");
issue_problem_end();
return;
```

This code is used in §13.

§**18.** See Virtual Machines for the grammar of what can be given as a VM requirement.

⟨Issue a problem message saying that the VM requirements are malformed 18⟩ ≡

```
quote_extension(1, ef);
quote_words(2, ef->VM_restriction_w1, ef->VM_restriction_w2);
handmade_problem(_P_(C4ExtMalformedVM));
issue_problem_segment(
    "Your source text makes use of the extension %1: but my copy "
    "stipulates that it is '%2', which is a description of the required "
    "story file format which I can't understand, and should be "
    "something like '(for Z-machine version 5 or 8 only)'.");
issue_problem_end();
```

This code is used in §15.

§**19.** Here the problem is not that the extension is broken in some way: it's just not what we can currently use. Therefore the correction should be a matter of removing the inclusion, not of altering the extension, so we report this problem at the inclusion line.

⟨Issue a problem message saying that the VM does not meet requirements 19⟩ ≡

```
current_sentence = ef->inclusion_sentence;
quote_source(1, current_sentence);
quote_words(2, ef->name_w1, ef->name_w2);
quote_words(3, ef->author_w1, ef->author_w2);
quote_words(4, ef->VM_restriction_w1, ef->VM_restriction_w2);
handmade_problem(_P_(C4ExtInadequateVM));
issue_problem_segment(
    "You wrote %1: but my copy of %2 by %3 stipulates that it "
    "is '%4'. That means it can only be used with certain of "
    "the possible compiled story file formats, and at the "
    "moment, we don't fit the requirements. (You can change "
    "the format used for this project on the Settings panel.)");
issue_problem_end();
```

This code is used in §15.

§**20.** Similarly, we check the "ends here" sentence. Here there are no side-effects: we merely verify that the name matches the one quoted in the "begins here". We only check this if the problem count is still 0, since we don't want to keep on nagging somebody who has already been told that the extension isn't the one he thinks it is.

```
void check_extension_ends_here(parse_node *PN, extension_file *ef) {
    int w1, w2;
    [[w1, w2 <-- PN]];
    [[w1, w2 == the ... --> w1, w2]];
    if ((problem_count == 0) &&
        (compare_word_range(ef->name_w1, ef->name_w2, w1, w2) == FALSE)) {
        current_sentence = PN;
        quote_extension(1, ef);
        quote_words(2, PN->word_ref1, PN->word_ref2);
        handmade_problem(_P_(C4ExtMisidentifiedEnds));
        issue_problem_segment(
            "The extension %1, which your source text makes use of, seems to be "
            "malformed: its 'begins here' sentence correctly identifies it, but "
            "then the 'ends here' sentence calls it '%2' instead. (They need "
```

```
            "to be a matching pair except that the end does not name the "
            "author: for instance, 'Hocus Pocus by Jan Ackerman begins here.' "
            "would match with 'Hocus Pocus ends here.')");
        issue_problem_end();
        return;
    }
}
```

The function check_extension_ends_here is called from 4/sent.

§**21. Sentence handlers for begins here and ends here.** The main traverses of the assertions are handled by code which calls "sentence handler" routines on each node in turn, depending on type. Here are the handlers for BEGINHERE and ENDHERE. As can be seen, all we really do is start again from a clean piece of paper.

Note that, because one extension can include another, these nodes may well be interleaved: we might find the sequence A begins, B begins, B ends, A ends. The careful checking done so far ensures that these will always properly nest. We don't at present make use of this, but we might in future.

```
sentence_handler BEGINHERE_SH_handler =
    { BEGINHERE_NT, -1, 0, handle_extension_begins };
sentence_handler ENDHERE_SH_handler =
    { ENDHERE_NT, -1, 0, handle_extension_ends };

void handle_extension_begins(parse_node *PN) {
    empty_headings(0); new_discussion(); near_start_of_extension = 1;
}

void handle_extension_ends(parse_node *PN) {
    empty_headings(0); near_start_of_extension = 0;
}
```

Extension Identifiers 4/eid

Purpose

To store, hash code and compare title/author pairs used to identify extensions which, though installed, are not necessarily used in the present source text.

4/eid.§5-8 The database of known EIDs; §9 How casing is normalised; §10 Documentation links

---

Definitions

¶1. Extensions are identified by the pair of title and author name, each of which is an ISO Latin-1 string limited in length, with certain bad-news characters excluded (such as `/` and `:`) so that they can be used directly in filenames. However, we will not want to compare these by string comparison: so we hash-code the combination for speed. The following structure holds a combination of the textual names and the hash code:

```
typedef struct extension_identifier {
    char author_name[MAX_EXTENSION_AUTHOR_LENGTH];
    char raw_author_name[MAX_EXTENSION_AUTHOR_LENGTH];
    char title[MAX_EXTENSION_TITLE_LENGTH];
    char raw_title[MAX_EXTENSION_TITLE_LENGTH];
    int extension_id_hash_code;                          hash code derived from the above
} extension_identifier;
```

The structure extension_identifier is shared with 4/ext, 4/excen, 4/edict and 4/edoc.

¶2. Each EID is given a hash code – an integer between 0 and the following constant minus 1, derived from its title and author name.

```
define EI_HASH_CODING_BASE 499
```

¶3. EIDs are created with one of the following contexts:

```
define NO_EIDB_CONTEXTS 5
define LOADED_EIDBC 0
define INSTALLED_EIDBC 1
define DICTIONARY_REFERRED_EIDBC 2
define HYPOTHETICAL_EIDBC 3
define USEWITH_EIDBC 4
```

```
typedef struct extension_identifier_database_entry {
    struct extension_identifier *eide_id;
    struct extension_identifier_database_entry *hash_next;   next one in hashed EID database
    int incidence_count[NO_EIDB_CONTEXTS];
} extension_identifier_database_entry;
```

The structure extension_identifier_database_entry is private to this section.

---

§**1.** Each EID structure is written only once, and its title and author name are not subsequently altered. We therefore hash-code on arrival. As when hashing vocabulary, we apply the X 30011 algorithm, this time with 499 (coprime to 30011) as base, to the text of the Unix-style pathname `Author/Title`.

It is important that no EID structure ever be modified or destroyed once created, so it must not be stored inside a transient data structure like a `specification`.

Though it is probably the case that the author name and title supplied are already of normalised casing, we do not want to rely on that. EIDs of the same extension but named with different casing conventions would fail to match: and this could happen if a new build of NI were published which made a subtle change to the casing conventions, but which continued to use an extension dictionary file first written by previous builds under the previous conventions.

```
void eid_new(extension_identifier *eid, char *an, char *ti, int context) {
    unsigned int hc = 0, i;
    truncated_strcpy(eid->raw_author_name, an, MAX_EXTENSION_AUTHOR_LENGTH);
    truncated_strcpy(eid->author_name, an, MAX_EXTENSION_AUTHOR_LENGTH);
    normalise_extension_casing(eid->author_name);
    truncated_strcpy(eid->raw_title, ti, MAX_EXTENSION_TITLE_LENGTH);
    truncated_strcpy(eid->title, ti, MAX_EXTENSION_TITLE_LENGTH);
    normalise_extension_casing(eid->title);
    char *norm_an = eid->author_name, *norm_ti = eid->title;
    for (i=0; norm_an[i]; i++) hc = hc*30011 + (norm_an[i]);
    hc = hc*30011 + '/';
    for (i=0; norm_ti[i]; i++) hc = hc*30011 + (norm_ti[i]);
    hc = hc % EI_HASH_CODING_BASE;
    eid->extension_id_hash_code = hc;
    add_EID_to_database(eid, context);
}

void eid_set_raw(extension_identifier *eid, char *raw_an, char *raw_ti) {
    strcpy(eid->raw_author_name, raw_an);
    strcpy(eid->raw_title, raw_ti);
}

void eid_write_to_HTML_file(OUTPUT_STREAM, extension_identifier *eid, int fancy) {
    print_literal_string_to_file(OUT, eid->raw_title);
    if (fancy) WRITE("<font color=\"#404040\">");
    WRITE(" by ");
    if (fancy) WRITE("</font>");
    print_literal_string_to_file(OUT, eid->raw_author_name);
}

void eid_write_link_to_HTML_file(OUTPUT_STREAM, extension_identifier *eid) {
    WRITE("<a href='Extensions/");
    print_literal_string_to_file(OUT, eid->author_name);
    WRITE("/");
    print_literal_string_to_file(OUT, eid->title);
    WRITE(".html' STYLE=\"text-decoration: none\"><font color=\"#404040\">");
    if (eid_is_standard_rules(eid)) print_literal_string_to_file(OUT, eid->title);
    else eid_write_to_HTML_file(OUT, eid, FALSE);
    WRITE("</font></a>");
}
```

The function eid_new is called from 4/ext, 4/excen, 4/edict and 4/head.
The function eid_set_raw is called from 4/excen.
The function eid_write_to_HTML_file is called from 4/edict, 4/edoc and 12/rb.
The function eid_write_link_to_HTML_file is called from 4/edict.

§**2.** Two EIDs with different hash codes definitely identify different extensions; if the code is the same, we must use `strcmp` on the actual title and author name. This is in effect case insensitive, since we normalised casing when the EIDs were created.

(Note that this is not a lexicographic function suitable for sorting EIDs into alphabetical order: it cannot be, since the hash code is not order-preserving. To emphasise this we return true or false rather than a `strcmp`-style delta value. For `eidcmp`, see below...)

```
int eid_match(extension_identifier *eid1, extension_identifier *eid2) {
    if ((eid1 == NULL) || (eid2 == NULL)) internal_error("bad eid match");
    if (eid1->extension_id_hash_code != eid2->extension_id_hash_code) return FALSE;
    if (strcmp(eid1->author_name, eid2->author_name) != 0) return FALSE;
    if (strcmp(eid1->title, eid2->title) != 0) return FALSE;
    return TRUE;
}
```

The function eid_match is called from 4/edict and 4/head.

§**3.** This is quite a deal slower, but trichotomous.

```
int eidcmp(extension_identifier *eid1, extension_identifier *eid2) {
    int d;
    if ((eid1 == NULL) || (eid2 == NULL)) internal_error("bad eid match");
    d = strcmp(eid1->author_name, eid2->author_name);
    if (d != 0) return d;
    return strcmp(eid1->title, eid2->title);
}
```

The function eidcmp is called from 4/edict.

§**4.** Because the Standard Rules are treated slightly differently by the documentation, and so forth, it's convenient to provide a single function which asks if a given EID is talking about them.

```
int an_eid_for_standard_rules_created = FALSE;
extension_identifier an_eid_for_standard_rules;
int eid_is_standard_rules(extension_identifier *eid) {
    if (an_eid_for_standard_rules_created == FALSE) {
        an_eid_for_standard_rules_created = TRUE;
        eid_new(&an_eid_for_standard_rules,
            "Graham Nelson", "Standard Rules", HYPOTHETICAL_EIDBC);
    }
    return eid_match(eid, &an_eid_for_standard_rules);
}
```

The function eid_is_standard_rules is called from 2/prob1, 4/ext and 4/edoc.

§**5. The database of known EIDs.** We will need to be able to give rapid answers to questions like "is there an installed extension with this EID?" and "does any entry in the dictionary relate to this EID?": there may be many extensions and very many dictionary entries, so we keep an incidence count of each EID and in what context it has been used, and store that in a hash table. Note that each distinct EID is recorded only once in the table: this is important, as although an individual extension can only be loaded or installed once, it could be referred to in the dictionary dozens or even hundreds of times.

The table is unsorted and is intended for rapid searching. Typically there will be only a handful of EIDs in the list of those with a given hash code: indeed, the typical number will be 0 or 1.

```
int EID_database_created = FALSE;
extension_identifier_database_entry *hash_of_EIDEs[EI_HASH_CODING_BASE];

void add_EID_to_database(extension_identifier *eid, int context) {
    extension_identifier_database_entry *eide;
    int i, hc;
    if (EID_database_created == FALSE) {
        EID_database_created = TRUE;
        for (hc=0; hc<EI_HASH_CODING_BASE; hc++) hash_of_EIDEs[hc] = NULL;
    }
    hc = eid->extension_id_hash_code;
    for (eide = hash_of_EIDEs[hc]; eide; eide = eide->hash_next)
        if (eid_match(eid, eide->eide_id)) {
            eide->incidence_count[context]++;
            return;
        }
    eide = CREATE(extension_identifier_database_entry);
    eide->hash_next = hash_of_EIDEs[hc]; hash_of_EIDEs[hc] = eide;
    eide->eide_id = eid;
    for (i=0; i<NO_EIDB_CONTEXTS; i++) eide->incidence_count[i] = 0;
    eide->incidence_count[context] = 1;
}
```

§**6.** The purpose of the hash table is to enable us to reply quickly when asked for one of the following usage counts:

```
int no_times_EID_used_in_context(extension_identifier *eid, int context) {
    extension_identifier_database_entry *eide;
    for (eide = hash_of_EIDEs[eid->extension_id_hash_code]; eide; eide = eide->hash_next)
        if (eid_match(eid, eide->eide_id)) return eide->incidence_count[context];
    return 0;
}
```

The function no_times_EID_used_in_context is called from 4/excen, 4/edict and 4/head.

§**7.** The EID hash table makes quite interesting reading, so:

```
void log_EID_hash_table(void) {
    int hc, total = 0;
    LOG("Extension identifier hash table:\n");
    for (hc=0; hc<EI_HASH_CODING_BASE; hc++) {
        extension_identifier_database_entry *eide;
        for (eide = hash_of_EIDEs[hc]; eide; eide = eide->hash_next) {
            total++;
            LOG("%03d %3d %3d %3d %3d  %50s  %50s\n",
                hc, eide->incidence_count[0], eide->incidence_count[1],
                eide->incidence_count[2], eide->incidence_count[3],
                eide->eide_id->author_name, eide->eide_id->title);
        }
    }
    LOG("%d entries in all\n", total);
}
```

The function log_EID_hash_table is called from 4/ext.

§**8.** I dislike to use `strncpy` because, and for some reason this surprises me every time, it truncates but fails to write a null termination character if the string to be copied is larger than the buffer to write to: the result is therefore not a well-formed string and we have to fix matters by hand. This I think makes for opaque code. So:

```
void truncated_strcpy(char *to, char *from, int max) {
    int i;
    for (i=0; ((from[i]) && (i<max-1)); i++) to[i] = from[i];
    to[i] = 0;
}
```

The function truncated_strcpy is called from 2/prob3, 4/ext, 4/edict, 5/bp, 7/kov, 12/phsf, 12/br and 14/i6t.

§**9. How casing is normalised.** Every word is capitalised, where a word begins at the start of the text, after a hyphen, or after a bracket. Thus "Every Word Counts", "Even Double-Barrelled Ones (And Even Parenthetically)".

```
void normalise_extension_casing(char *p) {
    int i, uc;
    for (i=0, uc = TRUE; p[i]; i++) {
        if (uc) p[i] = toupper(p[i]);
        else p[i] = tolower(p[i]);
        uc = FALSE;
        if (p[i] == ' ') uc = TRUE;
        if (p[i] == '-') uc = TRUE;
        if (p[i] == '(') uc = TRUE;
    }
}
```

The function normalise_extension_casing is called from 4/excen.

§**10. Documentation links.** This is where HTML links to extension documentation are created; the URL for each extension's page is generated from its ID.

```
void begin_extension_link(OUTPUT_STREAM, extension_identifier *eid, char *rubric) {
    WRITE("<a href='inform://Extensions/Extensions/%s/%s.html' ", eid->author_name, eid->title);
    if (rubric) WRITE("title=\"%s\" ", rubric);
    else WRITE("title=\"%s by %s\" ", eid->title, eid->author_name);
    WRITE("STYLE=\"text-decoration: none\">");
}

void end_extension_link(OUTPUT_STREAM, extension_identifier *eid) {
    WRITE("</a>\n");
}
```

The function begin_extension_link is called from 2/index and 4/excen.
The function end_extension_link is called from 2/index and 4/excen.

Extension Census 4/excen

Purpose

To conduct a census of all the extensions installed (whether used on this run or not), and keep the documentation index for them up to date.

Definitions

¶1. In addition to the extensions read in, there are the roads not taken: the ones which NI has at its disposal, but which the source text never asks to include. NI performs a "census" of installed extensions on every run, essentially by scanning the directories which hold them to see what the user has installed there. Each extension discovered will produce a single "extension census datum", or ECD.

```
typedef struct extension_census_datum {
    struct extension_identifier ecd_id;                    title, author, hash code
    char version_text[MAX_VERSION_NUMBER_LENGTH+1];        such as 23 or 14/060527
    char VM_requirement[512];                              such as "(for Z-machine only)"
    int built_in;                                          found in the Inform 7 application's private stock
    int overriding_a_built_in_extension;                   not built in, but overriding one which is
    char *domain;                                          pathname of the stock in which this was found
    char rubric[MAX_RUBRIC_LENGTH+1];                      brief description found in opening lines
    struct extension_census_datum *next;                   next one in lexicographic order
    MEMORY_MANAGEMENT
} extension_census_datum;
```

The structure extension_census_datum is shared with 4/edoc.

¶2. The extension census results are then tabulated in lexicographic order in an array of linked lists, one for each possible first-letter-of-author-name:

```
extension_census_datum *extension_census_results[256];     list starting with each letter
```

---

§**1.** This is a narrative section and describes the story of the census. Just as Caesar Augustus decreed that all the world should be taxed, and that each should return to his place of birth, so we will open and inspect every extension we can find, checking that each is in the right place.

Note that if the same extension is found in more than one domain, the first to be found is considered the definitive version: this is why the external area is searched first, so that the user can override built-in extensions by placing his own versions in the external area. (Should this convention ever be reversed, a matching change would need to be made in the code which opens extension files in Read Source Text.)

```
void extension_census(void) {
    ⟨Make sure the external extensions area exists, so that it can be searched 2⟩;
    begin_recording_census_errors();
    count user-installed extensions first
    take_census_of_domain(pathname_of_extensions, FALSE);
    and then count the built-in ones
    take_census_of_domain(pathname_of_built_in_extensions, TRUE);
    end_recording_census_errors();
}
```

The function extension_census is called from 4/ext.

§**2.** We will need to search both the built-in extension area, and also the external one. The latter cannot be guaranteed to exist – and indeed will not, if NI is being run for the first time after Inform is installed. Should anything go wrong we simply abandon the census: it wasn't all that crucial, and we don't want to deprive the user of the enjoyment of his successfully compiled story file just because we're (say) running with inadequate permissions to read the external area.

⟨Make sure the external extensions area exists, so that it can be searched 2⟩ ≡

```
    if (verify_installed_extensions_tree() == FALSE) return;
```

This code is used in §1.

§**3. Conducting the census.** An "extension domain", for these purposes, is a directory in the filing system which can contain extensions (providing these are themselves placed in subdirectories identifying their authorship). The built-in domain is special (it is read-only, for one thing), but in principle we could have any number of other domains. The following code scans one.

```
char *current_extension_domain;
void take_census_of_domain(char *pathname, int built_in) {
    current_extension_domain = pathname;
    census_from(pathname, TRUE, built_in, "");
}
```

§**4.** The following routine is not as recursive as it looks, since it runs at only two levels: a top level, when it is scanning the domain, and an inner level, when it is scanning the subfolder of the domain for a given author.

The reader may wince at the way we scan a directory – we essentially dump a catalogue listing to a temporary text file and then read it back in, one line at a time – but it works properly on all platforms, which is important given how poorly directory handling is standardised in C.

Because of the two-level recursion, there are two such temporary files, `Temporary1.txt` at the upper level and `Temporary0.txt` below. These are stored in the external Extensions area. In principle that could be problematic since two processes running Inform on the same machine may be simultaneously taking an extension census, so could lock each other out: probably we ought to include a process ID in the filenames. But then we would have further platform hassles, and we would need to delete the files when done, and worry about what happens if Inform is aborted half-way. (When `intest` does large multiprocessing test runs of Inform, indexing is turned off, so extension censuses are not being taken.)

```
void census_from(char *pathname, int top_level, int built_in, char *parent) {
    char path_to_folder[2*MAX_FILENAME_LENGTH];
    char path_to_temp[MAX_FILENAME_LENGTH];
    char item_name[MAX_FILENAME_LENGTH+1];
    FILE *TEMPF;
    int linecount = 0;
    transcode_ISO_string_to_locale(pathname, path_to_folder);
    sprintf(path_to_temp, "%s%cTemporary%d.txt", pathname_of_extension_docs,
        FOLDER_SEPARATOR, top_level);
    if (write_folder_contents_to_file(path_to_folder, path_to_temp) == FALSE) {
        LOGIF(EXTCENSUS, "Unable to obtain contents of <%s>\n", pathname);
        return;
    }
    TEMPF = iso_fopen(path_to_temp, "r");
    if (TEMPF == NULL) fatal_error("Unable to open temporary file for reading");
    while (truncated_locale_fgets(TEMPF, item_name, MAX_FILENAME_LENGTH+1) >= 1) {
```

```
        int n = strlen(item_name) - 1;
        if (n<0) continue;
        LOGIF(EXTCENSUS, "%d: %s\n", linecount++, item_name);
        if (top_level) ⟨Take census from a possible author folder 5⟩
        else ⟨Take census from a possible extension 6⟩;
    }
    fclose(TEMPF);
}
```

§**5.** At the upper level, we expect every item to be a subfolder whose name is that of a given author. We can identify folder names because of the terminating slash `/`: note that this character is used regardless of whether or not it is the platform's file separator, and that it is illegal in extension titles or author names. (See Filenames for more on how `write_folder_contents_to_file` describes a directory.)

It is a "census error" – meaning, we have detected a misinstallation of extensions – if any file is present, or any folder too long for its name to be an author name, except that items with names beginning with a `.` are ignored. (In particular, the folders `./` and `../` are ignored, but so too are OS X Finder files like `.DS_Store`, and other such junk. No author name or title is allowed to contain a `.` character, so this cannot throw away valid census entries.)

The author name `Reserved` is, of course, reserved: the author of an extension is not allowed to be "Reserved", and this subfolder is used by Inform for its own purposes. Otherwise any reasonably short name of filename-safe characters is valid as an author name.

Once we have a valid, non-reserved author subfolder, we recurse down to lower level to scan it.

⟨Take census from a possible author folder 5⟩ ≡

```
    if (item_name[0] == '.') continue;
    if (item_name[n] == '/') {
        char path_to_sub[MAX_FILENAME_LENGTH];
        item_name[n] = 0;                                   remove the terminal slash: it has served its purpose
        if (strcmp(item_name, "Reserved") == 0) continue;
        if (strlen(item_name) > MAX_EXTENSION_TITLE_LENGTH-1) {
            census_error("author name exceeds the maximum permitted length",
                item_name, NULL, NULL, NULL); continue;
        }
        sprintf(path_to_sub, "%s%c%s", pathname, FOLDER_SEPARATOR, item_name);
        census_from(path_to_sub, FALSE, built_in, item_name);
        continue;
    }
    census_error("non-folder found where author folders should be",
        item_name, NULL, NULL, NULL); continue;
```

This code is used in §4.

§**6.** At the lower level, . files or folders are again skipped; any other folders are a census error, since there should only be extension files present; and once again, we enforce the title length restriction.

As will be seen from the logic below, an extension is only given a census entry (and therefore included in the HTML documentation of installed extensions) if no census errors arise from it. An Inform user can therefore know that if an extension shows up on his documentation page, it is properly installed and identifies itself correctly, and moreover that it can be installed correctly on other Informs elsewhere (perhaps on other platforms).

define `MAX_TITLING_LINE_LENGTH 501` *lots, allowing for an improbably large number of virtual machine restrictions*

⟨Take census from a possible extension 6⟩ ≡

```
int overridden_by_an_extension_already_found = FALSE;
char candidate_title[MAX_EXTENSION_TITLE_LENGTH + 1],
    raw_title[MAX_EXTENSION_TITLE_LENGTH + 1];
char candidate_author_name[MAX_EXTENSION_TITLE_LENGTH + 1],
    raw_author_name[MAX_EXTENSION_TITLE_LENGTH + 1];
char titling_line[MAX_TITLING_LINE_LENGTH], rubric_text[MAX_RUBRIC_LENGTH + 1];
char version_text[MAX_TITLING_LINE_LENGTH], requirement_text[MAX_TITLING_LINE_LENGTH];
char claimed_author_name[MAX_TITLING_LINE_LENGTH], claimed_title[MAX_TITLING_LINE_LENGTH];
if (item_name[0] == '.') continue;
if (item_name[n] == '/') {
    census_error("folder or application in author folder",
        parent, item_name, NULL, NULL); continue;
}
if (strlen(item_name) > MAX_EXTENSION_TITLE_LENGTH-1) {
    census_error("title exceeds the maximum permitted length",
        parent, item_name, NULL, NULL); continue;
}
⟨Make candidate title and author name from normalised casing versions of filename and parent folder name 7⟩;
⟨Extract the titling line and rubric, if any, from the extension file 9⟩;
⟨Parse the version, title, author and VM requirements from the titling line 13⟩;
⟨Check that the candidate name and title match those claimed in the titling line 17⟩;
⟨See if we duplicate the title and author name of an extension already found in another domain 18⟩;
if (overridden_by_an_extension_already_found == FALSE) {
    extension_census_datum *ecd;
    ⟨Create a new census datum for this extension, which has passed all tests 19⟩;
    ⟨Add the new census datum into the census list, keeping this in lexicographic order 20⟩;
}
```

This code is used in §4.

§**7.** If we find an extension at the relative pathname `Emily Short/Locksmith` then we expect it to be Locksmith by Emily Short: these are the candidate author name and title respectively. (What the file actually contains is another matter, as we shall see.)

All titles and author names have to be stored carefully in case-normalised form at all times, and this extends to the filename and folder name. Enforcing this rule may seem needlessly bureaucratic, since for the majority of users (using typical Mac OS X and Windows installations) the filing system preserves the case of filenames but is not sensitive to case when searching for files: thus the folders `jimmy stewart` and `Jimmy Stewart` behave identically in practice. But we want to use `strcmp` for case-sensitive comparisons, for instance.

There are active Inform users who do have a case-sensitive filing system (on some of the Linux and Solaris ports), and we want extension files to continue to work perfectly if taken from one Inform installation and added to another. So the previously strict rules on casing of the filenames as stored have been waived.

⟨Make candidate title and author name from normalised casing versions of filename and parent folder name 7⟩ ≡

```
strcpy(candidate_author_name, parent);
strcpy(candidate_title, item_name);
⟨Remove filename extension for extensions, if any 8⟩;
strcpy(raw_title, candidate_title);
strcpy(raw_author_name, candidate_author_name);
normalise_extension_casing(candidate_author_name);
normalise_extension_casing(candidate_title);
if (FALSE) {
    if (strcmp(candidate_author_name, parent) != 0) {
        census_error("file is in a folder whose name does not use upper and "
            "lower case correctly (should be, e.g., 'Cary Grant' not 'cary "
            "grant' or 'CARY GRANT')",
            parent, item_name, NULL, NULL); continue;
    }
    if (strcmp(candidate_title, item_name) != 0) {
        census_error("file name does not use upper and "
            "lower case correctly (should be, e.g., 'Going To The Zoo' not 'going "
            "to the zoo' or 'Going to the Zoo')",
            parent, item_name, NULL, NULL); continue;
    }
}
```

This code is used in §6.

§**8.** We permit (encourage, actually) the filename extension ".i7x" for extensions, in any of its possible casings, and that of course isn't part of the title:

⟨Remove filename extension for extensions, if any 8⟩ ≡

```
if ((n>=5) &&
    (candidate_title[n-3] == '.') &&
    ((candidate_title[n-2] == 'i') || (candidate_title[n-2] == 'I')) &&
    (candidate_title[n-1] == '7') &&
    ((candidate_title[n] == 'x') || (candidate_title[n-2] == 'X')))
        candidate_title[n-3] = 0;
```

This code is used in §7.

§**9. Handling the extension file.** This and the next three paragraphs do the file-handling necessary to open the extension, extract its titling line and rubric, then close it again.

⟨Extract the titling line and rubric, if any, from the extension file 9⟩ ≡

```
FILE *EXTF;
⟨Open the extension file for reading 10⟩;
⟨Read the titling line of the extension and normalise its casing 11⟩;
⟨Read the rubric text, if any is present 12⟩;
fclose(EXTF);
```

This code is used in §6.

§**10.** The following should only fail in the event of some peculiar filing system failure (or of some other process having moved or deleted the file since we scanned the folder only moments ago).

⟨Open the extension file for reading 10⟩ ≡

```
char path_to_ext[MAX_FILENAME_LENGTH];
sprintf(path_to_ext, "%s%c%s%c%s",
    current_extension_domain, FOLDER_SEPARATOR, parent, FOLDER_SEPARATOR, item_name);
EXTF = iso_fopen_caseless(path_to_ext, "r");
if (EXTF == NULL) {
    census_error("file cannot be read",
        parent, item_name, NULL, NULL); continue;
}
```

This code is used in §9.

§**11.** The actual maximum number of characters in the titling line is one less than `MAX_TITLING_LINE_LENGTH`, to allow for the null terminator. The titling line is terminated by any of `0A`, `0D`, `0A 0D` or `0D 0A`, or by the local `\n` for good measure.

⟨Read the titling line of the extension and normalise its casing 11⟩ ≡

```
int titling_chars_read = 0, c;
titling_line[0] = 0;
while ((c = utf8_fgetc(EXTF, FALSE)) != EOF) {
    if (c == 0xFEFF) continue;                    skip the optional Unicode BOM pseudo-character
    if ((c == '\x0a') || (c == '\x0d') || (c == '\n')) break;
    if (titling_chars_read < MAX_TITLING_LINE_LENGTH - 1)
        titling_line[titling_chars_read++] = c;
}
titling_line[titling_chars_read--] = 0;
normalise_extension_casing(titling_line);
```

This code is used in §9.

§**12.** In the following, all possible newlines are converted to white space, and all white space before a quoted rubric text is ignored. We need to do this partly because users have probably keyed a double line break before the rubric, but also because we might have stopped reading the titling line halfway through a line division combination like `0A 0D`, so that the first thing we read here is a meaningless `0D`.

⟨Read the rubric text, if any is present 12⟩ ≡

```
int rubric_chars_read = 0, c, found_start = FALSE;
while ((c = utf8_fgetc(EXTF, FALSE)) != EOF) {
    if (rubric_chars_read >= MAX_RUBRIC_LENGTH) break;
    if ((c == '\x0a') || (c == '\x0d') || (c == '\n') || (c == '\t')) c = ' ';
    if ((c != ' ') && (found_start == FALSE)) {
        if (c == '"') found_start = TRUE;
        else break;
    } else {
        if (c == '"') break;
        if (found_start) rubric_text[rubric_chars_read++] = c;
    }
}
rubric_text[rubric_chars_read] = 0;
```

This code is used in §9.

§13. Parsing the titling line. In general, once case-normalised, a titling line looks like this:

Version 2/070423 Of Going To The Zoo (For Glulx Only) By Cary Grant Begins Here.

and the version information, the VM restriction and the full stop are all optional, but the division word "of" and the concluding "begin[s] here" are not. We break it up into pieces, so that

```
version_text = "2/070423"
claimed_title = "Going To The Zoo"
claimed_author_name = "Cary Grant"
requirement_text = "(For Glulx Only)"
```

It's tempting to do this by feeding it into the lexer and then reusing some of the code which parses these lines during sentence-breaking, but in fact we want to use the information rather differently, and besides: it seems useful to record some C code here which correctly parses a titling line, since this can easily be extracted and used in other utilities handling Inform extensions.

⟨Parse the version, title, author and VM requirements from the titling line 13⟩ ≡

```
int start = 0, end = strlen(titling_line) - 1;
while ((end>=0) && ((titling_line[end] == ' ') ||
    (titling_line[end] == '\t') || (titling_line[end] == '.'))) {
    titling_line[end] = 0; end--;          trim white space or full stops from the end of the titling line
}
if ((end < strlen(" Begin Here")) || (strcmp(titling_line+end-4, " Here") != 0)) {
    census_error("appears not to be an extension (its first line does "
        "not end 'begin(s) here', as extension titling lines must)",
        parent, item_name, NULL, NULL); continue;
}
end -= 5; if (titling_line[end] == 's') end--;
titling_line[end+1] = 0;                                        trim "s Here" or " Here"
if (strcmp(titling_line+end-5, " Begin") != 0) {
    census_error("appears not to be an extension (its first line does "
        "not end 'begin(s) here', as extension titling lines must)",
        parent, item_name, NULL, NULL); continue;
}
end -= 6; titling_line[end+1] = 0;                                        trim " Begin"
⟨Scan the version text, if any, and advance to the position past Version... Of 14⟩;
if (strncmp(titling_line+start, "The ", 4) == 0) start += 4;          advance past any "The "
⟨Divide the remaining text into a claimed author name and title, divided by By 15⟩;
⟨Extract the VM requirements text, if any, from the claimed title 16⟩;
```

This code is used in §6.

§**14.** Ah, the pleasures of C string hackery. Here, `begin` and `end` are the positions of the first and last character (not the null terminator) in the unparsed part of the titling line. To advance means to increase `begin`.

We make no attempt to check the version number for validity: the purpose of the census is to identify extensions and reject accidentally included other files, not to syntax-check all extensions to see if they would work if used.

⟨Scan the version text, if any, and advance to the position past Version... Of 14⟩ ≡

```
int l;
version_text[0] = 0;
if (strncmp(titling_line, "Version ", 8) == 0)
    for (l=0, start=0; titling_line[l]; l++)
        if (strncmp(titling_line + l, " Of ", 4) == 0) {
            for (start=8; start<l; start++) version_text[start-8] = titling_line[start];
            version_text[l-8] = 0;
            start = l+4;
            break;
        }
```

This code is used in §13.

§**15.** The earliest "by" is the divider: note that extension titles are not allowed to contain this word, so "North By Northwest By Cary Grant" is not a situation we need to contend with.

⟨Divide the remaining text into a claimed author name and title, divided by By 15⟩ ≡

```
int l, j;
claimed_author_name[0] = 0;
claimed_title[0] = 0;
for (l=start; titling_line[l]; l++)
    if (strncmp(titling_line+l, " By ", 4) == 0) {
        for (j=start; j<l; j++) claimed_title[j-start] = titling_line[j];
        claimed_title[l-start] = 0;
        for (j=l+4; titling_line[j]; j++) claimed_author_name[j-l-4] = titling_line[j];
        claimed_author_name[j-l-4] = 0;
        break;
    }
if ((claimed_author_name[0] == 0) || (claimed_title[0] == 0)) {
    census_error("appears not to be an extension (the titling line does "
        "not give both author and title)",
        parent, item_name, NULL, NULL); continue;
}
```

This code is used in §13.

§**16.** Similarly, extension titles are not allowed to contain parentheses, so this is unambiguous.

⟨Extract the VM requirements text, if any, from the claimed title 16⟩ ≡

```
int l;
requirement_text[0] = 0;
for (l=0; claimed_title[l]; l++)
    if (claimed_title[l] == '(') {
        strcpy(requirement_text, claimed_title + l);
        claimed_title[l] = 0;                                   truncate to just before open bracket
        while ((l>0) && (claimed_title[l-1] == ' ')) {          trim spaces from the end
            l--; claimed_title[l] = 0;
        }
        break;
    }
```

This code is used in §13.

§**17. Making sure this is the extension we expected to find.** It's easier for these confusions to arise than might be thought. For instance, if two different authors independently write extensions called "Followers", it would be easy to put a file of this name in the wrong author folder by mistake. Since extension installation is usually handled mechanically (and, we hope, correctly) by the Inform application, such problems are only likely to arise when users install extensions by hand. Still, it's prudent to check.

⟨Check that the candidate name and title match those claimed in the titling line 17⟩ ≡

```
int right_leafname = FALSE, right_folder = FALSE;
if (strcmp(claimed_title, candidate_title) == 0) right_leafname = TRUE;
if (strcmp(claimed_author_name, candidate_author_name) == 0) right_folder = TRUE;
if ((right_leafname == TRUE) && (right_folder == FALSE)) {
    census_error("an extension with the right filename but in the wrong "
        "author's folder",
        parent, item_name, claimed_author_name, claimed_title); continue;
}
if ((right_leafname == FALSE) && (right_folder == TRUE)) {
    census_error("an extension stored in the correct author's folder, but "
        "with the wrong filename",
        parent, item_name, claimed_author_name, claimed_title); continue;
}
if ((right_leafname == FALSE) && (right_folder == FALSE)) {
    census_error("an extension but with the wrong filename and put in the "
        "wrong author's folder",
        parent, item_name, claimed_author_name, claimed_title); continue;
}
```

This code is used in §6.

§**18. Adding the extension to the census, or not.** Recall that the higher-priority external domain is scanned first; the built-in domain is scanned second. So if we find that our new extension has the same title and author as one already known, it must be the case that we are now scanning the built-in area and that the previous one was an extension which the user had installed to override this built-in extension.

⟨See if we duplicate the title and author name of an extension already found in another domain 18⟩ ≡

```
extension_census_datum *other;
LOOP_OVER(other, extension_census_datum)
    if ((strcmp(candidate_author_name, other->ecd_id.author_name) == 0)
        && (strcmp(candidate_title, other->ecd_id.title) == 0)) {
        other->overriding_a_built_in_extension = TRUE;
        overridden_by_an_extension_already_found = TRUE;
    }
```

This code is used in §6.

§**19.** Assuming the new extension was not overridden in this way, we come here. Because we didn't check the version number text for validity, it might through being invalid be longer than we expect: in case this is so, we truncate it.

⟨Create a new census datum for this extension, which has passed all tests 19⟩ ≡

```
ecd = CREATE(extension_census_datum);
eid_new(&(ecd->ecd_id), candidate_author_name, candidate_title, INSTALLED_EIDBC);
eid_set_raw(&(ecd->ecd_id), raw_author_name, raw_title);
strcpy(ecd->VM_requirement, requirement_text);
version_text[MAX_VERSION_NUMBER_LENGTH] = 0;                    truncate to maximum legal length
strcpy(ecd->version_text, version_text);
ecd->domain = current_extension_domain;
ecd->built_in = built_in;
ecd->overriding_a_built_in_extension = FALSE;
ecd->next = NULL;
rubric_text[MAX_RUBRIC_LENGTH-1] = 0;
strcpy(ecd->rubric, rubric_text);
```

This code is used in §6.

§**20.** We now insertion-sort the new ECD into the census: that is, run through it from A to Z, stopping where the new one should be entered. It may seem that sorting is unnecessary, since the filename listings made to carry out the census will be in alphabetical order anyway: and on some platforms, some of the time, that might even be true.

We insertion-sort these ECDs, which would have rather poor running time if there are thousands rather than dozens of extensions. So we ameliorate this by using an ordered hash table – though that is a very grand way of putting it: the hash code used here is just the first letter of the author's name and the hash table is therefore only an array of alphabetised lists of all extensions by authors beginning with A, with B, and so on. The bunching of names means that this probably only speeds us up by a factor of 10 or so (E is a particular spike, thanks to the prolific work of Emily Short, but also Eric Eve): using the first letter of the title would be more efficient, but that wouldn't respect lexicographic order, since we sort by author then title not vice versa. The empty author name is not allowed, so there always is first letter (in the case of "Anonymous", it will be A).

Because the extension identifiers for ECDs always have title and name extension-normalised in casing, we can use `strcmp` to compare them and not worry about its being case-sensitive.

⟨Add the new census datum into the census list, keeping this in lexicographic order 20⟩ ≡

```
int initial_letter = candidate_author_name[0];
```

```
    extension_census_datum *prev = NULL;
    extension_census_datum *link = extension_census_results[initial_letter];
    while ((link) && (strcmp(link->ecd_id.author_name, ecd->ecd_id.author_name) < 0)) {
        prev = link; link = link->next;                    skip extensions by alphabetically earlier authors
    }
    while ((link) && (strcmp(link->ecd_id.author_name, ecd->ecd_id.author_name) == 0) &&
        (strcmp(link->ecd_id.title, ecd->ecd_id.title) < 0)) {
        prev = link; link = link->next;                  skip extensions by same author with earlier titles
    }
    if (prev == NULL) {                                          make new ECD the new first item in the list
        ecd->next = extension_census_results[initial_letter];
        extension_census_results[initial_letter] = ecd;
    } else {                                                  insert new ECD after prev in the list
        ecd->next = prev->next;
        prev->next = ecd;
    }
```

This code is used in §6.

§**21. Census errors.** To recap, the extension census process involves looking for all the extensions NI can find, but also checking them: are the files genuine, that is, do they appear to be suitable text files with the correct identifying first lines? Or have binary files crept in, or genuine extension but which have been given the wrong location or filename? When any of these checks fails, a census error is generated: there are about a dozen different kinds.

These are dumped to a temporary text file in the external extensions area, to be appended to the extensions directory page later on. Once again, this is not thread-safe: two simultaneous attempts by different Inform processes to take a census might collide.

```
int no_census_errors = 0;
STREAM CENERR_struct;
STREAM *CENERR = NULL;

void begin_recording_census_errors(void) {
    no_census_errors = 0;
    CENERR = NULL;
}

int currently_recording_census_errors(void) {
    if (CENERR) return TRUE;
    return FALSE;
}

void end_recording_census_errors(void) {
    if (CENERR) STREAM_CLOSE(CENERR);
    CENERR = NULL;
}
```

The function currently_recording_census_errors is called from 4/ext.

§**22.** When a census error arises, then, we write it as a line to the text file. The line ends with an HTML break tag `<br>` since this copy is destined to be used in an HTML catalogue.

```
void census_error(char *message, char *auth, char *title,
    char *claimed_author, char *claimed_title) {
    no_census_errors++;
    if (CENERR == NULL) {
        char path_to_errors[MAX_FILENAME_LENGTH];
        sprintf(path_to_errors, "%s%cReserved%cCensusErrors.txt",
            pathname_of_extensions, FOLDER_SEPARATOR, FOLDER_SEPARATOR);
        CENERR = &CENERR_struct;
        if (STREAM_OPEN_TO_FILE(CENERR, path_to_errors, UTF8_ENC) == FALSE)
            fatal_error2("Unable to write census error log", path_to_errors);
    }
    if (claimed_author)
        STREAM_WRITE(CENERR, "%s by %s - %s (the extension says it is '%s by %s')<br>\n",
            title, auth, message, claimed_title, claimed_author);
    else if ((auth) && (title)) STREAM_WRITE(CENERR, "%s by %s - %s<br>\n", title, auth, message);
    else STREAM_WRITE(CENERR, "%s - %s<br>\n", auth, message);
}
```

§**23.** And this is where the inclusion of that material into the catalogue is taken care of. First, we sometimes position a warning prominently at the top of the listing, because otherwise its position at the bottom will be invisible unless the user scrolls a long way:

```
void warn_about_census_errors(OUTPUT_STREAM) {
    if (no_census_errors == 0) return;                                  no need for a warning
    if (NUMBER_CREATED(extension_census_datum) < 20) return;            it's a short page anyway
    WRITE("<p><img border=0 src=inform:/doc_images/census_problem.png> "
        "<b>Warning</b>. One or more extensions have been installed incorrectly: "
        "see the details at the foot of the page for more.<p>");
}
```

§**24.** A minor subtlety here is that the census errors file is ISO Latin-1 encoded, with HTML tags in: we need to write it to a UTF-8 file, and therefore have to convert each line we copy.

define `LONGEST_POSSIBLE_CENSUS_ERROR MAX_TITLING_LINE_LENGTH*2`

```
void transcribe_census_errors(OUTPUT_STREAM) {
    FILE *RESULTS;
    char path_to_errors[MAX_FILENAME_LENGTH];
    char error_line[LONGEST_POSSIBLE_CENSUS_ERROR];
    if (no_census_errors == 0) return;                                  nothing to include, then
    sprintf(path_to_errors, "%s%cReserved%cCensusErrors.txt",
        pathname_of_extensions, FOLDER_SEPARATOR, FOLDER_SEPARATOR);
    RESULTS = iso_fopen(path_to_errors, "r");
    if (RESULTS == NULL) fatal_error2("Unable to read census error log", path_to_errors);
    ⟨Include the headnote explaining what census errors are 25⟩;
    while (truncated_iso_fgets(RESULTS, error_line, LONGEST_POSSIBLE_CENSUS_ERROR) >= 1) {
        WRITE("%s", error_line);
        WRITE("\n");
    }
    fclose(RESULTS);
}
```

§**25.** We only want to warn people here: not to stop them from using Inform until they put matters right. (Suppose, for instance, they are using an account not giving them sufficient privileges to modify files in the external extensions area: they'd then be locked out if anything was amiss there.)

⟨Include the headnote explaining what census errors are 25⟩ ≡

```
WRITE("<p><img border=0 src=inform:/doc_images/census_problem.png> "
    "<b>Warning</b>. Inform checks the folder of user-installed extensions "
    "each time it translates the source text, in order to keep this directory "
    "page up to date. Each file must be a properly labelled extension (with "
    "its titling line correctly identifying itself), and must be in the right "
    "place - e.g. 'Marbles by Daphne Quilt' must have the filename 'Marbles' "
    "(with no file extension) and be stored in the folder 'Daphne Quilt'. "
    "The title should be at most %d characters long; the author name, %d. "
    "At the last check, these rules were not being followed:<p>",
        MAX_EXTENSION_TITLE_LENGTH, MAX_EXTENSION_AUTHOR_LENGTH);
```

This code is used in §24.

§**26.** Here we write the copy for the directory page of the extensions documentation: the one which the user currently sees by clicking on the "Installed Extensions" link from the contents page of the documentation. It contains an alphabetised catalogue of extensions by author and then title, along with some useful information about them, and then a list of any oddities found in the external extensions area.

```
void write_extensions_census_to_HTML_file(OUTPUT_STREAM) {
    int key_vms = FALSE, key_override = FALSE, key_builtin = FALSE, key_bullet = FALSE;
    int initial_letter;
    warn_about_census_errors(OUT);
    for (initial_letter = 0x20; initial_letter < 0x100; initial_letter++) {
        extension_census_datum *ecd;
        char *current_author_name = "";
        for (ecd = extension_census_results[initial_letter]; ecd; ecd = ecd->next) {
            if (strcmp(current_author_name, ecd->ecd_id.author_name) != 0) {
                current_author_name = ecd->ecd_id.author_name;
                WRITE("<p><b>%s</b><br>", ecd->ecd_id.raw_author_name);
            }
            ⟨Print the census line for this extension 27⟩;
        }
    }
    ⟨Print the key to any symbols used in the census lines 29⟩;
    transcribe_census_errors(OUT);
}
```

The function write_extensions_census_to_HTML_file is called from 4/ext.

§**27.** The appearance of the line is

(bullet) The Title (icon) (VM requirement icons) Version (number)

where all is optional except the title part. The bullet appears if the extension has been loaded on this run of NI, or is in the dictionary as a result of having been loaded on some previous run of NI: it therefore indicates that this an extension the user sometimes uses.

```
define UNINDEXED_SYMBOL "<img border=\"0\" src=\"inform:/doc_images/unindexed_bullet.png\">"
define INDEXED_SYMBOL "<img border=\"0\" src=\"inform:/doc_images/indexed_bullet.png\">"
define BUILT_IN_SYMBOL "<img border=\"0\" src=\"inform:/doc_images/builtin_ext.png\">"
define OVERRIDING_SYMBOL "<img border=\"0\" src=\"inform:/doc_images/override_ext.png\">"
```

⟨Print the census line for this extension 27⟩ ≡

```
    char *bulletornot = UNINDEXED_SYMBOL;
    if ((no_times_EID_used_in_context(&(ecd->ecd_id), LOADED_EIDBC) > 0) ||
        (no_times_EID_used_in_context(&(ecd->ecd_id), DICTIONARY_REFERRED_EIDBC) > 0)) {
        bulletornot = INDEXED_SYMBOL; key_bullet = TRUE;
    }
    WRITE("    %s", bulletornot);
    begin_extension_link(OUT, &(ecd->ecd_id), ecd->rubric);
    WRITE("<font color=\"#404040\">%s</font>", ecd->ecd_id.title);
    end_extension_link(OUT, &(ecd->ecd_id));
    if (ecd->built_in) {
        WRITE(" %s", BUILT_IN_SYMBOL); key_builtin = TRUE; }
    if (ecd->overriding_a_built_in_extension) {
        WRITE(" %s", OVERRIDING_SYMBOL); key_override = TRUE; }
    if (ecd->VM_requirement[0]) {
        ⟨Append icons which signify the VM requirements of the extension 28⟩;
        key_vms = TRUE; }
    if (ecd->version_text[0])
        WRITE("   <small>Version %s</small> ", ecd->version_text);
    WRITE("<br>");
```

This code is used in §26.

§**28.** VM requirements are parsed by feeding them into the lexer and calling the same routines as would be used when parsing headings about VM requirements in a normal run of NI. Note that because the requirements are in round brackets, which the lexer will split off as distinct words, we can ignore the first and last word and just look at what is in between:

⟨Append icons which signify the VM requirements of the extension 28⟩ ≡

```
    int rw1 = lexer_wordcount, rw2;
    feed_into_lexer(ecd->VM_requirement, FALSE, FALSE);
    rw2 = lexer_wordcount - 1;
    feed_into_lexer("Another firebreak. ", FALSE, FALSE);
    WRITE(" ");
    write_VM_icons(OUT, rw1+1, rw2-1);
```

This code is used in §27.

§**29.** The key at the foot only explicates those symbols actually used, and doesn't explicate the "unindexed" symbol at all, since that's actually just a blank image used for horizontal spacing to keep margins straight.

⟨Print the key to any symbols used in the census lines 29⟩ ≡

```
if ((key_builtin) || (key_override) || (key_bullet) || (key_vms)) {
    WRITE("<p>Key: ");
    if (key_bullet) WRITE("%s Used and indexed ", INDEXED_SYMBOL);
    if (key_builtin) WRITE("%s Built in to Inform ", BUILT_IN_SYMBOL);
    if (key_override) WRITE("%s User-installed version overrides "
        "the one built in to Inform ", OVERRIDING_SYMBOL);
    if (key_vms) {
        WRITE("<br>");
        write_VM_key(OUT);
    }
}
```

This code is used in §26.

Extension Dictionary 4/edict

Purpose

To maintain a database of names and constructions in all extensions so far used by this installation of Inform, and spot potential namespace clashes.

Definitions

¶1. Not during the census, but rather when extensions are successfully used, a dictionary is kept of the terms defined in them: this is used to generate the dynamic documentation on installed extensions, and is stored between runs in a cache file inside the I7 application. This means dictionary entries are first read in from the cache; then the entries for any extension used by NI in its current run are revised, which may mean deleting some entries or adding new ones; and at last NI writes the final state of the dictionary back to the cache. In this way, changes in what an extension defines are reflected in the dictionary after each successful use of that extension.

```
define MAX_ED_CATEGORY_LENGTH 32
define MAX_ED_HEADWORD_LENGTH 128

typedef struct extension_dictionary_entry {
    struct extension_identifier ede_id;                          author name and title, with hash code
    char entry_text[MAX_ED_HEADWORD_LENGTH];                     text of the dictionary entry
    char sorting[MAX_ED_HEADWORD_LENGTH + 10];                   text reprocessed for sorting purposes
    char type[MAX_ED_CATEGORY_LENGTH];                           grammatical category, such as "kind"
    int erased;                                                  marked to be erased
    struct extension_dictionary_entry *next_in_sorted_dictionary;  link in linked list
    MEMORY_MANAGEMENT
} extension_dictionary_entry;

extension_dictionary_entry *first_in_sorted_dictionary = NULL;
```

The structure extension_dictionary_entry is private to this section.

¶2. Clashes occur if, say, two extensions define "chopper" as a kind of vehicle (for instance, meaning a helicopter in one and a motorcycle in the other). This results in two dictionary entries under "chopper" and is recorded as a clash between them. Often, more will turn up: perhaps "chopper" might elsewhere mean a butchery tool. In the event of 3 or more clashing entries, $A, B, C, ...$, a linked list of ordered pairs $(A, B), (A, C), ...$ is maintained where in each pair the first term (the left one) is from an extension lexicographically earlier than the second (the right one): see below.

```
typedef struct known_extension_clash {
    int first_known;                                  heads a linked list of clashes with a given ede1
    struct known_extension_clash *next;               next in linked list of clashes
    struct extension_dictionary_entry *leftx;         clash is between this entry...
    struct extension_dictionary_entry *rightx;        ...and this one
    int number_clashes;                               number of entries clashing between ede1 and ede2
    MEMORY_MANAGEMENT
} known_extension_clash;
```

The structure known_extension_clash is private to this section.

§**1.** The extension dictionary has no natural order as such. In order to generate the dictionary page of the documentation, we will sort it alphabetically, but it is not alphabetically stored either in memory or in its serialised form on disc. (It might seem advantageous, since we're going to sort it anyway, to use the sorted ordering when saving it back to disc, as at least the structure will then be nearly sorted most of the time: but in fact the reverse is true, because we will sort using the C library's implementation of quicksort, an algorithm whose worst-case performance is on nearly sorted lists.)

§**2.** The following sample is an extract of the dictionary in its serialised form on disc. The four columns are author, title, headword and category. The special entries with headword `---` and category "indexing" are simply markers that the extension in question is indexed in the dictionary.

Note that the stroke character is illegal in unquoted Inform source text, and therefore also in excerpts with meanings, in extension titles and in author names. It can therefore safely be used as a record divider.

In December 2007, the dictionary file of a user who had employed 155 different extensions (by 33 different authors) contained 2223 entries, the longest of which formed a line 95 characters long: the most prolific extension made 380 definitions. The total file size was about 130K. Some typical entries:

```
...
|Emily Short|Plurality|---|indexing|
|Emily Short|Plurality|prior named noun|value|
|Emily Short|Plurality|ambiguously plural|property|
|Emily Short|Plurality|ordinarily enumerated|property|
|Emily Short|Locksmith|---|indexing|
|Emily Short|Locksmith|passkey|kind|
|Emily Short|Locksmith|keychain|kind|
...
```

§**3.** The file is encoded as ISO Latin-1 and can in principle have any of `0A`, `0D`, `0A 0D` or `0D 0A` as line divider. Each line must be no longer than the following number of characters minus 1:

```
define MAX_ED_LINE_LENGTH 512
```

§**4.** The following logs the dictionary as it stands in memory, in a similar format but also recorded the erasure flag.

```
void log_extension_dictionary_entry(extension_dictionary_entry *ede) {
    LOG("ede: %4d %d |%s|%s|%s|%s|\n", ede->allocation_id,
        ede->erased, ede->ede_id.author_name, ede->ede_id.title,
        ede->entry_text, ede->type);
}

void log_extension_dictionary(void) {
    extension_dictionary_entry *ede;
    int n=0;
    LOGIF(EXTCENSUS, "Extension dictionary:\n");
    LOOP_OVER(ede, extension_dictionary_entry) {
        n++; LOGIF(EXTCENSUS, "$d", ede);
    }
    if (n==0) LOGIF(EXTCENSUS, "no entries\n");
}
```

The function log_extension_dictionary_entry is called from 2/dl.

§**5. Erasing entries.** The erasure flag is used to mark entries in the dictionary which are to be erased, in that they will not survive when we save it back from memory to disc. (Entries are never physically deleted from the memory structures.)

There are two reasons to erase entries. First, the following routine sets the erased flag for dictionary entries corresponding to an extension which, according to the census returns, is no longer installed. (This can happen if the user has uninstalled an extension since the last time NI successfully ran.)

```
void erase_entries_of_uninstalled_extensions(void) {
    extension_dictionary_entry *ede;
    LOGIF(EXTCENSUS, "Erasure of dictionary entries for uninstalled extensions\n");
    LOOP_OVER(ede, extension_dictionary_entry)
        if ((ede->erased == FALSE) &&
            (no_times_EID_used_in_context(&(ede->ede_id), INSTALLED_EIDBC) == 0)) {
            ede->erased = TRUE;
            LOGIF(EXTCENSUS, "Erased $d", ede);
        }
}
```

§**6.** The second reason arises when we are making the dictionary entries for an extension which was used on the current run. (For instance, if it created a kind of vehicle called "dragster", then we will make a dictionary entry for that.) Before making its dictionary entries, we first erase all entries for the same extension which are left in the dictionary from some previous run of NI, as those are now out of date.

```
void erase_entries_of_this_loaded_extension(extension_file *ef) {
    extension_dictionary_entry *ede;
    LOGIF(EXTCENSUS, "Erasure of dictionary entries for $x\n", ef);
    LOOP_OVER(ede, extension_dictionary_entry)
        if ((ede->erased == FALSE) &&
            (eid_match(&(ede->ede_id), &(ef->ef_id)))) {
            ede->erased = TRUE;
            LOGIF(EXTCENSUS, "Erased $d", ede);
        }
}
```

The function erase_entries_of_this_loaded_extension is called from 4/edoc.

§**7. Making new entries.** We provide two ways to add a new entry: from a C string or from a word range.

```
void new_dictionary_entry(char *category, extension_file *ef, int w1, int w2) {
    char headword[MAX_ED_HEADWORD_LENGTH];
    if ((w1<0) || (w2<w1)) return;                    a safety precaution: never index the empty text
    print_raw_text_to_string_truncated(w1, w2, headword, MAX_ED_HEADWORD_LENGTH);
    new_dictionary_entry_raw(category, ef->ef_id.author_name, ef->ef_id.title, headword);
}

void new_dictionary_entry_str(char *category, extension_file *ef, char *headword) {
    new_dictionary_entry_raw(category, ef->ef_id.author_name, ef->ef_id.title, headword);
}

void new_dictionary_entry_raw(char *category, char *author, char *title, char *headword) {
    extension_dictionary_entry *ede;
    ede = CREATE(extension_dictionary_entry);
    eid_new(&(ede->ede_id), author, title, DICTIONARY_REFERRED_EIDBC);
```

```
    truncated_strcpy(ede->entry_text, headword, MAX_ED_HEADWORD_LENGTH);
    truncated_strcpy(ede->type, category, MAX_ED_CATEGORY_LENGTH);
    ede->erased = FALSE;
    ede->next_in_sorted_dictionary = NULL;
    LOGIF(EXTCENSUS, "Created $d", ede);
}
```

The function new_dictionary_entry is called from 4/edoc.
The function new_dictionary_entry_str is called from 2/lexi and 4/edoc.

§**8. Loading from disc.** Not a surprising routine: open, convert one line at a time to dictionary entries, close.

```
void load_extension_dictionary(void) {
    FILE *DICTF; FILE *EMPTY_DICTF;
    char line_entry[MAX_ED_LINE_LENGTH];
    ⟨Open the serialised extensions dictionary file for reading 9⟩;
    LOGIF(EXTCENSUS, "Reading dictionary file\n");
    while (truncated_iso_fgets(DICTF, line_entry, MAX_ED_LINE_LENGTH-1) >= 1)
        ⟨Make dictionary entry from single line from the dictionary file 10⟩;
    LOGIF(EXTCENSUS, "Finished reading dictionary file\n");
    fclose(DICTF);
}
```

The function load_extension_dictionary is called from 4/ext.

§**9.** The extension dictionary file is stored as `Dictionary.txt` in the folder for the `Reserved` "author" in the external extensions area. If it doesn't exist, we try to make an empty one; as it may happen that the `Reserved` doesn't exist either, we try to make that too. Should these attempts to write to the external area fail, we simply return: there might be permissions reasons, and it doesn't matter too much if the dictionary isn't read. A fatal error results only if, having written the empty file, we are then unable to open it again: that must mean a file I/O error of some kind, which is bad enough news to bother the user with.

⟨Open the serialised extensions dictionary file for reading 9⟩ ≡

```
    char path_to_dictionary[MAX_FILENAME_LENGTH];
    sprintf(path_to_dictionary, "%s%cReserved%cDictionary.txt",
        pathname_of_extensions, FOLDER_SEPARATOR, FOLDER_SEPARATOR);
    DICTF = iso_fopen(path_to_dictionary, "r");
    if (DICTF == NULL) {
        if (verify_library_folder("Inform", "Extensions", NULL, "Reserved") == 0)
            return;
        LOGIF(EXTCENSUS, "Creating new empty dictionary file\n");
        EMPTY_DICTF = iso_fopen(path_to_dictionary, "w");
        if (EMPTY_DICTF == NULL) return;
        fclose(EMPTY_DICTF);
        DICTF = iso_fopen(path_to_dictionary, "r");
        if (DICTF == NULL)
            fatal_error2("Unable to open dictionary file", path_to_dictionary);
    }
```

This code is used in §8.

§**10.** We parse lines in a fairly forgiving way. Material before the initial stroke is ignored (this helps us cope with any spare newline characters if there are blank lines, or if the line division is multi-byte); material after the final stroke is also ignored, and any line not containing five vertical strokes (i.e., four stroke-divided columns) is ignored altogether. This means that any truncated, overlong lines are ineffectual but safe.

⟨Make dictionary entry from single line from the dictionary file 10⟩ ≡

```
int strokes = 0, pos = 0, inpos = 0;
char author[MAX_ED_LINE_LENGTH], title[MAX_ED_LINE_LENGTH];
char headword[MAX_ED_LINE_LENGTH], category[MAX_ED_LINE_LENGTH];
author[0] = 0; title[0] = 0; headword[0] = 0; category[0] = 0;
while (strokes <= 4) {
    if ((line_entry[pos] == 0) || (inpos >= MAX_ED_LINE_LENGTH-1)) break;
    if (line_entry[pos] == '|') {
        pos++; strokes++; inpos = 0; continue;
    }
    switch(strokes) {
        case 1: author[inpos] = line_entry[pos]; author[++inpos] = 0; break;
        case 2: title[inpos] = line_entry[pos]; title[++inpos] = 0; break;
        case 3: headword[inpos] = line_entry[pos]; headword[++inpos] = 0; break;
        case 4: category[inpos] = line_entry[pos]; category[++inpos] = 0; break;
    }
    pos++;
}
if (strokes >= 5) new_dictionary_entry_raw(category, author, title, headword);
```

This code is used in §8.

§**11. Saving to disc.** And inversely...

```
void write_dictionary_back(void) {
    extension_dictionary_entry *ede;
    STREAM DICTF_struct;
    STREAM *DICTF = &DICTF_struct;
    char path_to_dictionary[MAX_FILENAME_LENGTH];
    if (verify_installed_extensions_tree()) return;
    sprintf(path_to_dictionary, "%s%cReserved%cDictionary.txt",
        pathname_of_extensions, FOLDER_SEPARATOR, FOLDER_SEPARATOR);
    if (STREAM_OPEN_TO_FILE(DICTF, path_to_dictionary, UTF8_ENC) == FALSE) return;
    LOGIF(EXTCENSUS, "Writing dictionary file\n");
    LOOP_OVER(ede, extension_dictionary_entry)
        if (ede->erased == FALSE) {
            LOGIF(EXTCENSUS, "Writing $d", ede);
            ⟨Write line to the dictionary file from single entry 12⟩;
        } else LOGIF(EXTCENSUS, "Suppressing $d\n", ede);
    LOGIF(EXTCENSUS, "Finished writing dictionary file\n");
    STREAM_CLOSE(DICTF);
}
```

The function write_dictionary_back is called from 4/ext.

§**12.** We needn't worry overmuch about exceeding the maximum length, since any such lines are handled safely by the loading code above. In any case, they could only occur if it were true that

```
4 + MAX_ED_CATEGORY_LENGTH + MAX_ED_HEADWORD_LENGTH +
    MAX_EXTENSION_TITLE_LENGTH + MAX_EXTENSION_AUTHOR_LENGTH >= MAX_ED_LINE_LENGTH
```

and this is not nearly the case. (`MAX_ED_LINE_LENGTH` is larger than strictly necessary since it costs us only temporary stack space and allows for any future increase of the above maxima without fuss.)

⟨Write line to the dictionary file from single entry 12⟩ ≡

```
STREAM_WRITE(DICTF, "|%s|%s|%s|%s|\n",
    ede->ede_id.author_name, ede->ede_id.title,
    ede->entry_text, ede->type);
```

This code is used in §11.

§**13. Sorting the extension dictionary.** We pass this job on to the standard C library `qsort`, in hopes that it is reasonably efficiently implemented. We need to bear in mind that the extensions database can be expected to have some thousands of entries, and that the $O(n^2)$ insertion sorts used so casually elsewhere in NI – where lists are certainly much smaller – could cause misery here.

This routine returns the number of (unerased) entries in the dictionary, and on its exit the (unerased) entries each occur once in alphabetical order in the linked list beginning at `first_in_sorted_dictionary`. If two entries have identical headwords, the earliest created is the one which appears earlier in the sorted dictionary.

```
int sort_extension_dictionary(void) {
    extension_dictionary_entry **sorted_extension_dictionary = NULL;
    int no_entries = 0;
    LOGIF(EXTCENSUS, "Beginning dictionary sort\n");
    sorted_extension_dictionary = NULL;
    ⟨Count headwords and reprocess their texts for dictionary sorting 14⟩;
    if (no_entries == 0) {
        first_in_sorted_dictionary = NULL;
        return 0;
    }
    ⟨Allocate memory for, and fill, an array of pointers to the EDEs 15⟩;
    qsort(sorted_extension_dictionary, no_entries, sizeof(extension_dictionary_entry *),
        compare_ed_entries);
    ⟨String the sorted array together into a sorted linked list of EDEs 16⟩;
    ⟨Deallocate memory for the array again 17⟩;
    LOGIF(EXTCENSUS, "Sorted dictionary: %d entries\n", no_entries);
    return no_entries;
}
```

§**14.** Dictionary entries must be in mixed case: we might have both "green" the colour and "Green" the kind of person (an environmental activist), say. But we want to compare them with `strcmp`, which is much faster than its case-insensitive analogue. So we trade memory for speed and store a modified form of the headword in which spaces are removed and letters are reduced to lower case; note that this is no larger than the original, so there is no risk of the `sorting` string (which is 10 characters longer than the unprocessed version) overflowing. Note: later we shall rely on the first character of the sorting text being the lower-case form of the first character of the original word.

We then append the allocation ID number, padded with initial zeros. We do this so that (i) all sorting texts will be distinct, and (ii) alphabetical order for sorting texts derived from two identical headword texts will correspond to creation order. This means that `qsort`'s output will be predictable (whereas different implementations of Quicksort might use the freedom to sort unstably in different ways), and this seems a good idea for better testing.

⟨Count headwords and reprocess their texts for dictionary sorting 14⟩ ≡

```
extension_dictionary_entry *ede;
int i, j;
LOOP_OVER(ede, extension_dictionary_entry)
    if (ede->erased == FALSE) {
        no_entries++;
        strcpy(ede->sorting, ede->entry_text);
        for (i=0, j=0; ede->entry_text[j]; j++)
            if (ede->entry_text[j] != ' ')
                ede->sorting[i++] = tolower(ede->entry_text[j]);
        ede->sorting[i] = 0;
        sprintf(ede->sorting + i, "-%09d", ede->allocation_id);
        LOGIF(EXTCENSUS, "Sorted under '%s': $d", ede->sorting, ede);
    }
```

This code is used in §13.

§**15.** We unbundle the linked list of EDEs in creation order into an array temporarily allocated in memory:

⟨Allocate memory for, and fill, an array of pointers to the EDEs 15⟩ ≡

```
extension_dictionary_entry *ede;
int i = 0;
sorted_extension_dictionary = I7_calloc(no_entries,
    sizeof(extension_dictionary_entry *), EXTENSION_DICTIONARY_MREASON);
LOOP_OVER(ede, extension_dictionary_entry) {
    if (ede->erased == FALSE)
        sorted_extension_dictionary[i++] = ede;
}
```

This code is used in §13.

§**16.** We then use the sorted version of the same array to reorder the EDEs:

⟨String the sorted array together into a sorted linked list of EDEs 16⟩ ≡

```
int i;
first_in_sorted_dictionary = sorted_extension_dictionary[0];
for (i=0; i<no_entries-1; i++)
    sorted_extension_dictionary[i]->next_in_sorted_dictionary =
        sorted_extension_dictionary[i+1];
if (no_entries > 0)
    sorted_extension_dictionary[no_entries-1]->next_in_sorted_dictionary = NULL;
```

This code is used in §13.

§**17.** And for the sake of tidiness:

⟨Deallocate memory for the array again 17⟩ ≡
```
I7_free(sorted_extension_dictionary, EXTENSION_DICTIONARY_MREASON);
```

This code is used in §13.

§**18.** As always with `qsort`, there's a palaver about the types used for the comparison function so that the result will compile without errors. The comparison of two EDEs is in fact delegated to a `strcmp` comparison of their sorting texts:

```
int compare_ed_entries(const void *elem1, const void *elem2) {
    const extension_dictionary_entry **e1 = (const extension_dictionary_entry **) elem1;
    const extension_dictionary_entry **e2 = (const extension_dictionary_entry **) elem2;
    if ((*e1 == NULL) || (*e2 == NULL))
        internal_error("Disaster while sorting extension dictionary");
    return strcmp((*e1)->sorting, (*e2)->sorting);
}
```

§**19. Extension clashes.** All Inform extensions included share the main name-space of the source text, and this causes potential problems with name clashes between two different extensions if ever an author wants to include both at once. To try to detect these clashes, we automatically scan the dictionary for them, and provide warnings on the dynamic extension index.

```
known_extension_clash *kec_new(extension_dictionary_entry *L, extension_dictionary_entry *R,
    int first_known_flag) {
    known_extension_clash *kec = CREATE(known_extension_clash);
    kec->leftx = L;
    kec->rightx = R;
    kec->number_clashes = 1;
    kec->first_known = first_known_flag;
    kec->next = NULL;
    return kec;
}
```

§**20.** Every clash of names arises from definitions made in a pair of EDEs, which we shall call left and right. Each distinct KEC ("known extension clash") represents a different pair of extensions which clash, one example of a name clashing between them, and a count of the number of such names.

(a) Given a pair of extensions, the left one is the one whose author name followed by title is lexicographically earlier. Since we are only concerned with clashes between different extensions, this unambiguously decides which is leftmost, as title and author suffice to identify extensions.

(b) Similarly, given a pair of EDEs, the left one is the one whose definition arises from the lefthand extension. (So, for instance, any definition made in one of Eric Eve's extensions is always to the left of any definition in one of John Clemens's.) Different EDEs deriving from the same extension do not exemplify a clash.

(c) For each extension L, there is at most one KEC whose left EDE derives from L and which has the "first known" flag set.

(c.1) If such a KEC does not exist, then L does not clash with any other extension.

(c.2) If such a KEC does exist, then it is the head of a linked list of KECs all of which have lefthand EDE deriving from L, and in which no two entries have righthand EDEs deriving from the same extension as each other.

It follows that we can determine if extensions X and Y clash by arranging them as L and R (rule (a)), looking for L among the left EDEs of all KECs with the "first known" flag set (rule (c)), and then looking for Y among the right EDEs of all KECs in the list which hangs from that (rule (c.2)). Should either of these searches fail, there is no clash between X and Y. Should both succeed, then the KEC found provides a single example of the clash (in its left and right EDEs), together with the number of clashes.

If there are n extensions then there could in theory be $n(n-1)/2$ KECs, which might amount to a lot of storage. In practice, though, Inform source text tends to be dispersed around the cloud of English nouns and adjectives fairly well, and since extension authors use each other's extensions, there is also some social pressure to reduce the number of clashes. The user mentioned above who had installed 155 different extensions – for a possible 11,935 distinct clashing pairs – in fact observed 15 such pairs, mostly arising from part-finished drafts which had borrowed source text from pieces of other extensions. Of the few remaining, several were cases where the same name occurred in rival extensions aspiring to do much the same thing as each other: for instance, "current quip" was defined by two different conversation extensions. The only clashes of different meanings which might both be needed, and which seem to have arisen spontaneously, were from definitions of the words "seen" and "implicit", both treacherously ambiguous. Clashes did not seem to have arisen from homonyms like "lead" (the substance) versus "lead" (the attachment to a collar).

```
void extension_clash(extension_dictionary_entry *ede1, extension_dictionary_entry *ede2) {
    extension_dictionary_entry *left = NULL, *right = NULL;
    extension_identifier *leftx, *rightx;
    known_extension_clash *kec;
    if ((ede1 == NULL) || (ede2 == NULL)) internal_error("bad extension clash");
    int d = eidcmp(&(ede1->ede_id), &(ede2->ede_id));                    compare source extensions
    ⟨Ignore apparent clashes which are in fact not troublesome 21⟩;
    if (d < 0) { left = ede1; right = ede2; }
    if (d > 0) { left = ede2; right = ede1; }
    leftx = &(left->ede_id); rightx = &(right->ede_id);
    LOOP_OVER(kec, known_extension_clash)
        if ((kec->first_known) && (eid_match(leftx, &(kec->leftx->ede_id)))) {
            ⟨Search list of KECs deriving from the same left extension as this clash 22⟩;
            return;
        }
    kec = kec_new(left, right, TRUE);
}
```

§**21.** If two name clashes occur in the same extension then, since we can presume that this extension does actually work, the clash cannot cause problems. We also ignore a clash of a property name against some other form of name, because these occur quite often and cause little difficulty in practice: so they would only clutter up the dictionary with spurious warnings.

⟨Ignore apparent clashes which are in fact not troublesome 21⟩ ≡

```
    if (d == 0) return;                                  both definitions come from the same extension
    if ((strcmp(ede1->type, "property") == 0) && (strcmp(ede2->type, "property") != 0)) return;
    if ((strcmp(ede1->type, "property") != 0) && (strcmp(ede2->type, "property") == 0)) return;
```

This code is used in §20.

§**22.** If we can find the righthand extension on the righthand side of any KEC in the list, then the clash is not a new one: we simply increment the number of definition pairs clashing between the left and right extensions, and return. (Thus forgetting what the actual definitions causing the present clash were: we don't need them, as we already have an example of the definitions clashing between the two.) But if we can't find righthand extension anywhere in the list, we must add the new pair of definitions:

⟨Search list of KECs deriving from the same left extension as this clash 22⟩ ≡

```
while (kec) {
    if (eid_match(rightx, &(kec->rightx->ede_id))) {
        kec->number_clashes++; return;
    }
    if (kec->next == NULL) {
        kec->next = kec_new(left, right, FALSE); return;
    }
    kec = kec->next;
}
```

This code is used in §20.

§**23.** The above arrangement was designed to make it easy to print out the clashes in a concise, human-readable way, which is what we now do.

```
void list_known_extension_clashes(OUTPUT_STREAM) {
    known_extension_clash *kec;
    if (NUMBER_CREATED(known_extension_clash) == 0) return;
    ⟨Write the headnote about what extension clashes mean 24⟩;
    LOOP_OVER(kec, known_extension_clash)
        if (kec->first_known)
            ⟨Write a paragraph about extensions clashing with the lefthand one here 25⟩;
}
```

§**24.** Not the end of the world! Extension clashes are not an error condition: they are, if anything, a sign of life and activity.

⟨Write the headnote about what extension clashes mean 24⟩ ≡

```
WRITE("<p>\n<b>Clashes found.</b> The dictionary above shows that some "
    "extensions make incompatible definitions of the same words or phrases. "
    "When two extensions disagree like this, it is not necessarily a bad "
    "sign (they might simply be two ways to approach the same problem), "
    "but in general it means that it may not be safe to use both "
    "extensions at the same time. The following list shows some potential "
    "clashes.<p>\n");
```

This code is used in §23.

§**25.** As always, we need to be careful about writing the ISO text of clashing matter to the UTF-8 HTML file:

⟨Write a paragraph about extensions clashing with the lefthand one here 25⟩ ≡

```
known_extension_clash *example;
WRITE("<b>");
eid_write_to_HTML_file(OUT, &(kec->leftx->ede_id), FALSE);
WRITE("</b>: ");
for (example = kec; example; example = example->next) {
    WRITE("clash with <b>");
    eid_write_to_HTML_file(OUT, &(example->rightx->ede_id), FALSE);
    WRITE("</b>");
    if (example->number_clashes > 1)
        WRITE(" (on %d names, for instance ", example->number_clashes);
    else WRITE(" (on ");
    print_literal_string_to_file(OUT, example->leftx->entry_text);
    WRITE(")");
    if (example->next) WRITE("; ");
}
WRITE("<p>\n");
```

This code is used in §23.

§**26. Writing the HTML extension index.** This is the index of terms, not the directory of extensions: it is, in fact, the HTML rendering of the dictionary constructed above.

```
void write_extension_dictionary_to_HTML_file(OUTPUT_STREAM) {
    int n;
    char first_letter = 'a';
    extension_dictionary_entry *ede, *previous_ede, *next_ede;
    erase_entries_of_uninstalled_extensions();
    n = sort_extension_dictionary();
    if (n <= 0) return;
    for (previous_ede = NULL, ede = first_in_sorted_dictionary; ede;
        previous_ede = ede, ede = ede->next_in_sorted_dictionary) {
        if (strcmp(ede->type, "indexing") == 0) continue;
        next_ede = ede->next_in_sorted_dictionary;
        char this_first = tolower(ede->entry_text[0]);
        if (first_letter != this_first) {
            WRITE("<br>"); first_letter = this_first;
        }
        ⟨Write extension dictionary entry for this headword 27⟩;
    }
    list_known_extension_clashes(OUT);
}
```

The function write_extension_dictionary_to_HTML_file is called from 4/ext.

§**27.** A run of N words which are all the same should appear in tinted type throughout, while $N(N-1)/2$ clashes should be reported to the machinery above: if we find definitions A, B, C, for instance, the clashes are reported as A vs B, A vs C, then B vs C. This has $O(N^2)$ running time, so if there are 1000 extensions, each of which gives 1000 different meanings to the word "frog", we would be in some trouble here. Let's take the risk.

```
define TINT_FOR_SAME_WORD "#FF8080"
define EDES_DEFINE_SAME_WORD(X, Y) ((X) && (Y) && (strcmp(X->sorting, Y->sorting) == 0))
```

⟨Write extension dictionary entry for this headword 27⟩ ≡

```
int tint = FALSE;
if (EDES_DEFINE_SAME_WORD(ede, previous_ede)) tint = TRUE;
while (EDES_DEFINE_SAME_WORD(ede, next_ede)) {
    tint = TRUE;
    extension_clash(ede, next_ede);
    next_ede = next_ede->next_in_sorted_dictionary;
}
if (tint) WRITE("<font color=\"%s\">", TINT_FOR_SAME_WORD);
print_literal_string_to_file(OUT, ede->entry_text);
if (tint) WRITE("</font>");
WRITE(" - <i>%s</i>   <small>", ede->type);
eid_write_link_to_HTML_file(OUT, &(ede->ede_id));
WRITE("</small><br>");
```

This code is used in §26.

Extension Documentation 4/edoc

Purpose

To generate HTML documentation for extensions.

---

§**1.** Each extension gets its own page in the external documentation area, but this page can have two forms: the deluxe version, only produced if an extension is successfully used, and a cut-down placeholder version, used if NI has detected the extension but never used it (and so does not really understand what it entails). The following routine writes both kinds of page.

```
void write_detailed_extension_documentation(extension_file *ef) {
    write_extension_documentation(NULL, ef);
}
void write_sketchy_extension_documentation(extension_census_datum *ecd) {
    write_extension_documentation(ecd, NULL);
}
```

The function write_detailed_extension_documentation is called from 4/ext.

The function write_sketchy_extension_documentation is called from 4/ext.

§**2.** Thus we pass two arguments, `ecd` and `ef`, to `write_extension_documentation`: one is a valid pointer, the other null. If `ef` is valid, we can write a full page: if `ecd` is valid, only a sketchy one.

The outer shell routine calls the inner one first to generate the main page of the documentation (where `eg_number` is `-1`), then uses its return value (the number of examples provided, which may be 0) to generate associated files for each example. For instance, we might end up making, in sequence,

```
Documentation/Extensions/Emily Short/Locksmith.html
Documentation/Extensions/Emily Short/Locksmith-eg1.html
Documentation/Extensions/Emily Short/Locksmith-eg2.html
Documentation/Extensions/Emily Short/Locksmith-eg3.html
Documentation/Extensions/Emily Short/Locksmith-eg4.html
```

where these are pathnames relative to the external resources area.

```
void write_extension_documentation(extension_census_datum *ecd, extension_file *ef) {
    int c, eg_count;
    eg_count = write_extension_documentation_page(ecd, ef, -1);
    for (c=1; c<=eg_count; c++)
        write_extension_documentation_page(ecd, ef, c);
}
```

§**3.** Here then is the nub of it. An ECD is not really enough information to go on. We are not always obliged to make a sketchy page from an ECD: we decide against in a normal run where a page exists for it already, as otherwise a user with many extensions installed would detect an annoying slight delay on every run of NI – whereas a slight delay on each census-mode run is acceptable, since census-mode runs are made only when extensions are installed or uninstalled. If we do decide to make a page from an ECD, we in fact read the extension into the lexer so as to make an EF of it. Of course, it won't be a very interesting EF – since it wasn't used in compilation there will be no definitions arising from it, so the top half of its documentation page will be vacant – but it will at least provide the extension author's supplied documentation, if there is any, as well as the correct identifying headings and requirements.

```
int write_extension_documentation_page(extension_census_datum *ecd, extension_file *ef,
    int eg_number) {
    extension_identifier *eid = NULL;
    STREAM DOCF_struct;
    STREAM *DOCF = &DOCF_struct;
    FILE *TEST_DOCF;
    int page_exists_already, no_egs = 0;
    char leafname[MAX_FILENAME_LENGTH], pathname[MAX_FILENAME_LENGTH];
    if (ecd) eid = &(ecd->ecd_id); else if (ef) eid = &(ef->ef_id);
    else internal_error("WEDP incorrectly called");
    LOGIF(EXTCENSUS, "WEDP %s (%s by %s)/%d\n",
        (ecd)?"ecd":" ef", eid->title, eid->author_name, eg_number);
    ⟨Work out the leafname and pathname of the documentation file 4⟩;
    page_exists_already = FALSE;
    TEST_DOCF = iso_fopen(pathname, "r");
    if (TEST_DOCF) { page_exists_already = TRUE; fclose(TEST_DOCF); }
    LOGIF(EXTCENSUS, "WEDP %s: %s\n", (page_exists_already)?"exists":"does not exist",
        pathname);
    if (ecd) {
        if ((page_exists_already == FALSE) || (census_mode))
            ⟨Convert ECD to a text-only EF 5⟩;
        return 0;                          ensure no requests sent for further pages about the ECD: see below
    }
    if (ef == NULL) internal_error("null EF in extension documentation writer");
    if (verify_library_folder("Inform", "Documentation", "Extensions", eid->author_name) == 0)
        return 0;
    if (STREAM_OPEN_TO_FILE(DOCF, pathname, UTF8_ENC) == FALSE)
        return 0;                                  if we lack permissions, e.g., then write no documentation
    ⟨Write the actual extension documentation page to DOCF 6⟩;
    STREAM_CLOSE(DOCF);
    return no_egs;
}
```

§**4.** Straightforwardly:

⟨Work out the leafname and pathname of the documentation file 4⟩ ≡

```
    strcpy(leafname, eid->title);
    if (eg_number > 0) sprintf(leafname+strlen(leafname), "-eg%d", eg_number);
    sprintf(pathname, "%s%cExtensions%c%s%c%s.html", pathname_of_extension_docs,
        FOLDER_SEPARATOR, FOLDER_SEPARATOR, eid->author_name, FOLDER_SEPARATOR, leafname);
```

This code is used in §3.

§**5.** The reader may wonder why we perform the conversion in this slightly recursive way, by calling our parent routine again. Wouldn't it be simpler just to set `ecd` to null and let events take their course? The answer is that this would fail if there were examples, because we would return (say) 3 for the number of examples, and then the routine would be called 3 more times – but with the original ECD as argument each time: that would mean reading the file thrice more, reconverting to EF each time. So we restart the process from our EF, and return 0 in response to the ECD call to prevent any further ECD calls.

⟨Convert ECD to a text-only EF 5⟩ ≡

```
int aw1 = lexer_wordcount, aw2, tw1, tw2;
feed_into_lexer(eid->raw_author_name, FALSE, FALSE);
feed_into_lexer(" ", FALSE, FALSE);
aw2 = lexer_wordcount - 1;
tw1 = lexer_wordcount;
feed_into_lexer(eid->raw_title, FALSE, FALSE);
feed_into_lexer(" ", FALSE, FALSE);
tw2 = lexer_wordcount - 1;
feed_into_lexer("This sentence provides a firebreak, no more. ", FALSE, FALSE);
ef = load_extension(aw1, aw2, tw1, tw2, -1);
if (ef == NULL) return 0;                                   shouldn't happen: it was there only moments ago
write_extension_documentation(NULL, ef);
```

This code is used in §3.

§**6.** We now make much the same "paste into the gap in the template" copying exercise as when generating the home pages for extensions, though with a different template:

⟨Write the actual extension documentation page to DOCF 6⟩ ≡

```
char path_to_model[MAX_FILENAME_LENGTH];
char line_of_template[LONGEST_LINE_IN_EX_TEMPLATE];
FILE *TEMPLATE;
int skipping_between_markers = FALSE;
sprintf(path_to_model, "%s%cReserved%c%s",
    pathname_of_built_in_extensions, FOLDER_SEPARATOR, FOLDER_SEPARATOR,
    EXTENSION_FILE_MODEL_HTML);
TEMPLATE = iso_fopen(path_to_model, "r");
if (TEMPLATE == NULL)
    fatal_error2("Unable to open model extension documentation file for reading",
        path_to_model);
while (!(feof(TEMPLATE))) {
    int n = truncated_iso_fgets(TEMPLATE, line_of_template, LONGEST_LINE_IN_EX_TEMPLATE);
    if (n < 0) break;                                       file I/O error or end of file
    if (strcmp(line_of_template, "<a name=on>") == 0) {
        ⟨Write documentation for a specific extension into the page 7⟩;
        skipping_between_markers = TRUE;
    }
    if (skipping_between_markers == FALSE) STREAM_WRITE(DOCF, "%s", line_of_template);
    if (strcmp(line_of_template, "<a name=off>") == 0)
        skipping_between_markers = FALSE;
}
fclose(TEMPLATE);
```

This code is used in §3.

§**7.** And this is what we paste into the gap:

⟨Write documentation for a specific extension into the page 7⟩ ≡
```
STREAM_WRITE(DOCF, "<p>");
if (eid_is_standard_rules(eid) == FALSE)
    ⟨Write Javascript paste icon for source text to include this extension 8⟩;
STREAM_WRITE(DOCF, "<b>");
eid_write_to_HTML_file(DOCF, eid, TRUE);
STREAM_WRITE(DOCF, "</b><p><small>");
⟨Write up any restrictions on VM usage 9⟩;
⟨Write up the version number, if any, and location 10⟩;
STREAM_WRITE(DOCF, "</small><p>");
⟨Write up the rubric, if any 11⟩;
⟨Write up the table of contents for the extension author's supplied documentation, if any 12⟩;
⟨Document and dictionary the definitions made in extension file ef 14⟩;
STREAM_WRITE(DOCF, "<p><hr><p>");
⟨Write up the extension author's supplied documentation, if any 13⟩;
```

This code is used in §6.

§**8.** UTF-8 transcoding in the following is delegated to `write_javascript_paste`:

⟨Write Javascript paste icon for source text to include this extension 8⟩ ≡
```
char inclusion_text[MAX_EXTENSION_TITLE_LENGTH + MAX_EXTENSION_AUTHOR_LENGTH + 50];
sprintf(inclusion_text, "Include %s by %s.\n\n\n", eid->title, eid->author_name);
write_javascript_paste(DOCF, -1, -1, inclusion_text);
STREAM_WRITE(DOCF, " ");
```

This code is used in §7.

§**9.**

⟨Write up any restrictions on VM usage 9⟩ ≡
```
int rw1 = ef->VM_restriction_w1, rw2 = ef->VM_restriction_w2;
if (rw1 >= 0) {
    print_raw_text_to_file(rw1, rw2, DOCF);
    STREAM_WRITE(DOCF, " ");
    write_VM_icons(DOCF, rw1, rw2);
}
```

This code is used in §7.

§**10.**

⟨Write up the version number, if any, and location 10⟩ ≡
```
char the_version[MAX_VERSION_NUMBER_LENGTH+1];
if (ef->version_loaded >= 0)
    print_raw_text_to_string(ef->version_loaded, ef->version_loaded, the_version);
else the_version[0] = 0;
if (the_version[0]) STREAM_WRITE(DOCF, "<p>Version %s", the_version);
if (ef->loaded_from_built_in_area) {
    if (the_version[0] == 0) STREAM_WRITE(DOCF, "<p>Extension");
    STREAM_WRITE(DOCF, " built in to Inform");
}
```

This code is used in §7.

§**11.**

⟨Write up the rubric, if any 11⟩ ≡
```
if (ef->rubric_as_lexed[0])
    STREAM_WRITE(DOCF, "%s<p>", ef->rubric_as_lexed);
if (ef->extra_credit_as_lexed[0])
    STREAM_WRITE(DOCF, "<i>%s</i><p>", ef->extra_credit_as_lexed);
```
This code is used in §7.

§**12.** This appears above the definition paragraphs because it tends to be only large extensions which provide TOCs: and they, ipso facto, make many definitions. If the TOC were directly at the top of the supplied documentation, it might easily be scrolled down off screen when the user first visits the page.

⟨Write up the table of contents for the extension author's supplied documentation, if any 12⟩ ≡
```
if (ef->doc_w1 >= 0)
    edoc_set_table_of_contents(ef->doc_w1, ef->doc_w2, DOCF, leafname);
```
This code is used in §7.

§**13.**

⟨Write up the extension author's supplied documentation, if any 13⟩ ≡
```
if (ef->doc_w1 >= 0)
    no_egs = edoc_set_body_text(ef->doc_w1, ef->doc_w2, DOCF, eg_number, leafname);
else
    STREAM_WRITE(DOCF, "The extension provides no documentation.");
```
This code is used in §7.

§**14.** Nothing can prevent a certain repetitiousness intruding here, but there is just enough local knowledge required to make it foolhardy to try to automate this from a dump of the excerpt meanings table (say). The ordering of paragraphs, as in Roget's Thesaurus, tries to proceed from solid things through to diffuse linguistic ones. But the reader of the resulting documentation page could be forgiven for thinking it a miscellany.

⟨Document and dictionary the definitions made in extension file ef 14⟩ ≡
```
erase_entries_of_this_loaded_extension(ef);
new_dictionary_entry_str("indexing", ef, "---");
⟨Document and dictionary the kinds made in extension 15⟩;
⟨Document and dictionary the objects made in extension 16⟩;
⟨Document and dictionary the kinds of value made in extension 17⟩;
⟨Document and dictionary the global variables made in extension 18⟩;
⟨Document and dictionary the enumerated constant values made in extension 19⟩;
⟨Document and dictionary the kinds of action made in extension 20⟩;
⟨Document and dictionary the actions made in extension 21⟩;
⟨Document and dictionary the verbs made in extension 22⟩;
⟨Document and dictionary the adjectival phrases made in extension 23⟩;
⟨Document and dictionary the property names made in extension 24⟩;
```
This code is used in §7.

§**15.** Off we go, then. Kinds of object:

⟨Document and dictionary the kinds made in extension 15⟩ ≡

```
world_object *wo;
int kc = 0;
LOOP_OVER(wo, world_object) {
    if ((wo != kind_kind) && (wo->kind_flag)) {
        if (lw_array[wo->creating_sentence->word_ref1].lw_source.file_of_origin ==
            ef->read_into_file) {
            kc = document_headword(DOCF, kc, ef, "Kinds", "kind",
                wo->word_ref1, wo->word_ref2);
            if ((wo->kind != kind_kind) && (wo->kind != kind_thing)) {
                STREAM_WRITE(DOCF, " (a kind of ");
                print_raw_text_to_file(wo->kind->word_ref1,
                    wo->kind->word_ref2, DOCF);
                STREAM_WRITE(DOCF, ")");
            }
            if (wo->kind == kind_kind) STREAM_WRITE(DOCF, " (a kind of object)");
        }
    }
}
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**16.** Actual objects:

⟨Document and dictionary the objects made in extension 16⟩ ≡

```
world_object *wo;
int kc = 0;
LOOP_OVER(wo, world_object) {
    if ((wo->kind_flag == FALSE) &&
        (wo->creating_sentence) && (wo->word_ref1 >=0)) {
        if (lw_array[wo->creating_sentence->word_ref1].lw_source.file_of_origin ==
            ef->read_into_file) {
            char name_of_its_kind[512];
            print_raw_text_to_string(wo->kind->word_ref1,
                wo->kind->word_ref2, name_of_its_kind);
            kc = document_headword(DOCF, kc, ef, "Physical creations", name_of_its_kind,
                wo->word_ref1, wo->word_ref2);
            STREAM_WRITE(DOCF, " (a ");
            print_raw_text_to_file(wo->kind->word_ref1, wo->kind->word_ref2, DOCF);
            STREAM_WRITE(DOCF, ")");
        }
    }
}
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**17.** Kinds of value:

⟨Document and dictionary the kinds of value made in extension 17⟩ ≡

```
int i, kc = 0;
LOOP_OVER_DESIGNED_TYPE_IDS(i) {
    int w1, w2;
    type_ID_copy_name(i, &w1, &w2);
    if (lw_array[w1].lw_source.file_of_origin == ef->read_into_file)
        kc = document_headword(DOCF, kc, ef, "Kinds of value", "kind of value", w1, w2);
}
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**18.** Global variables:

⟨Document and dictionary the global variables made in extension 18⟩ ≡

```
quantity *q;
int kc = 0;
LOOP_OVER(q, quantity)
    if ((q->word_ref1 >= 0) &&
        (qty_is_a_global_variable(q)) &&
        (lw_array[q->word_ref1].lw_source.file_of_origin == ef->read_into_file) &&
        ([[q == ... understood]] == FALSE))
        kc = document_headword(DOCF, kc, ef, "Values that vary", "value",
            q->word_ref1, q->word_ref2);
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**19.** Constants:

⟨Document and dictionary the enumerated constant values made in extension 19⟩ ≡

```
quantity *q;
int kc = 0;
LOOP_OVER(q, quantity)
    if ((q->word_ref1 >= 0) &&
        (qty_is_a_variable(q) == FALSE) &&
        (kov_is_an_enumeration(qty_kind_of_value(q))) &&
        (lw_array[q->word_ref1].lw_source.file_of_origin == ef->read_into_file))
        kc = document_headword(DOCF, kc, ef, "Values", "value",
            q->word_ref1, q->word_ref2);
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**20.** Kinds of action:

⟨Document and dictionary the kinds of action made in extension 20⟩ ≡

```
named_action_pattern *nap;
int kc = 0;
LOOP_OVER(nap, named_action_pattern)
    if (lw_array[nap->word_ref1].lw_source.file_of_origin == ef->read_into_file)
        kc = document_headword(DOCF, kc, ef, "Kinds of action", "kind of action",
            nap->word_ref1, nap->word_ref2);
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**21.** Actions:

⟨Document and dictionary the actions made in extension 21⟩ ≡

```
action_name *acn;
int kc = 0;
LOOP_OVER(acn, action_name)
    if (lw_array[acn->word_ref1].lw_source.file_of_origin == ef->read_into_file)
        kc = document_headword(DOCF, kc, ef, "Actions", "action",
            acn->word_ref1, acn->word_ref2);
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**22.** Verbs (this one we delegate):

⟨Document and dictionary the verbs made in extension 22⟩ ≡

```
lexicon_list_verbs_in_file(DOCF, ef->read_into_file, ef);
```

This code is used in §14.

§**23.** Adjectival phrases:

⟨Document and dictionary the adjectival phrases made in extension 23⟩ ≡

```
adjectival_phrase *adj;
int kc = 0;
LOOP_OVER(adj, adjectival_phrase)
    if ((adj->word_ref1 >= 0) &&
        (lw_array[adj->word_ref1].lw_source.file_of_origin == ef->read_into_file))
        kc = document_headword(DOCF, kc, ef, "Adjectives", "adjective",
            adj->word_ref1, adj->word_ref2);
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**24.** Other adjectives:

⟨Document and dictionary the property names made in extension 24⟩ ≡

```
property_name *prn;
int kc = 0;
LOOP_OVER(prn, property_name)
    if ((prn->word_ref1 >= 0) &&
        (prn_is_shown_in_index(prn)) &&
        (prn_is_used_by_i6_library_only(prn) == FALSE) &&
        (lw_array[prn->word_ref1].lw_source.file_of_origin == ef->read_into_file))
        kc = document_headword(DOCF, kc, ef, "Properties", "property",
            prn->word_ref1, prn->word_ref2);
if (kc != 0) STREAM_WRITE(DOCF, "<p>");
```

This code is used in §14.

§**25.** Finally, the utility routine which keeps count (hence `kc`) and displays suitable lists, while entering each entry in turn into the extension dictionary.

```
int document_headword(OUTPUT_STREAM, int kc, extension_file *ef, char *par_heading,
    char *category, int w1, int w2) {
    if (kc++ == 0) WRITE("%s: ", par_heading);
    else WRITE(", ");
    WRITE("<b>");
    print_raw_text_to_file(w1, w2, OUT);
    WRITE("</b>");
    new_dictionary_entry(category, ef, w1, w2);
    return kc;
}
```

§**26.** And that at last brings us to a milestone: the end of the Land of Extensions. We can return to Inform's more usual concerns.

Virtual Machines 4/vm

Purpose

I7 supports a variety of virtual machines as targets. Most source text should be independent of the target VM, but sometimes numbering is needed, and this is where any VM dependencies are decided.

4/vm.§1-4 Table of supported VMs; §5-13 Parsing VM restrictions; §14 Determining a match with the current target VM; §15 Icons for virtual machines; §16 Describing the current VM; §17-25 Displaying VM restrictions

---

Definitions

¶1. We use the term "major VM" to mean one of the families we deal with: the Z-machine, for instance, is a major VM. A "minor VM" is a specific revision of this, such as version 5 of the Z-machine. The following table describes both major and minor VMs: records with version set to −1 are major, and the rest minor.

It is assumed that major VM names are single words: happily Z-machine has always traditionally been hyphenated. We also assume their names use only the plainest ASCII characters.

¶2. We store data on both major and minor VMs in the following simple structure.

The point of multiplying version numbers by 10,000 is to allow room for sub-versions in future: Glulx in particular has version numbers like 3.4.2, which we might want to represent as 30402. (At present we don't distinguish versions of Glulx because Glulx's gestalt mechanism means that it's much easier to construct story files which can cope nicely on different Glulx interpreter versions than would be the case for the Z-machine.) Given that the multiplier is larger than 1, it is impossible for −1 to be a valid version number of any VM, so this is used as a "not a version number" value.

define `VMULT 10000`

```
typedef struct VM_identifier {
    int VM_code;                                  one of the values above
    int VM_version;                               times the VMULT, or -1 to mean generic versionless VM
    char *VM_major_name;                          or NULL if not a major VM name
    char *VM_extension;                           canonical filename extension
    char *VM_blorbed_extension;                   when blorbed up
    char *VM_name;                                text to use with author
    char *VM_image;                               filename of image for icon denoting VM
    int VM_is_32_bit;                             true or false: false means 16-bit
    int VM_matches;                               true or false: computed
} VM_identifier;
```

The structure VM_identifier is private to this section.

¶3. We keep track of how array space is used in the VM, since this is in very short supply in the Z-machine. This is done purely so that we can index helpfully on the Contents index page.

```
typedef struct VM_usage_note {
    int word_ref1, word_ref2;                    name of the structure using this array space...
    char *usage_explained;                                ...or an explanation instead
    char *usage_category;                                          e.g., "relation"
    int bytes_used;                                 number of bytes (not words) given over to this
    int each_flag;                             is this a count of how many bytes per usage of something?
    MEMORY_MANAGEMENT;
} VM_usage_note;
```

The structure VM_usage_note is private to this section.

---

§**1. Table of supported VMs.** The following data determines what VMs we know about, and how they can be inferred from the present information passed by the GUI to NI at the command line - viz., the eventual file extension. The application passes this by including among the command-line switches a pair like so:

```
    -extension ulx
```

The second word must be one of the file extensions listed in the fourth column of the table of VM data below: the comparison is made case insensitively, and any initial full stop is skipped, so ".Z6" is equivalent to "z6".

```
define Z_VM 1                                    Joel Berez and Marc Blank, 1979, and later hands
define GLULX_VM 2                                                          Andrew Plotkin, 2000
define DEFAULT_TARGET_VM 3                   if no -extension is supplied, target row 3: Z-machine v8
```

```
VM_identifier table_of_VM_data[] = {
    { Z_VM,      -1, "z-machine",  NULL, "zblorb", "Z-Machine", "vm_z.png", FALSE, FALSE },
    { Z_VM, 5*VMULT, NULL,  "z5", "zblorb", "Z-Machine version 5", "vm_z5.png", FALSE, FALSE },
    { Z_VM, 6*VMULT, NULL,  "z6", "zblorb", "Z-Machine version 6", "vm_z6.png", FALSE, FALSE },
    { Z_VM, 8*VMULT, NULL,  "z8", "zblorb", "Z-Machine version 8", "vm_z8.png", FALSE, FALSE },
    { GLULX_VM,  -1, "glulx", "ulx", "gblorb", "Glulx", "vm_glulx.png", TRUE, FALSE },
    { -1,         0, NULL, NULL, NULL, NULL, FALSE, FALSE }
};
```

§**2.** At present, we infer the target virtual machine by looking at the file extension requested at the command line.

```
int target_VM;                                   an index in the above table, or -1 if unknown
void set_VM_identifier(char *file_extension) {
    char lower_case_ext[32];
    int i;
    target_VM = -1;
    if (file_extension == NULL) { target_VM = DEFAULT_TARGET_VM; return; }
    if (file_extension[0] == '.') file_extension++;
    strcpy(lower_case_ext, file_extension);
    for (i=0; lower_case_ext[i]; i++) lower_case_ext[i] = tolower(lower_case_ext[i]);
    for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
        if ((table_of_VM_data[i].VM_extension) &&
            (strcmp(lower_case_ext, table_of_VM_data[i].VM_extension) == 0)) target_VM = i;
}
```

The function set_VM_identifier is called from 14/main.

§**3.** To help Inform detect overflows, it needs to know whether integers in the target VM are 16 or 32 bits wide:

```
int target_VM_is_16_bit(void) {
    if (target_VM == -1) internal_error("target VM not set yet");
    if (table_of_VM_data[target_VM].VM_is_32_bit) return FALSE;
    return TRUE;
}
```

The function target_VM_is_16_bit is called from 5/litp, 5/lit and 7/dim.

§**4.** When releasing a blorbed story file, the file extension depends on the story file wrapped inside. (This is a dubious idea, in the opinion of the author of Inform – should not blorb be one unified wrapper? – but interpreter writers disagree.)

```
char *get_VM_blorbed_extension(void) {
    if (target_VM == -1) internal_error("target VM not set yet");
    return table_of_VM_data[target_VM].VM_blorbed_extension;
}
```

The function get_VM_blorbed_extension is called from 10/bib.

§**5. Parsing VM restrictions.** Given a word range, we see what set of virtual machines it specifies. For example, the result of calling

> for Z-machine version 5 or 8 only

is that the `VM_matches` field in the table above is set for the two minor VMs cited, and cleared for all of the others, while the `VM_matching_error_thrown` is false (since the text was valid). The same result is produced by

> for Z-machine versions 5 and 8 only

English being quirky that way.

```
define THROW_VM_MATCHING_ERROR_AND_RETURN { VM_matching_error_thrown = TRUE; return; }

int VM_matching_error_thrown = FALSE;                    an error occurred during parsing
int most_recent_major_VM;                                most recent major VM which matched, or −1
int version_can_be_inferred;                             from earlier in the word range parsed

void match_VM_against(int w1, int w2) {
    ⟨Clean the slate ready for a fresh VM parse 6⟩;
    if [[w1, w2 == for ... only --> w1, w2]] match_VM_from(w1, w2);
    else ⟨Signal a matching error, but recover by declaring every VM a valid match 7⟩;
}
```

§**6.** It is slightly lazy of this code to use global variables to preserve state through a sequence of function calls to `match_VM_from`, but sometimes a little laziness is what we deserve.

⟨Clean the slate ready for a fresh VM parse 6⟩ ≡

```
    int i;
    VM_matching_error_thrown = FALSE;
    most_recent_major_VM = -1;
    version_can_be_inferred = FALSE;
    for (i=0; table_of_VM_data[i].VM_code >= 0; i++) table_of_VM_data[i].VM_matches = FALSE;
```

This code is used in §5.

§**7.** If only some VMs match, code elsewhere has to do some finicky work. We will save it the trouble in the case where the specification did not make sense.

⟨Signal a matching error, but recover by declaring every VM a valid match 7⟩ ≡

```
int i;
for (i=0; table_of_VM_data[i].VM_code >= 0; i++) table_of_VM_data[i].VM_matches = TRUE;
THROW_VM_MATCHING_ERROR_AND_RETURN;
```

This code is used in §5.

§**8.** Given a list divided by "and" or "or", and perhaps using the serial comma, we split off into terms from left to right:

```
void match_VM_from(int w1, int w2) {
    if (is_list_divided(w1, w2, LOOK_FOR_AND + LOOK_FOR_OR)) {
        int lw1 = left_w1, lw2 = left_w2, rw1 = right_w1, rw2 = right_w2;
        match_VM_from(lw1, lw2);
        match_VM_from(rw1, rw2);
        return;
    }
    ⟨Parse latest term in word range list 9⟩;
}
```

§**9.** The word "version(s)" is optional if it has been given in a previous term of the list, since the last major VM was named: this allows "versions 4 and 8" to work.

⟨Parse latest term in word range list 9⟩ ≡

```
⟨Detect major VM name, if given, and advance one word 10⟩;
⟨Give up if no major VM name found in any term of the list so far 11⟩;
if (w1 <= w2) {
    int version_specified = -1;
    if [[w1, w2 == version/versions ... --> w1, w2]] version_can_be_inferred = TRUE;
    else if (version_can_be_inferred == FALSE) THROW_VM_MATCHING_ERROR_AND_RETURN;
    if (!((w1==w2) && (vocab_test_flags(w1, NUMBER_MC)))) THROW_VM_MATCHING_ERROR_AND_RETURN;
    version_specified = VMULT * vocab_get_literal_number_value(lw_array[w1].lw_identity);
    ⟨Score a match for this specific version of the major VM, if we know about it 13⟩;
} else {
    ⟨Score a match for every known version of the major VM 12⟩;
}
```

This code is used in §8.

§**10.** The word "version" is sometimes implicit, but not after a major VM name. Thus "Glulx 3" is not allowed: it has to be "Glulx version 3".

⟨Detect major VM name, if given, and advance one word 10⟩ ≡

```
int i;
for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
    if ((table_of_VM_data[i].VM_major_name) &&
        (compare_word_by_strcmp(w1, table_of_VM_data[i].VM_major_name))) {
        most_recent_major_VM = table_of_VM_data[i].VM_code;
        version_can_be_inferred = FALSE;
        w1++;
        break;
    }
```

This code is used in §9.

§**11.** The variable `VM_matching_error_thrown` may have been set either on this term or a previous one: for instance, if we are reading "Squirrel versions 4 and 7" then at the second term, "7", no major VM is named but the variable remains set from "Squirrel" having been parsed at the first term.

⟨Give up if no major VM name found in any term of the list so far 11⟩ ≡

```
if (most_recent_major_VM == -1) THROW_VM_MATCHING_ERROR_AND_RETURN;
```

This code is used in §9.

§**12.** We either make a run of matches:

⟨Score a match for every known version of the major VM 12⟩ ≡

```
int i;
for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
    if (table_of_VM_data[i].VM_code == most_recent_major_VM)
        table_of_VM_data[i].VM_matches = TRUE;
```

This code is used in §9.

§**13.** ...or else we make a single match, or even none at all. This would not be an error: if the request was for "version 71 of Chipmunk", and we were unable to compile to this VM (so that no such minor VM record appeared in the table) then the situation might be that we are reading the requirements of some extension used by other people, who have a later version of Inform than us, and which does compile to that VM.

⟨Score a match for this specific version of the major VM, if we know about it 13⟩ ≡

```
int i;
for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
    if ((table_of_VM_data[i].VM_code == most_recent_major_VM) &&
        (version_specified == table_of_VM_data[i].VM_version))
        table_of_VM_data[i].VM_matches = TRUE;
```

This code is used in §9.

§14. Determining a match with the current target VM. We can now answer the question: given a word range, is the current target VM a member of the set of VMs specified by the text in that word range? Only a reply of `FALSE` means definitely not.

```
int current_VM_matches_text(int w1, int w2) {
    if (target_VM == -1) internal_error("target VM not set yet");
    match_VM_against(w1, w2);
    if (VM_matching_error_thrown) return NOT_APPLICABLE;
    if (table_of_VM_data[target_VM].VM_matches) return TRUE;
    return FALSE;
}
```

The function current_VM_matches_text is called from 4/iext and 4/head.

§15. Icons for virtual machines. And everything else is cosmetic: printing, or showing icons to signify, the current VM or some set of permitted VMs. The following plots the icon associated with a given minor VM, and explicates what the icons mean:

```
void plot_VM_icon(OUTPUT_STREAM, int minor) {
    if (table_of_VM_data[minor].VM_image)
        WRITE("<img border=0 src=inform:/doc_images/%s> ",
            table_of_VM_data[minor].VM_image);
}
void write_VM_key(OUTPUT_STREAM) {
    int i;
    WRITE("Extensions compatible with specific story file formats only: ");
    for (i=0; table_of_VM_data[i].VM_code >= 0; i++) {
        if (i>0) WRITE(", ");
        plot_VM_icon(OUT, i);
        WRITE("%s", table_of_VM_data[i].VM_name);
    }
    WRITE("<p>");
}
```

The function write_VM_key is called from 4/excen.

§16. Describing the current VM.

```
void write_current_VM(OUTPUT_STREAM) {
    if (target_VM == -1) internal_error("target VM not set yet");
    WRITE("<p><hr>");
    index_anchor("STORYFILE");
    WRITE("<p>Story file format: ");
    plot_VM_icon(OUT, target_VM);
    if (table_of_VM_data[target_VM].VM_name) WRITE(table_of_VM_data[target_VM].VM_name);
    else WRITE("No name available\n");
    WRITE("<p>\n");
}
```

The function write_current_VM is called from 10/bib.

§**17. Displaying VM restrictions.** Given a word range, we parse it to set the match flags, then describe the result as concisely as we can with a row of icons.

```
void write_VM_icons(OUTPUT_STREAM, int w1, int w2) {
    int i;
    match_VM_against(w1, w2);
    ⟨Display nothing if every VM matches 18⟩;
    ⟨Display only the generic Z icon if every Z-machine VM version matches 19⟩;
    for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
        if (table_of_VM_data[i].VM_matches)
            plot_VM_icon(OUT, i);
}
```

The function write_VM_icons is called from 4/excen and 4/edoc.

§**18.** To avoid the extensions directory page being plastered with gaudy but uncommunicative icons, we leave blank space if the requirements are always met. The icons are to signal exceptions.

⟨Display nothing if every VM matches 18⟩ ≡

```
    int i, everything_matches = TRUE;
    for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
        if (table_of_VM_data[i].VM_matches == FALSE)
            everything_matches = FALSE;
    if (everything_matches) return;
```

This code is used in §17.

§**19.** This might happen if the user typed "for Z-machine only", but could also come about if he typed a specification naming in turn each minor version we know about, so the only way to check is to look at the match flag for each one.

⟨Display only the generic Z icon if every Z-machine VM version matches 19⟩ ≡

```
    int i, every_Z_matches = TRUE;
    for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
        if ((table_of_VM_data[i].VM_code == Z_VM) &&
            (table_of_VM_data[i].VM_matches == FALSE))
            every_Z_matches = FALSE;
    if (every_Z_matches)
        ⟨Replace minor Z VMs in the match set with the single major one 20⟩;
```

This code is used in §17.

§**20.** The following operation leaves the match set in a state which does not correspond to what parsing would tell us (indeed, that's the point): so we must not use the match set again without reparsing it. But in fact, the match set is always recalculated before being used, so this is fine.

⟨Replace minor Z VMs in the match set with the single major one 20⟩ ≡

```
    int i;
    for (i=0; table_of_VM_data[i].VM_code >= 0; i++)
        if (table_of_VM_data[i].VM_code == Z_VM) {
            if (table_of_VM_data[i].VM_major_name)                    the major VM line for Z
                table_of_VM_data[i].VM_matches = TRUE;
            else
                table_of_VM_data[i].VM_matches = FALSE;                one of the minor ones
        }
```

This code is used in §19.

§**21.** The following table in the index (on the Contents page) may be useful to a few diehard Z-machine hackers, determined to squeeze the maximum out of the tiny array space available.

define NOTEWORTHY_USAGE_THRESHOLD 50 *don't mention arrays smaller than this, in bytes*

```
void note_VM_usage(char *cat, int w1, int w2, char *name, int words, int bytes, int each) {
    int b = bytes + words*((target_VM_is_16_bit())?2:4);
    if ((each == FALSE) && (b < NOTEWORTHY_USAGE_THRESHOLD)) return;
    if (b == 0) return;
    VM_usage_note *VMun = CREATE(VM_usage_note);
    VMun->word_ref1 = w1; VMun->word_ref2 = w2;
    VMun->usage_explained = name;
    VMun->usage_category = cat;
    VMun->bytes_used = b;
    VMun->each_flag = each;
}
```

The function note_VM_usage is called from 5/rel, 9/scene, 9/cot, 10/tab and 11/act.

§**22.** The explanatory note here probably ought to use the words "approximately", "incomplete" and so forth. It's really no better than a guide.

```
void index_VM_usage(void) {
    int nr = NUMBER_CREATED(VM_usage_note);
    VM_usage_note **sorted = I7_calloc(nr, sizeof(VM_usage_note *), INDEX_SORTING_MREASON);
    INDEX("<p>In a Z-machine story file, array memory can be very limited. "
        "Switching to the Glulx setting removes all difficulty, but some authors "
        "like to squeeze the very most out of the Z-machine instead. This "
        "list shows about how much array space is used by some larger items "
        "the source text has chosen to create.</p>");
    ⟨Sort the array usages 24⟩;
    ⟨Tabulate the array usages 23⟩;
    I7_free(sorted, INDEX_SORTING_MREASON);
}
```

The function index_VM_usage is called from 10/bib.

§**23.** The rows in the table mention pathetically small numbers of bytes, of course, by any rational measure.

⟨Tabulate the array usages 23⟩ ≡

```
    begin_plain_html_table(ifl);
    int i;
    VM_usage_note *VMun;
    for (i=0; i<nr; i++) {
        VMun = sorted[i];
        first_html_column(ifl, 0);
        INDEX("%s", VMun->usage_category);
        next_html_column(ifl, 0);
        if (VMun->each_flag) INDEX("each ");
        if (VMun->usage_explained)
            INDEX("%s", VMun->usage_explained);
        else if (VMun->word_ref1 >= 0)
            print_text_to_file(VMun->word_ref1, VMun->word_ref2, ifl);
        if (VMun->word_ref1 >= 0) index_link(lw_array[VMun->word_ref1].lw_source);
        next_html_column(ifl, 0);
```

```
        INDEX("%d bytes", VMun->bytes_used);
        end_html_row(ifl);
    }
    end_html_table(ifl);
```

This code is used in §22.

§**24.** As usual, we sort with the C library's `qsort`.

⟨Sort the array usages 24⟩ ≡

```
    int i = 0;
    VM_usage_note *VMun;
    LOOP_OVER(VMun, VM_usage_note) sorted[i++] = VMun;
    qsort(sorted, nr, sizeof(VM_usage_note *), compare_VM_usage_notes);
```

This code is used in §22.

§**25.** The following means the table is sorted in decreasing order of bytes used, with ties resolved by listing the first-declared item first.

```
int compare_VM_usage_notes(const void *ent1, const void *ent2) {
    const VM_usage_note *v1 = *((const VM_usage_note **) ent1);
    const VM_usage_note *v2 = *((const VM_usage_note **) ent2);
    if (v2->bytes_used != v1->bytes_used) return v2->bytes_used - v1->bytes_used;
    return v1->word_ref1 - v2->word_ref2;
}
```

Headings 4/head

Purpose

To keep track of the hierarchy of headings and subheadings found in the source text.

4/head.§5-11 The heading tree; §12 Verifying the heading tree; §13-16 Miscellaneous heading services; §17-22 Headings with extension dependencies; §23-25 World objects under each heading; §26-34 The world object search list; §35-36 Describing the heading structure, 1: to the debugging log; §37-39 Describing the heading structure, 2: to the index; §40-42 Describing the heading structure, 3: to a freestanding XML file

37   {-callv:index_headings}
40   {-callv:write_headings_as_xml}
```

Definitions

¶1. To take up the narrative of how Inform runs once more, we have read the source text in from the primary source file and from the extensions it requested: nothing more will be supplied from disc, and the whole combined text is arranged as a string of sentence nodes, each direct children of the root. In this section, we are concerned with HEADING nodes.

Most of these occur when the user has explicitly typed a heading such as:

```
Part VII - The Ghost of the Aragon
```

The sentence-breaker called `declare_heading` each time it found one of these, but also when a new source file started, because a file boundary is construed as beginning with a hidden "heading" of a higher rank than any other, and the sentence-breaker made a corresponding HEADING node there too. This is important because the doctrine is that each heading starts afresh with a new hierarchy of lower-order headings: thus changing the Part means we can start again with Chapter 1 if we like, and so on. Because each source file starts with an implicit super-heading, each source file gets its own independent hierarchy of Volume, and so on. But the convention is also important because we need to be able to say that every word loaded from disc ultimately falls under some heading, even if the source text as typed by the designer does not obviously have any headings in it.

The hierarchy thus runs: File (0), Volume (1), Book (2), Part (3), Chapter (4), Section (5). (The implementation below allows for even lower levels of subheading, from 6 to 9, but Inform doesn't use them.) Every run of NI declares at least two File (0) headings, representing the start of main text and the start of the Standard Rules, and these latter have a couple of dozen headings themselves, so the typical number of headings in a source text is 30 to 100.

```
define NO_HEADING_LEVELS 10
```

¶2. Although it is implicit in the parse tree already, the heading structure is not easy to deduce, and so in this section we build a much smaller tree consisting just of the hierarchy of headings. The heading tree has nodes made from the following structures:

```
typedef struct heading {
    struct parse_node *sentence_declaring;                  if any: file starts are undeclared
    struct source_location start_location;                  first word under this heading is here
    int level;                                              0 for Volume (highest) to 5 for Section (lowest)
    int indentation;                                        in a hierarchical listing
    int index_definitions_made_under_this;                  for instance, global variables made here?
    int for_release;                                        include this material in a release version?
    int omit_material;                                      if set, simply ignore all of this
    int use_with_or_without;                                if TRUE, use with the extension; if FALSE, without
    struct extension_identifier for_use_with;               e.g. "for use with ... by ..."
    int in_place_of_w1, in_place_of_w2;                     e.g. "in place of ... in ... by ..."
    struct world_object *list_of_contents;                  world objects defined under this
    struct heading *parent_heading;
    struct heading *child_heading;
    struct heading *next_heading;
    MEMORY_MANAGEMENT
} heading;
```

The structure heading is private to this section.

¶3. The headings and subheadings are formed into a tree in which each heading contains its lesser-order headings. The pseudo-heading exists to be the root of this tree; the entire text falls under it. It is not a real heading at all, and has no "level" or "indentation" as such.

```
heading pseudo_heading;                                     The entire source falls under this top-level heading
```

¶4. As an example, a sequence in the primary source text of (Chapter I, Book Two, Section 5, Chapter I, Section 1, Chapter III) would be formed up into the heading tree:

```
(the pseudo-heading)      level −1, indentation −1
    (File: Standard Rules)      level 0, indentation 0
        ...
    (File: primary source text)      level 0, indentation 0
        Chapter I      level 4, indentation 1
        Book Two      level 2, indentation 1
            Section 5      level 5, indentation 2
            Chapter I      level 4, indentation 2
                Section 1      level 5, indentation 3
            Chapter III      level 4, indentation 2
```

Note that the level of a heading is not the same thing as its depth in this tree, which we call the "indentation", and there is no simple relationship between the two numbers. Clearly we want to start at the left margin. If a new heading is subordinate to its predecessor (i.e., has higher level), we want to indent further, but by the least amount needed – a single tap step. Adjacent equal-level headings are on a par with each other and should have the same indentation. But when the new heading is lower level than its predecessor (i.e., more important) then the indentation decreases to match the last one equally important.

We can secure the last of those properties with a formal definition as follows. The level ℓ_n of a heading depends only on its wording (or source file origin), but the indentation of the nth heading, i_n, depends on $(\ell_1, \ell_2, ..., \ell_n)$, the sequence of all levels so far:

$$i_n = i_{\max\{j \mid 0 \le j < n, \ell_j < \ell_n\}} + 1$$

where $\ell_0 = i_0 = -1$, so that this set always contains 0 and is therefore not empty. We deduce that

(a) $i_1 = 0$ and thereafter $i_n \ge 0$, since ℓ_n is never negative again,

(b) if $\ell_k = \ell_{k+1}$ then $i_k = i_{k+1}$, since the set over which the maximum is taken is the same,

(c) if $\ell_{k+1} > \ell_k$, a subheading of its predecessor, then $i_{k+1} = i_k + 1$, a single tab step outward.

That establishes the other properties we wanted, and shows that i_n is indeed the number of tab steps we should be determining.

Note that to calculate i_n we do not need the whole of $(\ell_1, ..., \ell_n)$: we only need to remember the values of

$$i_{\max\{j \mid 0 \le j < n, \ell_j < K\}}$$

for each possible heading level $K = 0, 1, ..., 9$. This requires much less storage: we call it the "last indentation above level K".

This leads to the following algorithm when looking at the headings in any individual file of source text: at the top of file,

```
for (i=0; i<NO_HEADING_LEVELS; i++) last_indentation_above_level[i] = -1;
```

Then parse for headings (they have an easily recognised lexical form); each time one is found, work out its `level` as 1, ..., 5 for Volume down to Section, and call:

```
int find_indentation(int level) {
    int i, ind = last_indentation_above_level[level] + 1;
    for (i=level+1; i<NO_HEADING_LEVELS; i++)
        last_indentation_above_level[i] = ind;
    return ind;
}
```

While this algorithm is trivially equivalent to finding the depth of a heading in the tree which we are going to build anyway, it is worth noting here for the benefit of anyone writing a tool to (let's say) typeset an Inform source text with a table of contents, or provide a navigation gadget in the user interface.

¶5. The primary source text, and indeed the source text in the extensions, can make whatever headings they like: no sequence is illegal. It is not for NI to decide on behalf of the author that it is eccentric to place Section C before Section B, for instance. The author might be doing so deliberately, to put the Chariot-race before the Baths, say; and the indexing means that it will be very apparent to the author what the heading structure currently is, so mistakes are unlikely to last long. This is a classic case where Inform trying to be too clever would annoy more often than assist.

---

§**1.** The heading tree is constructed all at once, after most of the sentence-breaking is done, but since a few sentences can in principle be added later, we watch for the remote chance of further headings being added, by keeping the following flag:

```
int heading_tree_made_at_least_once = FALSE;
```

§**2.** Now, then, the routine `declare_heading` is called by the sentence-breaker each time it constructs a new HEADING node. (Note that it is not called to create the pseudo-heading, which does not come from a node.)

A level 0 heading has text (the first sentence which happens to be in the new source file), but this has no significance other than its location, and cannot contain information about releasing or about virtual machines.

```
int last_indentation_above_level[NO_HEADING_LEVELS], lial_made = FALSE;

heading *declare_heading(parse_node *PN) {
    heading *h = CREATE(heading);
    h->parent_heading = NULL; h->child_heading = NULL; h->next_heading = NULL;
    h->list_of_contents = NULL;
    h->for_release = TRUE; h->omit_material = FALSE;
    h->index_definitions_made_under_this = TRUE;
    h->use_with_or_without = NOT_APPLICABLE;
    h->in_place_of_w1 = -1; h-> in_place_of_w2 = -2;
    if ((PN == NULL) || (PN->word_ref1 < 0)) internal_error("heading at textless node");
    internal_error_if_node_type_wrong(PN, HEADING_NT);
    h->sentence_declaring = PN;
    h->start_location = lw_array[PN->word_ref1].lw_source;
    h->level = pn_int_annotation(PN, heading_level_ANNOT);
    if (h->level > 0) ⟨Parse heading text for release or other stipulations 4⟩;
    if ((h->level < 0) || (h->level >= NO_HEADING_LEVELS)) internal_error("impossible level");
    ⟨Determine the indentation from the level 3⟩;
    LOGIF(HEADINGS, "Created heading $H", h);
    if (heading_tree_made_at_least_once) make_heading_tree();
    return h;
}
```

The function declare_heading is called from 4/sent.

§**3.** This implements the indentation algorithm described above.

⟨Determine the indentation from the level 3⟩ ≡

```
    int i;
    if (lial_made == FALSE) {
        for (i=0; i<NO_HEADING_LEVELS; i++) last_indentation_above_level[i] = -1;
        lial_made = TRUE;
    }
    h->indentation = last_indentation_above_level[h->level] + 1;
    for (i=h->level+1; i<NO_HEADING_LEVELS; i++)
        last_indentation_above_level[i] = h->indentation;
```

This code is used in §2.

§**4.** A heading which is "not for release" contains material which will be omitted in the release version of a project: generally speaking, that means debugging verbs, test scripts and the like.

⟨Parse heading text for release or other stipulations 4⟩ ≡

```
int i, j, w1, w2, vm1 = -1, vm2 = -1;
[[w1, w2 <-- PN]];
if [[w1, w2 == ... not for release]]
    h->for_release = FALSE;
if [[w1, w2 == ... unindexed]]
    h->index_definitions_made_under_this = FALSE;
for (i=w1; i<w2; i++)
    if (paired_brackets(i, w2)) { vm1 = i+1; vm2 = w2-1; w2 = i-1; break; }
if (vm1 >= 0) {
    if [[vm1, vm2 == for ... only]] {
        switch (current_VM_matches_text(vm1, vm2)) {
            case TRUE: break;
            case FALSE: h->omit_material = TRUE; break;
            case NOT_APPLICABLE:
                current_sentence = PN;
                sentence_problem(_P_(C4HeadingBadVM),
                    "this heading contains a stipulation about the Setting "
                    "for story file format which I can't understand",
                    "and should be something like '(for Z-machine version 5 "
                    "or 8 only)' or '(for Glulx only)'.");
                break;
        }
    }
    if [[vm1, vm2 == for use with/without ... by ... : i]] {
        char exft[MAX_FILENAME_LENGTH], exfa[MAX_FILENAME_LENGTH];
        if [[word vm1+2 == with]] h->use_with_or_without = TRUE;
        else h->use_with_or_without = FALSE;
        print_raw_text_to_string_truncated(vm1+3, i-1, exft, MAX_FILENAME_LENGTH);
        print_raw_text_to_string_truncated(i+1, vm2, exfa, MAX_FILENAME_LENGTH);
        eid_new(&(h->for_use_with), exfa, exft, USEWITH_EIDBC);
    }
    if ([[vm1, vm2 == in place of ... in ... : j]] &&
        [[j, vm2 == in ... by ... : i]]) {
        char exft[MAX_FILENAME_LENGTH], exfa[MAX_FILENAME_LENGTH];
        h->use_with_or_without = TRUE;
        h->in_place_of_w1 = vm1+3; h->in_place_of_w2 = j-1;
        print_raw_text_to_string_truncated(j+1, i-1, exft, MAX_FILENAME_LENGTH);
        print_raw_text_to_string_truncated(i+1, vm2, exfa, MAX_FILENAME_LENGTH);
        LOG("Req is <$W> in <%s> by <%s>\n", h->in_place_of_w1, h->in_place_of_w2, exft, exfa);
        eid_new(&(h->for_use_with), exfa, exft, USEWITH_EIDBC);
    }
    if [[vm1, vm2 == not for release]]
        h->for_release = FALSE;
    if [[vm1, vm2 == unindexed]]
        h->index_definitions_made_under_this = FALSE;
}
```

This code is used in §2.

§**5. The heading tree.** The headings were constructed above as freestanding nodes (except that the pseudo-heading already existed): here, we assemble them into a tree structure. Because we want to be able to call this more than once, perhaps to make revisions if late news comes in of a new heading (see above), we begin by removing any existing relationships between the heading nodes.

```
void make_heading_tree(void) {
    heading *h;
    ⟨Reduce the whole heading tree to a pile of twigs 6⟩;
    LOOP_OVER(h, heading) {
        ⟨If h is outside the tree, make it a child of the pseudo-heading 7⟩;
        ⟨Run through subsequent equal or subordinate headings to move them downward 8⟩;
    }
    heading_tree_made_at_least_once = TRUE;
    verify_heading_tree();
}
```

The function make_heading_tree is invoked by a command in a `.i6t` template file.

§**6.** Note that the loop over headings below loops through all those which were created by the memory manager: which is to say, all of them except for the pseudo-heading, which was explicitly placed in static memory above.

⟨Reduce the whole heading tree to a pile of twigs 6⟩ ≡

```
    heading *h;
    pseudo_heading.child_heading = NULL; pseudo_heading.parent_heading = NULL;
    pseudo_heading.next_heading = NULL;
    LOOP_OVER(h, heading) {
        h->parent_heading = NULL; h->child_heading = NULL; h->next_heading = NULL;
    }
```

This code is used in §5.

§**7.** The idea of the heading loop is that when we place a heading, we also place subsequent headings of lesser or equal status until we cannot do so any longer. That means that if we reach h and find that it has no parent, it must be subordinate to no earlier heading: thus, it must be attached to the pseudo-heading at the top of the tree.

⟨If h is outside the tree, make it a child of the pseudo-heading 7⟩ ≡

```
    if (h->parent_heading == NULL)
        make_child_heading(h, &pseudo_heading);
```

This code is used in §5.

§**8.** Note that the following could be summed up as "move subsequent headings as deep in the tree as we can see they need to be from h's perspective alone". This isn't always the final position. For instance, given the sequence Volume 1, Chapter I, Section A, Chapter II, the tree is adjusted twice:

```
when h = Volume 1:          then when h = Chapter I:
Volume 1                    Volume 1
    Chapter I                   Chapter I
    Section A                       Section A
    Chapter II                  Chapter II
```

since Section A is demoted twice, once by Volume 1, then by Chapter I. (This algorithm would in principle be quadratic in the number of headings if the possible depth of the tree were unbounded – every heading might have to demote every one of its successors – but in fact because the depth is at most 9, it runs in linear time.)

⟨Run through subsequent equal or subordinate headings to move them downward 8⟩ ≡

```
heading *subseq;
for (subseq = NEXT_OBJECT(h, heading);                    start from the next heading in source
     (subseq) && (subseq->level >= h->level);             for a run with level below or equal h
     subseq = NEXT_OBJECT(subseq, heading)) {             in source declaration order
     if (subseq->level == h->level) {                    a heading of equal status ends the run...
         make_child_heading(subseq, h->parent_heading); break;   ...and becomes h's sibling
     }
     make_child_heading(subseq, h);                      all lesser headings in the run become h's children
}
```

This code is used in §5.

§**9.** The above routine, then, calls `make_child_heading` to attach a heading to the tree as a child of a given parent:

```
void make_child_heading(heading *ch, heading *pa) {
    heading *former_pa = ch->parent_heading;
    if (former_pa == pa) return;
    ⟨Detach ch from the heading tree if it is already there 10⟩;
    ch->parent_heading = pa;
    ⟨Add ch to the end of the list of children of pa 11⟩;
}
```

§**10.** If ch is present in the tree, it must have a parent, unless it is the pseudo-heading: but the latter can never be moved, so it isn't. Therefore we can remove ch by striking it out from the children list of the parent. (Any children which ch has, grandchildren so to speak, come with it.)

⟨Detach ch from the heading tree if it is already there 10⟩ ≡

```
    if (former_pa) {
        if (former_pa->child_heading == ch)
            former_pa->child_heading = ch->next_heading;
        else {
            heading *sibling;
            for (sibling = former_pa->child_heading; sibling; sibling = sibling->next_heading)
                if (sibling->next_heading == ch) {
                    sibling->next_heading = ch->next_heading;
                    break;
                }
        }
    }
    ch->next_heading = NULL;
```

This code is used in §9.

§**11.** Two cases: the new parent is initially childless, or it isn't.

⟨Add ch to the end of the list of children of pa 11⟩ ≡

```
    heading *sibling;
    if (pa->child_heading == NULL) pa->child_heading = ch;
    else
        for (sibling = pa->child_heading; sibling; sibling = sibling->next_heading)
            if (sibling->next_heading == NULL) {
                sibling->next_heading = ch;
                break;
            }
```

This code is used in §9.

§**12. Verifying the heading tree.** We have now, in effect, computed the indentation value of each heading twice, by two entirely different methods: first by the mathematical argument above, then by observing that it is the depth in the heading tree. Seeing if these two methods have given the same answer provides a convenient check on our working.

```
int heading_tree_damaged = FALSE;
void verify_heading_tree(void) {
    verify_heading_tree_recursively(&pseudo_heading, -1);
    if (heading_tree_damaged) internal_error("heading tree failed to verify");
}
void verify_heading_tree_recursively(heading *h, int depth) {
    if (h == NULL) return;
    if ((h != &pseudo_heading) && (depth != h->indentation)) {
        heading_tree_damaged = TRUE;
        LOG("$H\n*** indentation should be %d ***\n", h, depth);
    }
    verify_heading_tree_recursively(h->child_heading, depth+1);
    verify_heading_tree_recursively(h->next_heading, depth);
}
```

§**13. Miscellaneous heading services.** The first of these we have already seen in use: the sentence-breaker calls it to ask whether sentences falling under the current heading should be included in the active source text. (For instance, sentences under a heading with the disclaimer "(for Glulx only)" will not be included if the target virtual machine on this run of NI is the Z-machine.)

```
int hd_include_material(heading *h) {
    if ((h->for_release == FALSE) && (for_release == TRUE)) return FALSE;
    if (h->omit_material) return FALSE;
    return TRUE;
}

int hd_indexed(heading *h) {
    if (h == NULL) return TRUE;                    definitions made nowhere are normally indexed
    return h->index_definitions_made_under_this;
}
```

The function hd_include_material is called from 4/sent.

The function hd_indexed is called from 9/qty and 12/phin.

§**14.** Two utilities to do with the file of origin:

```
int hd_in_same_file(heading *h1, heading *h2) {
    if ((h1 == NULL) || (h2 == NULL)) return FALSE;
    if (h1->start_location.file_of_origin == h2->start_location.file_of_origin) return TRUE;
    return FALSE;
}

extension_file *hd_get_extension_containing(heading *h) {
    if ((h == NULL) || (h->start_location.file_of_origin == NULL)) return NULL;
    return sf_get_extension_corresponding(h->start_location.file_of_origin);
}
```

The function hd_in_same_file is called from 12/phin.

The function hd_get_extension_containing is called from 11/act, 12/cph and 12/phin.

§**15.** Although File (0) headings do have text, contrary to the implication of the routine here, this text is only what happens to be first in the file: it isn't a heading actually typed by the user, which is all that we are interested in for this purpose. So we send back a null word range.

```
void hd_get_text_of_heading(heading *h, int *w1, int *w2) {
    if ((h == NULL) || (h->level == 0)) { *w1 = -1; *w2 = -1; return; }
    *w1 = h->sentence_declaring->word_ref1;
    *w2 = h->sentence_declaring->word_ref2;
}
```

The function hd_get_text_of_heading is called from 9/qty, 11/act and 12/phin.

§**16.** This routine determines the (closest) heading to which a scrap of text belongs, and is important since the parsing of noun phrases is affected by that choice of heading (as we shall see): to NI, headings provide something analogous to the scope of local variables in a conventional programming language.

Because every file has a File (0) heading registered at line 1, the loop in the following routine is guaranteed to return a valid heading provided the original source location is well formed (i.e., has a non-null source file and a line number of at least 1).

```
heading *heading_of(source_location sl) {
    heading *h;
    if (sl.file_of_origin == NULL) return NULL;
    LOOP_BACKWARDS_OVER(h, heading)
        if ((sl.file_of_origin == h->start_location.file_of_origin) &&
            (sl.line_number >= h->start_location.line_number)) return h;
    internal_error("unable to determine the heading level of source material");
    return NULL;
}
```

The function heading_of is called from 9/qty, 11/act, 12/cph and 12/phin.

§**17. Headings with extension dependencies.** If the content under a heading depended on the VM not in use, or was marked not for release in a release run, we were able to exclude it just by skipping. The same cannot be done when a heading says that it should be used only if a given extension is, or is not, being used, because when the heading is created we don't yet know which extensions are included. But when the following is called, we do know that.

```
void satisfy_heading_dependencies(void) {
    heading *h;
    LOOP_OVER(h, heading)
        if (h->use_with_or_without != NOT_APPLICABLE)
            satisfy_individual_heading_dependency(h);
}
```

The function satisfy_heading_dependencies is invoked by a command in a `.i6t` template file.

§**18.** And now the code to check an individual heading's usage. This whole thing is carefully timed so that we can still afford to cut up and rearrange the parse tree on quite a large scale, and that's just what we do.

```
void satisfy_individual_heading_dependency(heading *h) {
    int loaded = FALSE;
    extension_identifier *eid = &(h->for_use_with);
    if (h->level < 1) return;
    if (no_times_EID_used_in_context(eid, LOADED_EIDBC) != 0) loaded = TRUE;
    if (pn_int_annotation(h->sentence_declaring, suppress_heading_dependencies_ANNOT)) return;
    if (h->in_place_of_w1 >= 0) {
        heading *h2; int found = FALSE;
        if (loaded == FALSE) ⟨Can't replace heading in an unincluded extension 20⟩
        else {
            LOOP_OVER(h2, heading)
                if ((h2->sentence_declaring) &&
                    (compare_word_range(h->in_place_of_w1, h->in_place_of_w2,
                        h2->sentence_declaring->word_ref1, h2->sentence_declaring->word_ref2)) &&
                    (eid_match(ef_get_eid(hd_get_extension_containing(h2)), eid))) {
                    found = TRUE;
                    if (h->level != h2->level)
```

```
                    ⟨Can't replace heading unless level matches 22⟩;
                excise_material_under(h2, NULL);
                excise_material_under(h, h2->sentence_declaring);
                break;
            }
        if (found == FALSE) ⟨Can't find heading in the given extension 21⟩;
    }
} else
    if (h->use_with_or_without != loaded) excise_material_under(h, NULL);
}
```

§**19.** To excise, we simply amend the "next" link from the heading to point to the next heading, or to null if no such exists; we repeat until we hit a heading of equal or greater importance than the original, or the end of the current extension, or the end of the whole source text. (Thus, all headings remain in the parse tree; only the material subordinate to them disappears.) If another parse node is supplied then the nodes extracted are strung onto it in sequence rather than being thrown away.

Any heading which is excised is marked so that it won't have its own dependencies checked. This clarifies several cases, and in particular ensures that if Chapter X is excised then a subordinate Section Y cannot live on by replacing something elsewhere (which would effectively delete the content elsewhere). Since subordinate headings always come later in the parse tree than higher ones, there is no risk that Section Y has already had its dependencies checked.

```
void excise_material_under(heading *h, parse_node *transfer_to) {
    int lev = h->level;
    parse_node *hpn;
    parse_node *end_of_transfer = NULL;
    if (transfer_to) end_of_transfer = transfer_to->next;
    if (h->sentence_declaring == NULL) internal_error("stipulations on a non-sentence heading");
    hpn = h->sentence_declaring;
    do {
        parse_node *pn;
        pn_annotate_int(hpn, suppress_heading_dependencies_ANNOT, TRUE);
        for (pn = hpn->next; ((pn) && (pn_get_node_type(pn) != HEADING_NT) && (pn_get_node_type(pn)
!= ENDHERE_NT)); pn = pn->next)
            if (transfer_to) { transfer_to->next = pn; transfer_to = pn; }
        hpn->next = pn;
        hpn = pn;
    } while ((hpn) && (pn_int_annotation(hpn, heading_level_ANNOT) > lev) &&
        (pn_get_node_type(hpn) != ENDHERE_NT));
    if (transfer_to) transfer_to->next = end_of_transfer;
}
```

§**20.**

⟨Can't replace heading in an unincluded extension 20⟩ ≡

```
    current_sentence = h->sentence_declaring;
    sentence_problem(_P_(C4HeadingInPlaceOfUnincluded),
        "no extension of that name is included",
        "so it is not possible to replace one of its headings with this one.");
```

This code is used in §18.

§**21.**

⟨Can't find heading in the given extension 21⟩ ≡

```
current_sentence = h->sentence_declaring;
sentence_problem(_P_(C4HeadingInPlaceOfUnknown),
    "no heading of that name appears to be in the given extension",
    "so it is not possible to replace it with this one.");
```

This code is used in §18.

§**22.**

⟨Can't replace heading unless level matches 22⟩ ≡

```
current_sentence = h->sentence_declaring;
sentence_problem(_P_(C4UnequalHeadingInPlaceOf),
    "these headings are not of the same level",
    "so it is not possible to make the replacement. (Level here means "
    "being a Volume, Book, Part, Chapter or Section: for instance, "
    "only a Chapter heading can be used 'in place of' a Chapter.)");
```

This code is used in §18.

§**23. World objects under each heading.** Every heading carries with it a linked list of the world objects created in sentences which belong to it, in the sense of the `heading_of` routine defined above. When any world object is created, the following is called to let the current sentence's heading know that it has a new friend.

But the assertion-maker giveth and the assertion-maker taketh away: blessed be the name of the assertion-maker. World objects are sometimes temporarily created and then destroyed again, and in particular this can legally happen when the current sentence is outside of any heading, in text manufactured internally.

```
int no_headless_wos = 0;
void attach_wo_to_heading(world_object *new_wo) {
    heading *h = heading_of(lw_array[current_sentence->word_ref1].lw_source);
    new_wo->under_what_heading = h;
    if (h == NULL) { no_headless_wos++; return; }
    if (h->list_of_contents == NULL) h->list_of_contents = new_wo;
    else {
        world_object *wh;
        for (wh = h->list_of_contents; wh; wh = wh->next_under_heading)
            if (wh->next_under_heading == NULL) {
                wh->next_under_heading = new_wo;
                return;
            }
    }
}
```

The function attach_wo_to_heading is called from 9/wo.

§**24.** Here a tentative world object definition has been cancelled, so that we need to strike it out of the heading's list again. (This is no longer used, in fact.)

```
void detach_wo_from_heading(world_object *moribund) {
    heading *h = moribund->under_what_heading;
    if (h) {
        moribund->under_what_heading = NULL;
        if (h->list_of_contents == moribund)
            h->list_of_contents = moribund->next_under_heading;
        else {
            world_object *item;
            for (item = h->list_of_contents; item; item = item->next_under_heading)
                if (item->next_under_heading == moribund) {
                    item->next_under_heading = moribund->next_under_heading;
                    return;
                }
        }
    } else no_headless_wos--;
}
```

§**25.** The following verification checks that every world object is listed in the object list for exactly one heading. (It abuses the `room_flag` field shabbily to do this, using it not as a flag or anything to do with rooms but as an instance count: but `room_flag` is not used until the model world is being set up, which is long after all the object creations and uncreations, when the following routine is used.) The point of the check is not so much to make sure the object lists are properly formed, as the code making those is pretty elementary: it's really a test that the source text is well-formed with everything placed under a heading, and no sentence having fallen through a crack.

```
void verify_heading_divisions(void) {
    world_object *wo; heading *h;
    int total = 0, disaster = FALSE;
    LOOP_OVER(wo, world_object) wo->room_flag = 0;
    LOOP_OVER(h, heading)
        for (wo=h->list_of_contents; wo!=NULL; wo=wo->next_under_heading)
            wo->room_flag++, total++;
    LOOP_OVER(wo, world_object) if (wo != kind_kind)
        if (wo->room_flag > 1) {
            LOG("$O occurs under %d headings\n", wo, wo->room_flag);
            disaster = TRUE;
        }
    if (total + no_headless_wos + 1 != NUMBER_CREATED(world_object)) {
        LOG("%d WOs != %d headed + %d headless + 1 kind_kind\n",
            NUMBER_CREATED(world_object), total, no_headless_wos);
        disaster = TRUE;
    }
    if (disaster) internal_error_tree_unsafe("heading contents list failed verification");
    LOOP_OVER(wo, world_object) wo->room_flag = FALSE;
}
```

The function verify_heading_divisions is called from 9/wo.

§**26. The world object search list.** Identifying noun phrases is tricky. Many plausible phrases could refer in principle to several different world objects: "east", for instance, might mean the direction or, say, "east garden". And what if the source mentions many chairs, and now refers simply to "the chair"? This problem is not so acute for nouns referring to abstractions, where we can simply forbid duplicate definitions and require an exact wording when talking about them. But for world objects – which represent the solid and often repetitive items and places of the simulated world – it cannot be ducked. We can hardly tell an Inform author to create at most one item whose name contains the word "jar", for instance.

All programming languages face similar problems. In C, for instance, a local variable named `east` will be recognised in preference to a global one of the same name (to some extent external linking provides a third level again). The way this is done is usually explained in terms of the "scope" of a definition, the part of the source for which it is valid: the winner, in cases of ambiguity, being the definition of narrowest scope which is valid at the position in question. In our terms, a stand-alone C program has a heading tree like so, with two semantically meaningful heading levels, File (0) and Routine (1), and then sublevels provided by braced blocks:

```
File
    main()
    routine1()
        interior block of a loop
        ...
    routine2()
    ...
```

The resolution of a name at a given position P is unambiguous: find the heading H to which P belongs; if the name is defined there, accept that; if not move H upwards and try again; if it is not defined even at File (0) level, issue an error: the term is undefined.

Inform is different in two respects, one trivial, the other not. The trivial difference is that an Inform name can be defined midway through the matter (though as a result of the C99 revision, ANSI C now also allows variables to be created mid-block, in fact: and some C compilers even implement this).

The big difference is that in Inform, names are always visible across headings. They can be used before being defined; Section 2 of Part II is free to mention the elephant defined in Section 7 of Part VIII, say. English text is like this: a typical essay has one great big namespace.

We resolve this by searching backwards through recent object creations in the current heading, then in the current heading level above that, and so on up to the top conceptual level of the source. Thus a "chair" in the current chapter will always have priority over any in previous chapters, and so on. However, kinds are always given priority over mere instances, in order that "door" will retain its generic meaning even if, say, "an oak door" is created.

§**27.** This means that, under every heading, the search sequence is different. So for the sake of efficiency we construct a linked list of world objects in priority order the first time we search under a new heading, then simply use that thereafter: we also keep track of the tail of this list. Sections other than this one cannot read the list itself, and use the following definition to iterate through it.

```
define LOOP_OVER_WO_SEARCH_LIST(wo)
    for (wo = wo_search_start; wo; wo = wo->next_to_search)

world_object *wo_search_start = NULL, *wo_search_finish = NULL;
```

§28. The search sequence is, in effect, a cache storing a former computation, and like all caches it can fall out of date if the circumstances change so that the same computation would now produce a different outcome. That can only happen here if any world object is created or destroyed: the assertion-maker calls the following routine to let us know.

```
heading *wo_search_list_valid_for_this_heading = NULL;                    initially it's unbuilt
void hd_disturb_headings(void) {
    wo_search_list_valid_for_this_heading = NULL;
}
```

The function hd_disturb_headings is called from 9/wo.

§29. Leaving aside the cache, then, we build a list as the kind "kind", then all the other kinds as found by recursively searching headings, then all the world objects found in the same way.

```
void construct_wo_search_list(void) {
    heading *h = NULL;
    ⟨Work out the heading from which we wish to search 30⟩;
    if (h == wo_search_list_valid_for_this_heading) return;                    rely on the cache
    LOGIF(HEADINGS, "Rebuilding WO search list from: $H\n", h);
    ⟨Start the search list containing just the kind "kind" 31⟩;
    build_wo_search_list_from(h, NULL, TRUE);                                  pass 1: add the kinds
    build_wo_search_list_from(h, NULL, FALSE);                                 pass 2: add the world objects
    ⟨Verify that the search list indeed contains every world object just once 32⟩;
    wo_search_list_valid_for_this_heading = h;
}
```

The function construct_wo_search_list is called from 9/wo.

§30. Basically, we calculate the search list from the point of view of the current sentence:

⟨Work out the heading from which we wish to search 30⟩ ≡

```
    if ((current_sentence == NULL) || (current_sentence->word_ref1 < 0))
        internal_error("cannot establish position P: there is no current sentence");
    source_location position_P = lw_array[current_sentence->word_ref1].lw_source;
    h = heading_of(position_P);
    if (h == NULL) internal_error("no heading for position P");
```

This code is used in §29.

§31. We initialise the list to consist only of the kind "kind" – which belongs to no heading: it is the unique world object created within Inform itself at start-up.

The pseudo-heading has no list of contents because all objects are created in source files, each certainly underneath a File (0) heading, so nothing should ever get that far.

⟨Start the search list containing just the kind "kind" 31⟩ ≡

```
    wo_search_start = kind_kind;
    wo_search_finish = kind_kind;
    kind_kind->next_to_search = NULL;
    pseudo_heading.list_of_contents = NULL;                    should always be true, but just in case
```

This code is used in §29.

§**32.** The potential for disaster if this algorithm should be incorrect is high, so we perform a quick count to see if everything made it onto the list and produce an internal error if not.

⟨Verify that the search list indeed contains every world object just once 32⟩ ≡

```
int c; world_object *wo;
for (c=0, wo = wo_search_start; wo != NULL; wo = wo->next_to_search) c++;
if (c != wo_get_no_wos_now_existing()) {
    LOG("Reordering failed from $H\n", h);
    LOG("%d wos created, %d in ordering\n", wo_get_no_wos_now_existing(), c);
    log_all_headings();
    LOG("Making fresh tree:\n");
    make_heading_tree();
    log_all_headings();
    internal_error_tree_unsafe("reordering of objects failed");
}
```

This code is used in §29.

§**33.** The following adds all objects under heading H to the search list, using its own list of contents, and then recurses to add all objects under subheadings of H other than the one which has just recursed up to H. With that done, we recurse up to the superheading of H.

To prove that `build_wo_search_list_from` is called exactly once for each heading in the tree, forget about the up/down orientation and consider it as a graph instead. At each node we try going to every possible other node, except the way we came (at the start of the traverse, the "way we came" being null): clearly this ensures that all of our neighbours have been visited. Since every heading ultimately depends from the pseudo-heading, the graph is connected, and therefore every heading must eventually be visited. No heading can be visited twice, because that would mean that a cycle of nodes $H_1, H_2, ..., H_i, H_1$ must exist: since we have a tree structure, there are no loops, and so $H_i = H_2$, $H_{i-1} = H_3$, and so on – we must be walking a path and then retracing our steps in reverse. That being so, there is a point where we turned back: we went from H_j to H_{j+1} to H_j again. And this violates the principle that at each node we move outwards in every direction *except* the way we came, a contradiction.

The routine looks as if it may have a large recursion depth – maybe as deep as the number of headings – but because we go downwards and then upwards, the maximum recursion depth of the routine is less than $2L + 1$ where L is the number of levels in the tree other than the pseudo-heading, which provides an upper bound of about 21, regardless of the size of the source text. The running time is linear in both the number of headings and the number of world objects in the source text.

```
void build_wo_search_list_from(heading *within, heading *way_we_came, int kinds) {
    world_object *wo; heading *subhead;
    if (within == NULL) return;
    for (wo = within->list_of_contents; wo; wo=wo->next_under_heading)
        if ((wo != kind_kind) && (wo->kind_flag == kinds))
            ⟨Add WO to the end of the search list 34⟩;
    recurse downwards through subordinate headings, other than the way we came up
    for (subhead = within->child_heading; subhead; subhead = subhead->next_heading)
        if (subhead != way_we_came)
            build_wo_search_list_from(subhead, within, kinds);
    recurse upwards to superior headings, unless we came here through a downward recursion
    if (within->parent_heading != way_we_came)
        build_wo_search_list_from(within->parent_heading, within, kinds);
}
```

§**34.** Note that `wo_search_finish` is always guaranteed non-`NULL` here, since the list was initialised containing the kind "kind", rather than being initialised empty.

⟨Add WO to the end of the search list 34⟩ ≡

```
if (wo_search_finish->next_to_search != NULL)
    internal_error("end of WO search list has frayed somehow");
wo_search_finish->next_to_search = wo;
wo_search_finish = wo_search_finish->next_to_search;
wo_search_finish->next_to_search = NULL;
```

This code is used in §33.

§**35. Describing the heading structure, 1: to the debugging log.** Finally, three ways to describe the run of headings: to the debugging log, to the index of the project, and to a freestanding XML file.

```
void log_heading(heading *h) {
    if (h==NULL) { LOG("<null heading>\n"); return; }
    if (h==&pseudo_heading) { LOG("<pseudo_heading>\n"); return; }
    LOG("H%d ", h->allocation_id);
    if (h->start_location.file_of_origin) LOG("<%s, line %d>",
        sf_get_filename(h->start_location.file_of_origin), h->start_location.line_number);
    else LOG("<nowhere>");
    LOG(" level:%d indentation:%d", h->level, h->indentation);
}
```

The function log_heading is called from 2/dl.

§**36.** And here we log the whole heading tree by recursing through it, and surreptitiously check that it is correctly formed at the same time.

```
void log_all_headings(void) {
    heading *h;
    LOOP_OVER(h, heading) LOG("$H", h);
    LOG("\n");
    log_headings_recursively(&pseudo_heading, 0);
}
void log_headings_recursively(heading *h, int depth) {
    int i;
    if (h==NULL) return;
    for (i=0; i<depth; i++) LOG("  ");
    LOG("$H\n");
    if (depth -1 != h->indentation) LOG("*** indentation should be %d ***\n", depth-1);
    log_headings_recursively(h->child_heading, depth+1);
    log_headings_recursively(h->next_heading, depth);
}
```

§37. Describing the heading structure, 2: to the index.

```
int headings_indexed = 0;
void index_headings(void) {
    INDEX("<b>Contents Page</b><p>");
    index_heading_recursively(pseudo_heading.child_heading);
    if (headings_indexed == 0) {
        INDEX("<p><i>The source text is not divided by headings.</i></p>\n");
    }
    INDEX("<hr><p>");
}
```

The function index_headings is invoked by a command in a `.i6t` template file.

§**38.** We index only headings of level 1 and up – so, not the pseudo-heading or the File (0) ones – and which are not within any extensions – so, are in the primary source text written by the user.

```
void index_heading_recursively(heading *h) {
    if (h == NULL) return;
    if ((h->level >= 1) &&
        (sf_get_extension_corresponding(h->start_location.file_of_origin) == NULL)) {
        indent to correct tab position
        open_html_paragraph(ifl, h->indentation, "tight");
        int j; for (j=0; j¡h-¿indentation; j++) INDEX("nbsp;nbsp;nbsp;nbsp;");
        write the text of the heading title
        print_raw_text_to_file(h->sentence_declaring->word_ref1,
            h->sentence_declaring->word_ref2, ifl);
        place a link to the relevant line of the primary source text
        index_link(h->start_location);
        INDEX("</p>\n");
        ⟨List all the objects and kinds created under the given heading, one tap stop deeper 39⟩;
        headings_indexed++;
    }
    index_heading_recursively(h->child_heading);
    index_heading_recursively(h->next_heading);
}
```

§**39.** We skip any objects or kinds without names (i.e., whose `creator` is null). The rest appear in italic type, and without links to source text since this in practice strews distractingly many orange berries across the page.

⟨List all the objects and kinds created under the given heading, one tap stop deeper 39⟩ ≡

```
world_object *wo;
int c = 0;
for (wo=h->list_of_contents; wo!=NULL; wo=wo->next_under_heading)
    if (wo->word_ref1 >= 0) {
        if (c++ == 0) {
            /* int j;
            for (j=0; j<h->indentation + 1; j++) INDEX("    "); */
            open_html_paragraph(ifl, h->indentation + 1, "tight");
            INDEX("<font color=\"#808080\">");
        } else INDEX(", ");
        INDEX("<i>");
        print_raw_text_to_file(wo->word_ref1, wo->word_ref2, ifl);
        INDEX("</i>");
    }
if (c > 0) INDEX("</font></p>\n");
```

This code is used in §38.

§**40. Describing the heading structure, 3: to a freestanding XML file.** This is provided as a convenience to the application using NI, which may want to have a pull-down menu or similar gadget allowing the user to jump to a given heading. This tells the interface where every heading is, thus saving it from having to parse the source.

The property list contains a single dictionary, whose keys are the numbers 0, 1, 2, ..., $n-1$, where there are n headings in all. (The pseudo-heading is not included.) A special key, the only non-numerical one, called "Application Version", contains the NI build number in its usual form: "4Q34", for instance.

```
void write_headings_as_xml(void) {
    STREAM xf_struct; STREAM *xf = &xf_struct;
    char *fn = index_filename(XML_HEADINGS_LEAFNAME, -1);
    if (STREAM_OPEN_TO_FILE(xf, fn, UTF8_ENC) == FALSE)
        fatal_error2("Can't open headings file", fn);
    write_headings_as_xml_inner(xf);
    STREAM_CLOSE(xf);
}

void write_headings_as_xml_inner(OUTPUT_STREAM) {
    heading *h;
    ⟨Write DTD indication for XML headings file 41⟩;
    WRITE("<plist version=\"1.0\"><dict>\n");
    INDENT;
    WRITE("<key>Application Version</key><string>%s</string>\n", NI_BUILD);
    LOOP_OVER(h, heading) {
        WRITE("<key>%d</key><dict>\n", h->allocation_id);
        INDENT;
        ⟨Write the dictionary of properties for a single heading 42⟩;
        OUTDENT;
        WRITE("</dict>\n");
    }
    OUTDENT;
```

```
    WRITE("</dict></plist>\n");
}
```

The function write_headings_as_xml is invoked by a command in a `.i6t` template file.

§**41.** We use a convenient Apple DTD:

⟨Write DTD indication for XML headings file 41⟩ ≡

```
    WRITE("<?xml version=\"1.0\" encoding=\"UTF-8\"?>\n"
        "<!DOCTYPE plist PUBLIC \"-//Apple Computer//DTD PLIST 1.0//EN\" "
        "\"http://www.apple.com/DTDs/PropertyList-1.0.dtd\">\n");
```

This code is used in §40.

§**42.** Note that a level of 0, and a title of `--`, signifies a File (0) level heading: external tools can probably ignore such records. Similarly, it is unlikely that they will ever see a record without a "Filename" key – this would mean a heading arising from text created internally within NI, which will only happen if someone has done something funny with `.i6t` files – but should this arise then the best recourse is to ignore the heading.

⟨Write the dictionary of properties for a single heading 42⟩ ≡

```
    if (h->start_location.file_of_origin)
        WRITE("<key>Filename</key><string>%s</string>\n",
            sf_get_filename(h->start_location.file_of_origin));
    WRITE("<key>Line</key><integer>%d</integer>\n", h->start_location.line_number);
    if (h->sentence_declaring != NULL) {
        WRITE("<key>Title</key><string>");
        print_raw_text_to_file(h->sentence_declaring->word_ref1,
            h->sentence_declaring->word_ref2, OUT);
        WRITE("</string>\n");
    } else {
        WRITE("<key>Title</key><string>--</string>\n");
    }
    WRITE("<key>Level</key><integer>%d</integer>\n", h->level);
    WRITE("<key>Indentation</key><integer>%d</integer>\n", h->indentation);
```

This code is used in §40.

Verb Phrases 4/verb

Purpose

To construct verb-phrase nodes in the parse tree.

Template interpreter commands

```
1   {-callv:traverse_for_verbs}
```

Definitions

¶1. At this point in the narrative, we have read files from disc, lexed the text into a stream of words, and broken this into a list of sentences; we have identified requests to include extensions, and fully acted on these, so that we can now forget about that whole complication; and we have built a tree of headings and subheadings (and file divisions) so that we have a clear map of the overall structure of the source text. Sentences intended for use only in some circumstances (for instance, when compiling for the Glulx virtual machine) have been omitted as necessary, so that we can forget about that complication, too.

This gives as much information as we can squeeze out by easily specified mechanical means: we have attacked the text at the very small scale, letters and words, and at the very large, headings and files. This zig-zag in scale will continue. In the rest of this chapter, we find the overall structure of sentences; in chapters 5, 6, and 7 we descend to the level of excerpts of two or three words at a time, and will not get back up to sentence level again until chapter 8. As for going up further to the larger structure of multi-sentence rules, that will have to wait until chapter 12.

¶2. The parse tree is currently a long, long list: each sentence is a node which is a child of the root, but no sentence has any child nodes of its own. (That is about to change.) We can divide these sentences into three:

(a) Structural sentences – headings, extension requests, extension bookends. All these have now been dealt with.

(b) Sentences inside rules: rule preambles (`ROUTINE_NT` nodes) and phrases (`COMMAND_NT`). These will not even be looked at until the second phase of compilation, after the model world has been created.

(c) Sentences with primary verbs, having node type `SENTENCE_NT`. These are the assertions: they make statements about the initial state of the model world – the existence of places and things, and their properties at the start of play – and which describe patterns of behaviour during play.

In the present section of code, then, we identify the primary verbs of assertion sentences, and deal right away with some of the easier cases, while leaving the harder ones for chapter 8 to sort out.

¶3. Every `SENTENCE_NT` node is annotated with a verb type from the enumeration below. All of the assertions which create objects and kinds, and put them into relationships with each other – a tremendous variety of possible sentences, between them making up about three-quarters of all `SENTENCE_NT` nodes in typical source – fall into one of two verb types:

define `ASSERT_VB` 10 *"The bat and ball are on the table."*
define `HAS_VB` 11 *"The silver bars have score 10."*

¶4. All other sentences are exceptional cases with much more specific wording. Though there may appear to be a great many of these, each is relatively rarely-used, and some are so exceptional that most Inform users are unaware of them. First, some verb types which we might call *notational*, since they change Inform's notation:

define USEMEANS_VB 20 *"Use American dialect means ..."*
define TRANSLATES_VB 21 *"Lighted translates into I6 as "light""*
define TRANSLATESU_VB 22 *"Black king chess piece translates into Unicode as 9818"*
define PLURAL_VB 23 *"The plural of woman is women."*
define SPECIFIES_VB 24 *"10'23 specifies a running time."*

¶5. Secondly, ways to create constructions other than objects. (Objects and kinds are constructed by standard assertions: these more abstract forms are made using special sentence forms partly to avoid misinterpreting their names as objects, and partly to allow us to use more elaborate and specific grammar for the details, as with actions.)

define DEFINED_BY_VB 30 *"The colours are defined by Table 1."*
define EPISODE_VB 31 *"The story is episode..."*
define FIGURE_VB 32 *"Figure... is the file..."*
define SOUND_VB 33 *"Sound... is the file..."*
define FILE_VB 34 *"File... is the file..."*
define CANBE_VB 35 *"A door can be open or closed."*
define NEW_ACTION_VB 36 *"Taking something is an action."*
define NEW_ACTIVITY_VB 37 *"Description is an activity."*
define NEW_VERB_VB 38 *"The verb to eat..."*
define NEW_RELATION_VB 39 *"Knowledge relates..."*

¶6. Thirdly, some relationships between these abstractions. (Whereas, again, relationships between objects are established with ordinary assertions.)

define IN_RULEBOOK_VB 40 *"The time passes rule is listed in the turn sequence rulebook."*
define NOT_IN_RULEBOOK_VB 41 *"The blossom rule is not listed in..."*
define BEGINS_WHEN_VB 42 *"Scene begins when ..."*
define ENDS_WHEN_VB 43 *"Scene ends when ..."*

¶7. Finally, the remaining verb types are all direct commands to Inform – note the imperative forms they take: Use, Understand, Include, and so forth. In a sense the whole source text is an instruction to Inform, but mostly it's a passive one: the implicit message is "make the world so that all this comes right". Here, on the other hand, the user actually speaks directly. This is a point of the design which has sometimes seemed a little doubtful – wouldn't it be more consistent for all of these sentences to be more passively worded? – but pragmatism won out: circumlocutions such as "American dialect is used." or "The story file is released along with..." are plausible enough, but

"take noun" is understood as taking the noun.

would mean a lot of important sentences being oddly punctuated with no initial capital letter, while forcing meaningless extra words, as in

The command "take noun" is understood as taking the noun.

might prove annoying. Users seem to find the directness of the imperative easier to use, at any rate, and perhaps the difference in mood helps to clarify that these are sentences rather different in implication from the usual sort.

define USE_VB 50 *"Use American dialect."*

```
define UNDERSTAND_VB 51                    "Understand "take [noun]" as taking the noun."
define TEST_VB 52                          "Test ... with "...".."
define DEBUG_VB 53                         "Include ... in the debugging log."
define DOC_VB 54                           "Document ... at ..."
define RELEASE_VB 55                       "Release along with..."
define MAP_PARAMETER_VB 56                 "Index map with ..."
```

---

§**1.** As with headings, so with SENTENCE_NT nodes: we want the ability to come back later and add some more. That means that the primary-verb-finder needs to be able to make more than one pass through. To handle this, all SENTENCE_NT nodes are annotated on creation with the "sentence unparsed" marker: we run through the top level of the parse tree, look at all nodes with this marker, parse their associated sentences, and remove the marker from them. (So, for instance, if this is run twice in quick succession, the second run-through does nothing.)

```
void traverse_for_verbs(void) {
    parse_node *PN;
    for (TREE_START(PN); PN; TREE_NEXT(PN))
        if ((pn_get_node_type(PN) == SENTENCE_NT) &&
            (pn_int_annotation(PN, sentence_unparsed_ANNOT))) {
            look_for_verb_phrase(PN);
            check_sentence_for_direction_creation(PN);
            pn_annotate_int(PN, sentence_unparsed_ANNOT, FALSE);
        }
}
```

The function traverse_for_verbs is invoked by a command in a .i6t template file.

§**2. Primary verbs.** As will be seen below, the parsing of all the exceptional cases – those which come out as anything other than ASSERT_VB or HAS_VB – is done very crudely. The first match wins, and there is no backtracking. It might reasonably be asked: why don't we handle all this with the S-grammar, the much more sophisticated parser of conditions such as "if six bricks are in the skip"? We would have to make some new verbs and relations, but we would get much better resolution of ambiguities, and could cut out some of the tedious code below. There are two answers: first, because some of these verbs handle noun phrases which are exotic in structure and could not be fitted easily into the S-grammar's noun phrase definition (consider the sentence constructing an action); second, because we expect at least some of the noun phrases in these sentences to be previously undeclared names. To parse

> The coral snake is in the green bucket.

at a time when neither snake nor bucket has been mentioned before, we really have little option but to look for "is" plus preposition, and cannot use the words either side as any support for the hypothesis that this is indeed the verb. (The main S-grammar parser would accept "NP_1 is in NP_2" only where it could satisfy itself that the two noun phrases were well-formed.) So that's why we don't use the S-grammar at this early stage. The reason we don't backtrack is that it seems to be unnecessary in practice, and anyway in principle we don't really want people to use these sentences in ways that are misleading to the eye.

The order in which the possibilities are checked is important: we must check "X is an action" before "X is Y", for instance.

```
void look_for_verb_phrase(parse_node *PN) {
    int w1, w2;
    [[w1, w2 <-- PN]];
    ⟨Maybe this is a Unicode translation sentence 3⟩;
    ⟨Maybe this is an Understand or Test sentence 4⟩;
```

```
    ⟨Maybe this is a debugging log sentence 5⟩;
    ⟨Maybe this is a Document... at... sentence 6⟩;
    ⟨Maybe this is a scene anchoring sentence 7⟩;
    ⟨Maybe this is some new notation 8⟩;
    ⟨Maybe this is a resource-declaring sentence 9⟩;
    ⟨Maybe this is an action or activity declaration 10⟩;
    ⟨Maybe this is a verb or relation declaration 11⟩;
    ⟨Maybe this is a property declaration 12⟩;
    ⟨Maybe this is a rule-positioning sentence 13⟩;
    ⟨More likely this is an assertion about objects and kinds 14⟩;
    ⟨If not, it might be an I6 translation 19⟩;
    ⟨Or possibly a use option, release instruction or index map hint 20⟩;
    ⟨Issue a problem message if a primary verb in the past tense is found 21⟩;
}
```

The function look_for_verb_phrase is called from 4/sent and 4/ofs.

§**3.** We check Unicode translations first of all, because we haven't any control over the wording of character names in the Unicode standard. Among the 12,997 definitions used in the Unicode Full Character Names extension are such choice examples as "downwards arrow from bar", "arabic hamza above", "kangxi radical use" and so forth, and we don't want to misread "from", "above", "use", and so on, as prepositions or verbs: in sentences like this one they are nouns.

As we shall see, `try_verb` looks for the given sequence of words in mid-sentence, assigning the given verb type to the sentence node and returning true if it succeeds.

⟨Maybe this is a Unicode translation sentence 3⟩ ≡

```
    if (try_verb(translates_V, into_V, unicode_V, PN, TRANSLATESU_VB, 0))
        return;
```

This code is used in §2.

§**4.** "Understand... as..." and "Test... with...":

⟨Maybe this is an Understand or Test sentence 4⟩ ≡

```
    if ([[w1, w2 == understand ...]] &&
        (try_verb(as_V, 0, 0, PN, UNDERSTAND_VB, 0))) return;
    if ([[w1, w2 == test ...]] &&
        (try_verb(with_V, 0, 0, PN, TEST_VB, 0))) return;
```

This code is used in §2.

§**5.** Two special sentence forms for toggling what does and doesn't go into the debugging log: most users do not know about this feature, but in fact it's fully enabled in the shipping version of the application.

We act immediately on these sentences, so that debugging information is available at the earliest opportunity. Following the successful call to `try_verb`, the sentence will have the not very grammatically sound subtree:

```
SENTENCE_NT "Include object creations in the debugging log"
    VERB_NT "in the debugging"
    NOUNPHRASE_NT "Include object creations"
    NOUNPHRASE_NT "log"
```

We don't care that this is a bit of a mess: we simply take the first noun phrase, strip it of its first word (necessarily "Include") and pass the text to the logging aspects code.

⟨Maybe this is a debugging log sentence 5⟩ ≡

```
if ([[w1, w2 == include ...]] &&
    (try_verb(in_V, the_V, debugging_V, PN, DEBUG_VB, 0))) {
    set_debugging_aspect(
        PN->down->next->word_ref1+1, PN->down->next->word_ref2, TRUE);
    return;
}
if ([[w1, w2 == omit ...]] &&
    (try_verb(from_V, the_V, debugging_V, PN, DEBUG_VB, 0))) {
    set_debugging_aspect(
        PN->down->next->word_ref1+1, PN->down->next->word_ref2, FALSE);
    return;
}
```

This code is used in §2.

§**6.** A special sentence intended for use only in the Standard Rules, for relating documentation symbols to section numbers of the documentation.

⟨Maybe this is a Document... at... sentence 6⟩ ≡

```
if ([[w1, w2 == document ...]] &&
    (try_verb(at_V, 0, 0, PN, DOC_VB, 0))) return;
```

This code is used in §2.

§**7.** For anchoring scenes together. The syntax for different scene endings means that the sentence form we need to recognise is a little bit worryingly general: anything in the form "...ends... when..." What saves the situation is that "when" clauses, though often attached to rules, are almost never naturally found in assertion sentences other than "Understand" ones (and we have already dealt with those).

⟨Maybe this is a scene anchoring sentence 7⟩ ≡

```
int i, j;
if (try_verb(begins_V, when_V, 0, PN, BEGINS_WHEN_VB, 0)) return;
if (try_verb(ends_V, when_V, 0, PN, ENDS_WHEN_VB, 0)) return;
if ([[w1, w2 == ... ends ... when ... : i, j]] &&
    (try_verb(when_V, 0, 0, PN, ENDS_WHEN_VB, 0))) return;
```

This code is used in §2.

§**8.** Three easy cases to dispose of:

⟨Maybe this is some new notation 8⟩ ≡
```
if (try_verb(specifies_V, 0, 0, PN, SPECIFIES_VB, 0)) return;
if (try_verb(are_V, defined_V, by_V, PN, DEFINED_BY_VB, 0)) return;
if ([[w1, w2 == the story is episode ...]] &&
    (try_verb(story_V, is_V, episode_V, PN, EPISODE_VB, 0))) return;
if ([[w1, w2 == the plural of ...]] &&
    (try_verb(is_V, 0, 0, PN, PLURAL_VB, 0))) return;
```

This code is used in §2.

§**9.** And the various external resources which can be added to a project. The syntax for files is a little more involved: the word "the" is optional, and so is a keyword giving the nature of the file.

⟨Maybe this is a resource-declaring sentence 9⟩ ≡
```
int fw1 = w1, fw2 = w2;
if ([[w1, w2 == figure ...]] &&
    (try_verb(is_V, the_V, file_V, PN, FIGURE_VB, 0))) return;
if ([[w1, w2 == sound effect ...]] &&
    (try_verb(is_V, the_V, file_V, PN, SOUND_VB, 0))) return;
if ([[w1, w2 == sound ...]] &&
    (try_verb(is_V, the_V, file_V, PN, SOUND_VB, 0))) return;
[[fw1, fw2 == the ... --> fw1, fw2]];
[[fw1, fw2 == text/binary ... --> fw1, fw2]];
if ([[fw1, fw2 == file ...]] &&
    (try_verb(is_V, called_V, 0, PN, FILE_VB, 0))) return;
```

This code is used in §2.

§**10.** We could conceivably have implemented "action" and "activity" as pseudo-kinds, and thus handled sentences like these through ordinary assertions, but it would have been a lot of fuss. So we do it the simple-minded way.

Note that activity declarations always simply end "is an activity.", thus having nothing interesting by way of an object noun phrase, whereas action declarations continue with usually extensive further text: "... is an action applying to two visible things.", say.

⟨Maybe this is an action or activity declaration 10⟩ ≡
```
if ([[w1, w2 == ... is an activity]] &&
    (try_verb(is_V, an_V, 0, PN, NEW_ACTIVITY_VB, 0))) return;
if (try_verb(is_V, an_V, action_V, PN, NEW_ACTION_VB, 0)) return;
```

This code is used in §2.

§**11.** Definitions of verbs and relations must be acted on immediately, because they may affect the way we find primary verbs in sentences which follow directly on – that is, the very next sentence might use the verb being defined here, so we can't wait.

⟨Maybe this is a verb or relation declaration 11⟩ ≡

```
if ([[w1, w2 == the verb to ...]] &&
    (try_verb(implies_V, 0, 0, PN, NEW_VERB_VB, 0))) {
    parse_new_verb(PN);
    return;
}
if ([[w1, w2 == ### relates ...]] &&
    (try_verb(to_V, 0, 0, PN, NEW_RELATION_VB, 0))) {
    parse_new_relation(PN);
    return;
}
```

This code is used in §2.

§**12.** "Can be", "can have", "is either":

⟨Maybe this is a property declaration 12⟩ ≡

```
int i;
if ([[w1, w2 == ... can ... : i]] && [[i, w2 == can have ...]]) {
    sentence_problem(_P_(C4CanHave),
        "'can have' is not a form allowed by Inform",
        "though it looks as it might be. If you want to set up a property "
        "with a limited number of options, you can say 'A room can be "
        "spacious, cramped or adequate.', for instance; if you want a "
        "property with a value, 'A room has a number called the secret "
        "code number.'. So 'can be' and 'has' are fine, but not 'can have'.");
    return;
}
if (try_verb(can_V, be_V, 0, PN, CANBE_VB, 0)) return;
if (try_verb(is_V, either_V, 0, PN, CANBE_VB, 0)) return;
```

This code is used in §2.

§**13.** Sentences giving positions in rulebooks use the preposition "listed":

⟨Maybe this is a rule-positioning sentence 13⟩ ≡

```
if (try_verb(is_V, listed_V, 0, PN, IN_RULEBOOK_VB, 0)) return;
if (try_verb(are_V, listed_V, 0, PN, IN_RULEBOOK_VB, 0)) return;
if (try_verb(is_V, not_V, listed_V, PN, NOT_IN_RULEBOOK_VB, 0)) return;
if (try_verb(are_V, not_V, listed_V, PN, NOT_IN_RULEBOOK_VB, 0)) return;
```

This code is used in §2.

§14. In some sense, the other cases are all exceptions: this is the big one, the general assertion reader, which uses the same verbs and prepositions as the fully general *S*-grammar.

It is potentially quite slow to test every word against every possible verb, even though there are typically fairly few verbs in the *S*-grammar, so we confine ourselves to words flagged in the vocabulary as being used in verbs. It's important to note that (for reasons given above) there can be no backtracking here: we will have to accept the first match we can. That makes it necessary to test these verbs in the correct order, and this is why we make three passes. "To have" has top priority, because the matter on either side may contain some surprising words, thanks to the syntax for declaring property values. "To be" is then given priority over everything else; and otherwise the leftmost valid verb phrase is accepted. The reason "to be" is given precedence is partly philosophical (it is after all the linguistic expression of the equality relation, which plays a special role in predicate calculus), but also practical. Consider:

The Fisher-Price carry cot is a container.

In this sentence, "carry" is intended as part of the subject noun phrase, but we have no way of telling that: if we didn't give "to be" priority over "to carry" we would construe this sentence as saying that a group of people called The Fisher-Price, perhaps a rock group, are carrying an object called "cot is a container", perhaps their new EP of remixed techno lullabies. (Far fewer plausible noun phrases contain "is" than contain other verbs such as "carry".)

⟨More likely this is an assertion about objects and kinds 14⟩ ≡

```
int pos, there_flag = FALSE;
if [[w1, w2 == there is/are ...]] {
    there_flag = TRUE;
    w1 += 2;
}
for (pos = w1+1; pos<w2; pos++) if ([[word pos == has/have]] && (![[word pos-1 == not]]))
    ⟨Look for a present-tense verb phrase at the current position 15⟩;
for (pos = w1+1; pos<w2; pos++) if [[word pos == is/are]]
    ⟨Look for a present-tense verb phrase at the current position 15⟩;
for (pos = w1+1; pos<w2; pos++) if (vocab_test_flags(pos, CVERB_MC))
    ⟨Look for a present-tense verb phrase at the current position 15⟩;
if (there_flag) {
    for (pos = w1+1; pos<w2; pos++) if (vocab_test_flags(pos, PREPOSITION_MC)) {
        preposition_usage *pu;
        LOOP_OVER(pu, preposition_usage) {
            int j = pu_parse_text_against(pos, w2, pu, FALSE);
            if (j >= 0) {
                binary_predicate *bp = bp_get_reversal(pu_get_meaning(pu));
                assign_verb(PN, j, w2, w1, pos-1, pos, j-1, ASSERT_VB, bp);
                ⟨Insert a RELATIONSHIP node into the parse tree 18⟩;
                return;
            }
        }
    }
    w1 -= 2; pos = w1+1; there_flag = FALSE;
    ⟨Look for a present-tense verb phrase at the current position 15⟩;
}
```

This code is used in §2.

§**15.** The loop here is taken over all valid verb phrases in the *S*-grammar, but then there are a string of exemptions. Many *S*-sentences valid in conditions are not valid in assertions, and besides, we don't have the luxury (as the *S*-sentence parser has) of knowing in advance all the possible noun phrases we might meet – so we have to be very cautious, and not accept any verb where there are good reasons to suspect that it is not meant by the user.

(1) We discard verbs in the past tense: they are not legal in assertions.

(2) We discard "is not" and "are not". For the time being, if we see something like "Velma is not a thinker" then we will parse it as "(Velma) is (not a thinker)", allowing "not a thinker" to be a noun phrase. (Assertions are generally supposed to be positive statements, not negative ones, but we don't necessarily know about this one yet. If "thinker" is an either/or property with a single possible antonym – "doer", let's say – then we want to construe this sentence as if it read "Velma is a doer". So, anyway, we allow "not" at the front of the object noun phrase, and disallow "is not" and "are not" in order that this can happen.) All other negated verb usages are parsed here – but only in order for them to run into the problem message below.

(3) We discard a verb in a relative phrase, since it is not the primary verb of the sentence: for instance, the "is" in "cat which is in the basket" will not be considered.

(4) We discard a verb if the subject noun phrase would read simply "the".

(5) We discard a verb if it is unexpectedly given in upper case form. Thus "The Glory That Is Rome is a room" will be read as "(The Glory That Is Rome) is (a room)", not "(The Glory That) is (Rome is a room)".

⟨Look for a present-tense verb phrase at the current position 15⟩ ≡
```
verb_usage *vu;
LOOP_OVER(vu, verb_usage)
    if ((vu_get_tense_used(vu) == IS_TENSE) &&
        (vu != negated_to_be) && (vu != negated_plural_to_be) &&
        (!((pos==w1+1) && [[word w1 == the]])) &&
        (unexpectedly_upper_case(pos) == FALSE)) {
        int rp = FALSE;
        if ((pos > w1) && [[word pos-1 == which/who/that]]) rp = TRUE;
        if (rp == there_flag)
            ⟨Test the words at the current position against this verb usage 16⟩;
    }
```
This code is used in §14.

§**16.** We delegate to the *S*-sentence parser to actually match the text of the verb usage.

As noted above, "to be" plays a special role because of its unique conceptual role in language and in predicate calculus: it describes or assigns the identity of things. It is less obvious why we treat "to have" differently: surely this is just another relationship? The answer is that it is indeed a relationship in sentences like "Peter has the magic flute", but not in "Peter has carrying capacity 2": we overload "to have" with two independent meanings, and this will be tricky to resolve, so it gets its own verb type for the assertion-maker to read.

⟨Test the words at the current position against this verb usage 16⟩ ≡
```
int j = vu_parse_text_against(pos, w2, vu);
if (j >= 0) {
    int subj1 = w1, subj2 = pos-1, obj1 = j, obj2 = w2;
    if (rp) subj2--;                        remove the word "which" if the verb used in a relative phrase
    ⟨Issue a problem message if the primary verb has a negative sense 17⟩;
    if (vu_get_meaning(vu) == a_has_b_predicate) {
        assign_verb(PN, subj1, subj2, obj1, obj2, pos, j-pos, HAS_VB, vu_get_meaning(vu));
    } else {
        binary_predicate *bp = vu_get_meaning(vu);
        assign_verb(PN, subj1, subj2, obj1, obj2, pos, j-pos, ASSERT_VB, vu_get_meaning(vu));
        if (bp != a_is_b_predicate)
            ⟨Insert a RELATIONSHIP node into the parse tree 18⟩;
    }
    return;
}
```
This code is used in §15.

§**17.** This catches sentences like "Timothy does not carry the ring". See above for how and why "is not" and "are not" are exempted from this for now:

⟨Issue a problem message if the primary verb has a negative sense 17⟩ ≡
```
if (vu_is_used_negatively(vu)) {
    negative_sentence_problem(_P_(C4NegatedVerb1));
    return;
}
```
This code is used in §16.

§**18.** Every primary verb other than "to be" and "to have" expresses a relationship between the objects referred to by its subject and object noun phrases, and this relationship is a binary predicate in our calculus. So, for instance, we make the transformation

```
SENTENCE_NT "The cat is on the mat"  --->  SENTENCE_NT "The cat is on the mat"
    VERB_NT "is on"                            VERB_NT "is on"
    NOUNPHRASE_NT "cat"                        NOUNPHRASE_NT "cat"
    NOUNPHRASE_NT "mat"                        RELATIONSHIP_NT "is on" = supports
                                                   NOUNPHRASE_NT "mat"
```

The sense of the binary predicate is reversed here because we are applying it to the object of the sentence not the subject: we thus turn the idea of the cat being supported by the mat into the exactly equivalent idea of the mat supporting the cat.

⟨Insert a RELATIONSHIP node into the parse tree 18⟩ ≡

```
parse_node *REL_PN = new_node(RELATIONSHIP_NT);
pn_set_relationship(REL_PN, bp_get_reversal(bp));
REL_PN->down = PN->down->next->next;
REL_PN->word_ref1 = pos; REL_PN->word_ref2 = j-1;
PN->down->next->next = REL_PN;
```

This code is used in §14,16,14,16,14,16.

§**19.** Mapping verbal names like "can't take what's already taken rule" onto I6 identifiers used in the I6 library is something done almost always by the Standard Rules, and thus so early in the source text that only standard verbs have been created. So these can afford to be low-priority sentence forms:

⟨If not, it might be an I6 translation 19⟩ ≡

```
if (try_verb(translates_V, into_V, i6_V, PN, TRANSLATES_VB, 0)) return;
```

This code is used in §2.

§**20.** And that just leaves use options, release instructions and hints for the map index. The `USE_VB` verb, uniquely, constructs a sentence subtree with only a single noun phrase: the text of that which is to be used.

```
SENTENCE_NT "Use American spelling"
    VERB_NT "use"
    NOUNPHRASE_NT "American spelling"
```

⟨Or possibly a use option, release instruction or index map hint 20⟩ ≡

```
if [[w1, w2 == use ...]] {
    parse_node *VP_PN, *NP_PN;
    if (try_verb(translates_V, as_V, 0, PN, USEMEANS_VB, 0)) return;
    VP_PN = new_node(VERB_NT);
    VP_PN->word_ref1 = PN->word_ref1; VP_PN->word_ref2 = PN->word_ref1;
    pn_annotate_int(VP_PN, verb_id_ANNOT, USE_VB);
    graft(VP_PN, PN);
    NP_PN = new_nounphrase_raw(PN->word_ref1+1, PN->word_ref2);
    graft(NP_PN, PN);
    return;
}
if ([[w1, w2 == release along with ...]] &&
    (try_verb(along_V, with_V, 0, PN, RELEASE_VB, 0))) return;
if ([[w1, w2 == index map with ...]] &&
    (try_verb(map_V, with_V, 0, PN, MAP_PARAMETER_VB, 0))) return;
```

This code is used in §2.

§**21.** This final case never matches a legal sentence: it simply hoovers up usages of past tense assertion verbs in order to give them a better Problem message than the one they will otherwise receive later on.

⟨Issue a problem message if a primary verb in the past tense is found 21⟩ ≡

```
    int pos;
    for (pos = w1+1; pos<w2; pos++) if (vocab_test_flags(pos, CVERB_MC)) {
        verb_usage *vu;
        if ((pos > w1) && [[word pos-1 == which/who/that]]) continue;
        if ((pos==w1+1) && [[word w1 == the]]) continue;
        if (unexpectedly_upper_case(pos)) continue;
        LOOP_OVER(vu, verb_usage)
            if (vu_get_tense_used(vu) != IS_TENSE) {
                int j = vu_parse_text_against(pos, w2, vu);
                if (j >= 0) {
                    LOG("Past tense verb <$W> in <$W>\n", pos, j-1, w1, w2);
                    sentence_problem(_P_(C4NonPresentTense),
                    "assertions about the initial state of play must be "
                    "given in the present tense",
                    "so 'The cat is in the basket' is fine but not 'The "
                    "cat has been in the basket'. Time is presumed to start "
                    "only when the game begins, so there is no anterior "
                    "state which we can speak of.");
                    return;
                }
            }
    }
```

This code is used in §2.

§**22. Detecting exceptional verbs.** All of the exceptional sentence forms (except `USE_VB`) test for their verbs using the routine `try_verb`, which looks for a sequence of one to three words in the middle of the sentence, optionally requiring them not to be preceded by a given "avoid" word.

```
int try_verb(vocabulary_entry *t1, vocabulary_entry *t2, vocabulary_entry *t3,
    parse_node *pn, int the_verb, vocabulary_entry *avoid_t) {
    int i, count = 1;
    i = is_sequence_intermediate(t1, t2, t3, avoid_t, pn->word_ref1, pn->word_ref2);
    if (i == -1) return FALSE;
    if (t2 != 0) count++; if (t3 != 0) count++;
    assign_verb(pn, pn->word_ref1, i-1, i+count, pn->word_ref2, i, count, the_verb, NULL);
    return TRUE;
}
```

§**23. Building verb subtrees.** Whenever any primary verb (except `USE_VB`) is discovered – either by one of the exceptional cases, using `try_verb`, or through the restricted *S*-grammar parser above – the following routine is always called. It gives the sentence node three children: verb phrase, subject noun phrase, object noun phrase.

```
SENTENCE_NT "Railway Departure begins when the player is in the train"
    VERB_NT "begins when"
    NOUNPHRASE_NT "Railway Departure"
    NOUNPHRASE_NT "the player is in the train"
```

This is an example of the simplest form of verb subtree, arising from a "raw" verb type: nothing at all is done with the noun phrases, which simply consume all the words to the left and right of the VP.

Alternatively, a verb type can be "cooked", which means that the noun phrases will be worked on a little: articles and qualifiers converted to annotations, and some sub-clauses discovered (as we shall see in the next section). For instance:

```
SENTENCE_NT "An oak table is usually a supporter"
    VERB_NT "is" certainty:LIKELY_CE
    NOUNPHRASE_NT "oak table" article:indefinite
    NOUNPHRASE_NT "supporter" article:indefinite
```

The use of qualifiers is interesting here, because again it deviates from the practice of the main *S*-grammar. We allow "usually" and such like words on either side of the VP in a sentence, but only here in assertions: not in the main *S*-grammar. This is because the assertion

A box is usually closed.

is essentially a statement about the future, not the present or the past, whereas conditions used in phrases and rules must always be determinable at once: it makes no sense to write "if a box is usually closed", since Inform cannot know what will generally happen, only what is now the case and what has been the case in the past.

§**24.** The noun phrase grammar used for NPs of cooked verbs sometimes needs some temporary context – it needs to know in particular whether it is serving the copular verb "to be" or not. The following global variable is temporarily used to save passing it endlessly as a function argument:

```
int assertion_NP_is_in_VP_for_to_be = FALSE;
```

§**25.** Other than setting this flag, we need only determine raw vs. cooked and then make the three parts of the subtree.

```
void assign_verb(parse_node *SENTENCE_PN, int subj1, int subj2, int obj1, int obj2,
    int pos, int count, int verb_type, binary_predicate *bp) {
    int raw_mode, restrict_object_to_lists = FALSE, admits_qualifiers = FALSE,
        verb_w1 = pos, verb_w2 = pos + count - 1;
    ⟨Determine whether this primary verb is raw or cooked 26⟩;
    ⟨Make the VERB node in the sentence subtree 27⟩;
    assertion_NP_is_in_VP_for_to_be = FALSE;
    if (bp == a_is_b_predicate) assertion_NP_is_in_VP_for_to_be = TRUE;
    ⟨Make the NOUNPHRASE node(s) for the subject 29⟩;
    ⟨Make the NOUNPHRASE node(s) for the object of other verbs 30⟩;
}
```

§**26.** Basically, the only cooked verbs are those whose noun phrases are likely to be actual objects or kinds.

⟨Determine whether this primary verb is raw or cooked 26⟩ ≡
```
switch(verb_type) {
    case ASSERT_VB: case HAS_VB:
        raw_mode = FALSE; restrict_object_to_lists = FALSE; admits_qualifiers = TRUE; break;
    case DEFINED_BY_VB:
        raw_mode = FALSE; restrict_object_to_lists = FALSE; admits_qualifiers = FALSE; break;
    case CANBE_VB:
        raw_mode = FALSE; restrict_object_to_lists = TRUE; admits_qualifiers = FALSE; break;
    default:
        raw_mode = TRUE; admits_qualifiers = FALSE; break;
}
```
This code is used in §25.

§**27.** The verb node has two possible annotations: the verb ID, which is the type number we have been using above, and the level of certainty, which is set in the following section (but only for cooked verbs).

⟨Make the VERB node in the sentence subtree 27⟩ ≡
```
parse_node *VP_PN = new_node(VERB_NT);
if (admits_qualifiers) ⟨Spread the verb phrase right or left to include any qualifier 28⟩;
VP_PN->word_ref1 = verb_w1; VP_PN->word_ref2 = verb_w2;
pn_annotate_int(VP_PN, verb_id_ANNOT, verb_type);
graft(VP_PN, SENTENCE_PN);
```
This code is used in §25.

§**28.** Look before and after the verb phrase to see if any qualifier is used, and if so spread the word range of the verb phrase left or right as needed; and annotate its node in the parse tree with the certainty level implied.

⟨Spread the verb phrase right or left to include any qualifier 28⟩ ≡
```
int w1, w2, certainty = UNKNOWN_CE, quals_found = 0;
[[w1, w2 <-- SENTENCE_PN]];
if (pos > w1+1) {
    certainty = try_qualifier(pos-1);
    if (certainty != UNKNOWN_CE) verb_w1--, subj2--, quals_found++;
}
if (pos < w2-1) {
    certainty = try_qualifier(pos+count);
    if (certainty != UNKNOWN_CE) verb_w2++, obj1++, quals_found++;
}
if (quals_found == 1)
    pn_annotate_int(VP_PN, verbal_certainty_ANNOT, certainty);
if (quals_found == 2)
    sentence_problem(_P_(C4TwoLikelihoods),
        "this sentence seems to have a likelihood qualification on both "
        "sides of the verb",
        "which is not allowed. 'The black door certainly is usually open' "
        "might possibly be grammatical English in some idioms, but Inform "
        "doesn't like a sentence in this shape because the 'certainly' "
        "on one side of the verb and the 'usually' on the other are "
        "rival indications of certainty.");
```
This code is used in §27.

§**29.** The subject is then just a nounphrase made from all the words to the left of the verb:

⟨Make the NOUNPHRASE node(s) for the subject 29⟩ ≡

```
parse_node *SUBJECT_NP_PN;
if (raw_mode) SUBJECT_NP_PN = new_nounphrase_raw(subj1, subj2);
else SUBJECT_NP_PN = new_nounphrase_worldly(subj1, subj2, TRUE);
graft(SUBJECT_NP_PN, SENTENCE_PN);
```

This code is used in §25.

§**30.** While the object is a nounphrase made from all the words to the right. We allow the objects of a few cooked verbs to be cooked only lightly, so to speak (rare?): a mode in which lists are broken up into individual items, but other clauses are not detached.

⟨Make the NOUNPHRASE node(s) for the object of other verbs 30⟩ ≡

```
parse_node *OBJECT_NP_PN;
if (raw_mode) OBJECT_NP_PN = new_nounphrase_raw(obj1, obj2);
else if (restrict_object_to_lists) OBJECT_NP_PN = new_nounphrase_listdivided(obj1, obj2);
else OBJECT_NP_PN = new_nounphrase_worldly(obj1, obj2, FALSE);
graft(OBJECT_NP_PN, SENTENCE_PN);
```

This code is used in §25.

§**31. Qualifiers.** Parsing of qualifiers which express varying degrees of certainty:

```
int try_qualifier(int w) {
    if [[word w == always/certainly]] return CERTAIN_CE;
    if [[word w == usually/normally]] return LIKELY_CE;
    if [[word w == rarely/seldom]] return UNLIKELY_CE;
    if [[word w == never]] return IMPOSSIBLE_CE;
    return UNKNOWN_CE;
}
```

§**32. Logging verb numbers.**

```
void log_verb_number(int verb_number) {
    switch(verb_number) {
        case ASSERT_VB: LOG("ASSERT_VB"); break;
        case BEGINS_WHEN_VB: LOG("BEGINS_WHEN_VB"); break;
        case CANBE_VB: LOG("CANBE_VB"); break;
        case DEBUG_VB: LOG("DEBUG_VB"); break;
        case DEFINED_BY_VB: LOG("DEFINED_BY_VB"); break;
        case DOC_VB: LOG("DOC_VB"); break;
        case ENDS_WHEN_VB: LOG("ENDS_WHEN_VB"); break;
        case EPISODE_VB: LOG("EPISODE_VB"); break;
        case FIGURE_VB: LOG("FIGURE_VB"); break;
        case FILE_VB: LOG("FILE_VB"); break;
        case HAS_VB: LOG("HAS_VB"); break;
        case IN_RULEBOOK_VB: LOG("IN_RULEBOOK_VB"); break;
        case MAP_PARAMETER_VB: LOG("MAP_PARAMETER_VB"); break;
        case NEW_ACTION_VB: LOG("NEW_ACTION_VB"); break;
        case NEW_ACTIVITY_VB: LOG("NEW_ACTIVITY_VB"); break;
        case NEW_RELATION_VB: LOG("NEW_RELATION_VB"); break;
        case NEW_VERB_VB: LOG("NEW_VERB_VB"); break;
```

```
        case NOT_IN_RULEBOOK_VB: LOG("NOT_IN_RULEBOOK_VB"); break;
        case PLURAL_VB: LOG("PLURAL_VB"); break;
        case RELEASE_VB: LOG("RELEASE_VB"); break;
        case SOUND_VB: LOG("SOUND_VB"); break;
        case SPECIFIES_VB: LOG("SPECIFIES_VB"); break;
        case TEST_VB: LOG("TEST_VB"); break;
        case TRANSLATESU_VB: LOG("TRANSLATESU_VB"); break;
        case UNDERSTAND_VB: LOG("UNDERSTAND_VB"); break;
        case USEMEANS_VB: LOG("USEMEANS_VB"); break;
        case USE_VB: LOG("USE_VB"); break;
        default: LOG("(number %d)", verb_number); break;
    }
}
```

The function log_verb_number is called from 2/dl.

Noun Phrases 4/noun

Purpose

To construct noun-phrase subtrees for assertion sentences found in the parse tree.

Definitions

¶1. Noun phrase nodes are built at four levels of elaboration, which we take in turn:

(NP1) Raw: where the text is entirely untouched and unannotated.
(NP2) Articled: where any initial English article is converted to an annotation.
(NP3) List-divided: where, in addition, a list is broken up into individual items.
(NP4) Worldly: where, in addition, pronouns, relative clauses establishing relationships and properties (and other grammar meaningful only for references to physical objects and kinds) are parsed.

At levels (NP1) and (NP2), a NP produces a single `NOUNPHRASE_NT` node; at level (NP3), the result is a subtree contining `NOUNPHRASE_NT` and `AND_NT` nodes; but at level (NP4) this subtree may include any of `RELATIONSHIP_NT`, `CALLED_NT`, `WITH_NT`, `AND_NT`, `KIND_NT`, `X_OF_Y_NT`, `FROM_NT`, or `NOUNPHRASE_NT`.

Because a small proportion of noun phrase subtrees is thrown away, due to backtracking on mistaken guesses at parsing of sentences, it is important that creating an (NP) should have no side-effects beyond the construction of the tree itself (and, of course, the memory used up, but we won't worry about that: the proportion thrown away really is small).

---

§1. (NP1) Raw noun phrases. There are many situations (even if all of them are individually rare) when a NP must be constructed as a raw sequence of words, with no internal structure even being considered. Two special cases are also legal: where $w_1 = w_2 = -1$, signifying an empty text arising from some earlier problem; and $w_1 = w_2 = -2$, signifying an empty text arising from a relative clause whose noun phrase is implicit rather than spelled out in words, and whose meaning is that the player is the object referred to.

```
parse_node *new_nounphrase_raw(int w1, int w2) {
    parse_node *PN;
    PN = new_node(NOUNPHRASE_NT);
    pn_annotate_int(PN, nounphrase_article_ANNOT, NO_ART);
    PN->word_ref1 = w1; PN->word_ref2 = w2;
    return PN;
}
```

The function new_nounphrase_raw is called from 2/prob3, 4/sent, 4/verb, 5/unitr, 8/sob, 8/refpt, 9/pp, 10/tab, 13/tfg and 13/gtok.

§**2.** Sometimes we want to look at the article (if any) used in a raw NP, and absorb that into annotations, removing it from the wording. For instance, in

On the table is a thing called a part of the broken box.

we want to remove the initial article from the calling-name to produce "part of the broken box". (If we handled this NP as other than raw, we might spuriously make a subtree with `RELATIONSHIP_NT` in thanks to the apparent "part of" clause.) Note that unexpectedly upper-case articles are left well alone: this is why

On the table is a thing called A Town Called Alice.

creates an object called "A Town Called Alice", not an indefinitely-articled one called "Town Called Alice". Note that articles are not removed if that would leave the text empty.

```
parse_node *fix_articles_in_raw_NP(parse_node *RAW_NP) {
    int w1, w2;
    [[w1, w2 <-- RAW_NP]];
    pn_annotate_int(RAW_NP, nounphrase_article_ANNOT, NO_ART);
    pn_annotate_int(RAW_NP, plural_reference_ANNOT, FALSE);
    if (unexpectedly_upper_case(w1) == FALSE) {
        if [[w1, w2 == some ... --> w1, w2]] {
            pn_annotate_int(RAW_NP, nounphrase_article_ANNOT, INDEF_ART);
            pn_annotate_int(RAW_NP, plural_reference_ANNOT, TRUE);
        } else if [[w1, w2 == a/an ... --> w1, w2]]
            pn_annotate_int(RAW_NP, nounphrase_article_ANNOT, INDEF_ART);
        else if [[w1, w2 == the ... --> w1, w2]]
            pn_annotate_int(RAW_NP, nounphrase_article_ANNOT, DEF_ART);
    }
    RAW_NP->word_ref1 = w1; RAW_NP->word_ref2 = w2;
    return RAW_NP;
}
```

The function fix_articles_in_raw_NP is called from 4/ofs and 10/tab.

§**3. (NP2) Articled noun phrases.** We simply make a raw NP and then apply the article-fixing routine:

```
parse_node *new_nounphrase_articled(int w1, int w2) {
    parse_node *RAW_NP = new_nounphrase_raw(w1, w2);
    return fix_articles_in_raw_NP(RAW_NP);
}
```

The function new_nounphrase_articled is called from 8/refpt, 9/map and 10/bib.

§4. **(NP3) List-divided noun phrases.** This is a list, divided by "and" and perhaps using the serial comma, of articled NPs. We build into a lopsided binary tree: thus "the lion, a witch, and some wardrobes" becomes

```
AND_NT ","
    PROPERTYLIST_NT "lion" article:definite
    AND_NT ", and"
        PROPERTYLIST_NT "witch" article:indefinite
        PROPERTYLIST_NT "wardrobe" article:indefinite pluralreference:true
```

(The binary structure is chosen since it allows us to use a simple recursion to run through possibilities, and also to preserve each connective of the text in the `AND_NT` nodes.)

```
parse_node *new_nounphrase_listdivided(int w1, int w2) {
    if (is_list_divided(w1, w2, LOOK_FOR_AND)) {
        int lw1 = left_w1, lw2 = left_w2, rw1 = right_w1, rw2 = right_w2;
        parse_node *AND_PN = new_node(AND_NT);
        AND_PN->word_ref1 = left_w2 + 1; AND_PN->word_ref2 = right_w1 - 1;
        AND_PN->down = new_nounphrase_listdivided(lw1, lw2);
        AND_PN->down->next = new_nounphrase_listdivided(rw1, rw2);
        return AND_PN;
    }
    return new_nounphrase_articled(w1, w2);
}
```

The function new_nounphrase_listdivided is called from 4/verb.

§5. **(NP4) Worldly noun phrases.** The function `new_nounphrase_worldly` constructs the sometimes complicated, and certainly varied, subtrees of the parse tree making up noun phrases which refer to world objects, kinds and their properties. Each possibility is diagrammed below, but we should remember that `new_nounphrase_worldly` is recursive, so that any of the subtree diagrams below can appear in the position of any `NOUNPHRASE_NT` node in any of the diagrams.

The following shell routine simply checks an invariant on entry and exit: experience shows that this is a routine which needs careful handling, and we want to be confident about what it does.

```
parse_node *new_nounphrase_worldly(int w1, int w2, int as_subject) {
    parse_node *NEW_NP;
    if ((w1 == -1) && (w2 == -1)) return new_nounphrase_raw(-1, -1);          used for error recovery
    if ((w1 == -2) && (w2 == -2)) return new_nounphrase_raw(-2, -2);          used for implicit NPs
    if ((w1<0) || (w1 > w2)) {
        LOG("NPW improperly applied to %d, %d\n$W\n", w1, w2, w1, w2);
        internal_error("NPW improperly applied");
    }
    NEW_NP = new_nounphrase_worldly_unchecked(w1, w2, as_subject);
    if (NEW_NP->word_ref1 > NEW_NP->word_ref2) {
        LOG("NPW on <$W>, %d, %d\n$T", w1, w2, NEW_NP->word_ref1, NEW_NP->word_ref2, NEW_NP);
        internal_error("malformed NPW made");
    }
    return NEW_NP;
}
```

The function new_nounphrase_worldly is called from 4/verb, 6/treec, 8/refpt, 8/creat, 10/tab and 10/eqns.

§**6.** And now the inner routine, which tries for eight constructions in turn. The sequence of checking these is very important, because it decides which clauses are represented higher in the tree when multiple structures are present within the NP. For instance, we want to turn

[A] in a container called the flask and cap with flange

into the subtree:

```
RELATIONSHIP_NT "in" = containment
    CALLED_NT "called"
        NOUNPHRASE_NT "container" article:indefinite
        NOUNPHRASE_NT "flask and cap with flange" article:definite
```

but we also want:

[B] in a container with carrying capacity 10 and diameter 12

```
RELATIONSHIP_NT "in" = containment
    WITH_NT "with"
        NOUNPHRASE_NT "container" article:indefinite
        AND_NT "and"
            PROPERTYLIST_NT "carrying capacity 10"
            PROPERTYLIST_NT "diameter 12"
```

These two cases together force our conventions: from sentence [A] we see that initial relative clauses (in) must beat callings ("called") which must beat property clauses ("with"), while from [B] we see that property clauses must beat lists ("and"). These all have to beat "of" and "from", which seem to be about linguistically equal, because these constructions must be easily reversible, as we shall see, and the best way to ensure that is to make sure they can only appear right down close to leaves in the tree. This dictates

```
RELATIONSHIP_NT > CALLED_NT > WITH_NT > AND_NT > X_OF_Y_NT = FROM_NT
```

in the sense that a subtree construction higher in this chain will take precedence over (and therefore be higher up in the tree than) one that is lower. That leaves just the seventh construction: "kind of ...". To avoid misreading this as an "of", and to protect "called", we need

```
CALLED_NT > KIND_NT > X_OF_Y_NT
```

but otherwise we are fairly free where to put it (though the resulting trees will take different shapes in some cases if we move it around, we could write code which handled any of the outcomes about equally well). In fact, we choose to make it lowest possible, so the final precedence order is:

```
RELATIONSHIP_NT > CALLED_NT > WITH_NT > AND_NT > KIND_NT > X_OF_Y_NT = FROM_NT
```

Once all possible constructions have been recursively exhausted, every leaf we end up at is treated simply as an (NP2) – except that we allow a special article annotation for the pronouns.

```
parse_node *new_nounphrase_worldly_unchecked(int w1, int w2, int as_subject) {
    parse_node *ARTICLED_NP;
    if ((assertion_NP_is_in_VP_for_to_be) &&
        (unexpectedly_upper_case(w1) == FALSE))
        ⟨Consider initial relative clauses which establish relationships 7⟩;
    ⟨Consider a calling clause which gives a possibly tricky name 9⟩;
    ⟨Consider a with or having clause which specifies properties 10⟩;
    ⟨Consider a comma- and and-separated list of noun phrases 11⟩;
    ⟨Consider "kind" or a "kind of" clause 12⟩;
    ⟨Consider a "from" or "of" clause 13⟩;
    ARTICLED_NP = new_nounphrase_articled(w1, w2);
    if [[w1, w2 == it/he/she/they/them]]
        pn_annotate_int(ARTICLED_NP, nounphrase_article_ANNOT, IT_ART);
    return ARTICLED_NP;
}
```

§**7.** This is one of three places in the *A*-grammar where `RELATIONSHIP_NT` nodes can enter the parse tree. One was when the primary verb of a sentence implied a relationship (other than the special cases for "to have" and "to be"); the other happens here, where the verb "to be" has been used but in concert with a NP beginning with a preposition. (The third happens later when noun phrases like "east from the Drawing Room" are examined.)

It might seem grammatically odd to be parsing prepositions here, when they surely ought to belong to the VP rather than either of the NPs. But English is, in fact, odd this way: it allows declarative statements, but no other sentences, to use "subject-verb inversion". An assertion such as

> In the garden is a tortoise.

is impossible to parse with a naive grammar for relative clauses, because the "in" is miles away from its governing verb. (This quirk is called an inversion since the sentence is equivalent to the easier to construe "A tortoise is in the garden".) Subject-verb inversion can't be allowed in all cases, though; we might pedantically argue that the Yoda-like utterance

> Holding the light sabre is the young Jedi.

is grammatically correct, but if so then we have to read

> Holding Area is a room.

as a statement that a room is holding something called "Area", which then causes Inform to throw problem messages about confusion between people and rooms (since it knows that only people can hold things). This is the reason why, rather tiresomely, we need an `as_subject` flag in this routine – to tell when we're applying subject-verb inversion, and to forbid it in the case of a participle like "holding", "carrying" or "wearing".

At any rate, we may well find ourselves parsing a NP like "in the garden", whichever side of the copular verb it may be. We turn it into

```
RELATIONSHIP_NT "in" = containment
    NOUNPHRASE_NT "garden" article:definite
```

To do this, we check each preposition in the *S*-grammar. We do, however, guard against "inside of..." and "inside from...": this is because we need to handle those as map connections and not spatial containment in the normal sense. (A long-standing IF convention is that "in" and "out" are directions on a par with "north" and "south", and behave like lateral connections between rooms, but this does cause ambiguities with spatial containment, which is conceptually quite different.)

⟨Consider initial relative clauses which establish relationships 7⟩ ≡

```
    ⟨Consider initial relative clauses with implied objects 8⟩;
    if ((![[w1, w2 == inside of/from ...]]) &&
        ((as_subject == FALSE) || (vocab_test_flags(w1, ING_MC) == FALSE))) {
        preposition_usage *pu;
        LOOP_OVER(pu, preposition_usage) {
            int i = pu_parse_text_against(w1, w2, pu, FALSE);
            if ((i>w1) && (i<=w2))
                return new_rel_node(STANDARD_RELN, bp_get_reversal(pu_get_meaning(pu)), w1, i-1, i,
w2);
        }
    }
```

This code is used in §6.

§**8.** A complication is that the relationship might be with something unstated. For instance, "here" generally means a containment by the room currently being discussed; "carried" implies that the player does the carrying. These cases form stunted `RELATIONSHIP_NT` subtrees having two forms:

```
RELATIONSHIP_NT "worn" = wears    RELATIONSHIP_NT "here" inference-to-draw:PARENTAGE_HERE_INF
    NOUNPHRASE_NT <-2, -2>
```

(A nounphrase with $w_1 = w_2 = -2$ is considered to refer to the player.)

⟨Consider initial relative clauses with implied objects 8⟩ ≡

```
if [[w1, w2 == here]] return new_rel_node(PARENTAGE_HERE_RELN, NULL, w1,w2, -1,-1);
if [[w1, w2 == worn]] return new_rel_node(STANDARD_RELN, a_wears_b_predicate, w1,w2, -2,-2);
if [[w1, w2 == carried]] return new_rel_node(STANDARD_RELN, a_carries_b_predicate, w1,w2, -2,-2);
```

This code is used in §7.

§**9. Calling subtrees.** Here something like "a container called the saucepan and lid" is split into:

```
CALLED_NT "with"
    NOUNPHRASE_NT "container" article:indefinite
    NOUNPHRASE_NT "saucepan and lid" article:definite
```

Note that the called-name is treated as an articled NP, not a worldly NP, and this protects it from being split into subclauses itself – which is why the "and" in "saucepan and lid" does not result in a list subtree, in the above example.

⟨Consider a calling clause which gives a possibly tricky name 9⟩ ≡

```
int i = is_word_intermediate(called_V, w1, w2);
if ((i >= 1) && (compare_word(i-1, OPENBRACKET_V)==FALSE)) {
    parse_node *CALLED_PN = new_node(CALLED_NT);
    CALLED_PN->word_ref1 = i; CALLED_PN->word_ref2 = i;
    CALLED_PN->down = new_nounphrase_worldly(w1, i-1, FALSE);
    CALLED_PN->down->next = new_nounphrase_articled(i+1, w2);
    return CALLED_PN;
}
```

This code is used in §6.

§**10. Property subtrees.** We would normally split a NP such as "a container having carrying capacity 10" into:

```
WITH_NT "having"
    NOUNPHRASE_NT "container" article:indefinite
    PROPERTYLIST_NT "carrying capacity 10"
```

However, we watch out for brackets – since those certainly prove us wrong – and also for the text "...it with action", which is present (for instance) in the name "locking it with action" – a valid NP where the word "action" is not intended to be a property list.

⟨Consider a with or having clause which specifies properties 10⟩ ≡

```
int i;
if ((([[w1, w2 == ... with ... : i]] || [[w1, w2 == ... having ... : i]]) &&
    (![[word i+1 == CLOSEBRACKET/OPENBRACKET]]) &&
    (!([[word i-1 == it]] && [[word i+1 == action]]))) {
    parse_node *WITH_PN = new_node(WITH_NT);
    WITH_PN->word_ref1 = i; WITH_PN->word_ref2 = i;
    WITH_PN->down = new_nounphrase_worldly(w1, i-1, FALSE);
    WITH_PN->down->next = new_property_list(i+1, w2);
    return WITH_PN;
}
```

This code is used in §6.

§11. List subtrees. These look just like list-divided noun phrases (see diagram above), except that each leaf can be a general worldly noun phrase subtree.

⟨Consider a comma- and and-separated list of noun phrases 11⟩ ≡

```
if (is_list_divided(w1, w2, LOOK_FOR_AND)) {
    parse_node *AND_PN = new_node(AND_NT);
    int lw1 = left_w1, lw2 = left_w2, rw1 = right_w1, rw2 = right_w2;
    AND_PN->down = new_nounphrase_worldly(lw1, lw2, FALSE);
    AND_PN->down->next = new_nounphrase_worldly(rw1, rw2, FALSE);
    return AND_PN;
}
```

This code is used in §6.

§12. Kind of clauses. Two very simple subtrees:

```
KIND "kind"        KIND "kind of vehicle"
                       NOUNPHRASE_NT "vehicle"
```

Note that indefinite articles are permitted before the word "kind(s)", but definite articles are not.

⟨Consider "kind" or a "kind of" clause 12⟩ ≡

```
int k1 = w1, k2 = w2;
[[k1, k2 == a/some ... --> k1, k2]];
if [[k1, k2 == kind/kinds]] {
    parse_node *KIND_NODE = new_node(KIND_NT);
    KIND_NODE->word_ref1 = k1; KIND_NODE->word_ref2 = k2;
    return KIND_NODE;
}
if [[k1, k2 == kind/kinds of ...]] {
    parse_node *KIND_NODE = new_node(KIND_NT);
    KIND_NODE->word_ref1 = k1; KIND_NODE->word_ref2 = k2;
    KIND_NODE->down = new_nounphrase_worldly(k1+2, k2, FALSE);
    return KIND_NODE;
}
```

This code is used in §6.

§13. From and of clauses. These have equal precedence, so we scan for them together, and go for the leftmost one found. They have the form:

```
FROM_NT "east from the Deer Park"
    NOUNPHRASE_NT "Deer Park" article:definite
    NOUNPHRASE_NT "east"
```

and similarly for `X_OF_Y_NT`. The perhaps contrary convention that the first child is the point of reference, while the second child is the method of reference, dates from Inform 7's earliest days: it does no harm.

```
On the shelf is Of Mice And Men and The Girl From Ipanema.
```

(Note that a routine in the Of and From section warns us off breaking "of" at certain bad positions. That only ever happens on a second attempt, where we are reconstructing the NPs for a sentence having got them wrong the first time by overzealously breaking at "of".)

⟨Consider a "from" or "of" clause 13⟩ ≡

```
int pos;
for (pos = w1+1; pos < w2; pos++) {
    int clause = NOUNPHRASE_NT;
    if (unexpectedly_upper_case(pos)) continue;
    if [[pos, w2 == in the presence of ...]] { pos += 4; continue; }
    if ([[pos, w2 == of ...]] &&
        (bad_of_break_position(pos, w1, w2) == FALSE)) clause = X_OF_Y_NT;
    if [[pos, w2 == from ...]] clause = FROM_NT;
    if (clause != NOUNPHRASE_NT) {
        parse_node *CLAUSE_NODE = new_node(clause);
        CLAUSE_NODE->word_ref1 = w1; CLAUSE_NODE->word_ref2 = w2;
        CLAUSE_NODE->down = new_nounphrase_worldly(pos+1, w2, FALSE);
        CLAUSE_NODE->down->next = new_nounphrase_worldly(w1, pos-1, FALSE);
        return CLAUSE_NODE;
    }
}
```

This code is used in §6.

§14. Relationship nodes. A modest utility routine to construct and annotation RELATIONSHIP nodes.

```
define STANDARD_RELN 0                                   the default annotation value
define PARENTAGE_HERE_RELN 1
define DIRECTION_RELN 2

parse_node *new_rel_node(int reln_type, binary_predicate *bp, int rw1, int rw2, int tw1, int tw2) {
    parse_node *REL = new_node(RELATIONSHIP_NT);
    REL->word_ref1 = rw1; REL->word_ref2 = rw2;
    if (bp) pn_set_relationship(REL, bp);
    else pn_annotate_int(REL, relationship_node_type_ANNOT, reln_type);
    if (tw1 != -1) REL->down = new_nounphrase_worldly(tw1, tw2, FALSE);
    return REL;
}
```

§15. Property lists as noun phrases. These are parsed in only the most rudimentary fashion at this early stage, because they cannot properly be understood until later (they will often refer to objects not yet created). We form lists into lopsided binary trees, so that "carrying capacity 10, dexterity 21, and skill 40" would return the following subtree:

```
AND_NT ","
    PROPERTYLIST_NT "carrying capacity 10"
    AND_NT ", and"
        PROPERTYLIST_NT "dexterity 21"
        PROPERTYLIST_NT "skill 40"
```

(See list-divided NPs above, which have a similar pattern.)

```
parse_node *new_property_list(int w1, int w2) {
    parse_node *PLIST_PN;
    if (is_list_divided(w1, w2, LOOK_FOR_AND)) {
        int lw1 = left_w1, lw2 = left_w2, rw1 = right_w1, rw2 = right_w2;
        parse_node *AND_PN = new_node(AND_NT);
        AND_PN->word_ref1 = left_w2+1; AND_PN->word_ref2 = right_w1-1;
        AND_PN->down = new_property_list(lw1, lw2);
        AND_PN->down->next = new_property_list(rw1, rw2);
        return AND_PN;
    }
    PLIST_PN = new_node(PROPERTYLIST_NT);
    PLIST_PN->word_ref1 = w1; PLIST_PN->word_ref2 = w2;
    return PLIST_PN;
}
```

§16. The player is not yourself. Finally two small utilities for the noun phrase referring to the player's avatar-object. "The player" is a variable in Inform 7, not a constant, and assertions of spatial relationships cannot be made concerning variables, so if we stuck rigidly to the rules then

> The player carries an umbrella.

...would have to produce a problem message. We don't want this: the user thinks of "the player" as a constant, even though it isn't, and sentences like this one are therefore the natural thing to write. So we transform "the player" to the constant "yourself" whenever it turns up in assertions:

```
void turn_player_to_yourself(parse_node *pn) {
    if [[pn == player]] pn_make_player_noun_phrase(pn);
}
void pn_make_player_noun_phrase(parse_node *pn) {
    pn_set_node_type(pn, NOUNPHRASE_NT);
    pn_set_refers_to(pn, wo_yourself);
}
```

The function turn_player_to_yourself is called from 8/relv.

The function pn_make_player_noun_phrase is called from 8/refpt and 8/mass.

Of and From 4/ofs

Purpose

To verify that "of" and "from" subtrees in assertion sentence noun phrases are validly used, and reconstruct their sentences without them if they are not.

Template interpreter commands

```
5   {-callv:tidy_up_ofs_and_froms}
```

Definitions

¶1. At this point in the narrative, the source text has been parsed into a large parse tree in which every assertion is represented by a `SENTENCE_NT` node. This is a child of the root of the tree, and its own children form a subtree which parses it into a verb phrase and associated noun phrases. Pretty well whenever it possibly could, the noun-phrase-maker created `X_OF_Y_NT` and `FROM_NT` subtrees in these noun phrases.

But `X_OF_Y_NT` and `FROM_NT` nodes are valid only when describing a value property associated with something ("description of the cards"), or a map direction leading away from somewhere ("east from Casino Royale"), which means that the noun-phrase-maker will have been wildly overzealous in creating these. It had to be: it had no way of knowing, so early in Inform's run, which handful of the many such nodes it made were actually valid. It didn't know what the property names were, nor what the direction names were. (For chicken-and-egg reasons, it couldn't know this.) So it almost certainly made some spurious noun phrase subtrees like this one:

```
X_OF_Y_NT "worn patch of carpet"
    NOUNPHRASE_NT "carpet"
    PROPERTYLIST_NT "worn patch"
```

Now comes the reckoning. The existing parse tree may contain a few bogus nodes, but it's good enough to determine all the property and direction names. This then enables us to go back and check all the `X_OF_Y_NT` and `FROM_NT` subtrees, expunging the ones which are spurious.

---

§**1.** Mostly we can use careful parsing to distinguish usages of "of": but there is one dire case when we can't, or not at any rate without knowledge which we may not have yet. This is the case occurring when a property name itself contains the word "of", as in:

```
A woman has a text called point of view.
```

The "of" there is no trouble: but the first "of" here is a nightmare –

```
The point of view of Kathy is "All grammar is bunk."
```

We call the first "of" a "bad of break position", because we don't want a worldly noun phrase in this sentence to break into the subtree:

```
X_OF_Y_NT "point of view of Kathy"
    NOUNPHRASE_NT "Kathy"
    X_OF_Y_NT "point of view"
        NOUNPHRASE_NT "view"
        PROPERTYLIST_NT "point"
```

The only way we can tell good of-breaks from bad is by knowing all the property names: the following routine performs the necessary test, determining whether $w_1 < p < w_2$ is a good position at which to break.

(Bad breaks would also occur if "of" was inside a direction name, or inside one of the permitted pseudo-property names, but in fact this never happens with the standard configuration and at present the user cannot change that, so we needn't worry.)

```
int bad_of_break_position(int pos, int w1, int w2) {
    property_name *prn;
    LOOP_OVER(prn, property_name) {
        int i, pn1 = prn->word_ref1, pn2 = prn->word_ref2;
        for (i=pn1; i<=pn2; i++)
            if [[word i == of]]
                ⟨Can the property's name be found inside the word range with this "of" at the break position? 2⟩;
    }
    return FALSE;
}
```

The function bad_of_break_position is called from 4/noun.

§**2.** If the answer to this question is "yes", then we have a bad break:

⟨Can the property's name be found inside the word range with this "of" at the break position? 2⟩ ≡

```
    int pm1 = pos - (i-pn1), pm2 = pm1 + (pn2-pn1);
    if ((pm1 >= w1) && (pm2 <= w2) &&
        (compare_word_range(pm1, pm2, pn1, pn2))) {
            LOG("Let's not break at pos %d = $W in <$W>, given $Y.\n",
                pos, pos, pos, w1, w2, prn);
            return TRUE;
    }
```

This code is used in §1.

§**3. Tree surgery.** The following routine performs the necessary correction to expunge a bogus `X_OF_Y_NT` or `FROM_NT` construction.

```
    X_OF_Y_NT "worn patch of carpet"  --->  NOUNPHRASE_NT "worn patch of carpet"
        NOUNPHRASE_NT "carpet"
        PROPERTYLIST_NT "worn patch"
```

Since the constructions have equal precedence in the nounphrase-maker, they might be nested, so we could find something like:

```
    X_OF_Y_NT "worn patch of carpet from hell"
        FROM_NT "carpet from hell"
            NOUNPHRASE_NT "hell"
            NOUNPHRASE_NT "carpet"
        PROPERTYLIST_NT "worn patch"
```

However, if any higher-up construction was invalid, then so are any constructions lower down: so it is safe to deal with this any such tree by drastic means.

```
void expunge_X_OF_Y_subtree(parse_node *pn) {
    pn_set_node_type(pn, NOUNPHRASE_NT);
    pn->down = NULL;
    fix_articles_in_raw_NP(pn);
}
void expunge_FROM_subtree(parse_node *pn) {
    pn_set_node_type(pn, NOUNPHRASE_NT);
    pn->down = NULL;
    fix_articles_in_raw_NP(pn);
}
```

§**4.** The other operation we need is to alter these subtrees to relationships. For instance:

```
FROM_NT "east from Essex"  --->  RELATIONSHIP_NT "east from Essex" type:direction
    NOUNPHRASE_NT "Essex"            NOUNPHRASE_NT "Essex"
    NOUNPHRASE_NT "east"             NOUNPHRASE_NT "east"
```

(This is still a third form of `RELATIONSHIP_NT` subtree: one with two children.)

```
void convert_clause_to_RELATIONSHIP(parse_node *pn) {
    pn_set_node_type(pn, RELATIONSHIP_NT);
    pn_annotate_int(pn, relationship_node_type_ANNOT, DIRECTION_RELN);
}
```

§**5. Tidying up ofs and from.** In deciding whether "worn patch of carpet" is to be treated as a single noun, as a property ("worn patch") belonging to a noun ("carpet"), or as a direction ("worn patch") relative to a noun ("carpet") – consider the cases "description of carpet" and "east of the lawn" – the key thing is to understand the meaning of the subject ("worn patch"). Unfortunately, the NI model world will not be created, much less named, for quite a long time to come: so we cannot simply parse the subject as an expression. At this early stage the best we can do is to scan ahead through the parse tree to try to find direction and property declarations. We do this with a sequence of three traversals:

(1.) Look for property and direction declarations. Create the property names called for; do not actually create the directions (that will happen much later), but remember their names.
(2.) Reconstruct the parse trees of any sentences which refer to property names which themselves contain an "of" (as may happen if, for instance, there is a property called "point of view").
(3.) Look for location phrases like "east from the lawn", which we can distinguish from other uses of "from" now that we know the direction names; at the same time look for "X of Y" phrases where the "of" should not be treated as a possessive, and expunge them.

```
void tidy_up_ofs_and_froms(void) {
    verify_integrity_of_subtree(tree_root, FALSE);
    traverse_for_property_names(tree_root->down);
    traverse_for_nonbreaking_ofs(tree_root->down);
    traverse_for_FROM_NT_subtrees(tree_root->down);
}
```

The function tidy_up_ofs_and_froms is invoked by a command in a `.i6t` template file.

§**6.** The following array is used only by Traversals 1 to 3, and is how we remember direction names.

define `MAX_DIRECTIONS 100` *the Standard Rules define only 12, so this is plenty*

```
parse_node *directions_noticed[MAX_DIRECTIONS];
binary_predicate *direction_relations_noticed[MAX_DIRECTIONS];
int no_directions_noticed = 0;
```

§**7. Traversal 1.** We now come to the routine which traverses the entire tree looking for property declarations.

In this as in the subsequent traversals, we use a loop rather than recursion to span the width of the tree: otherwise NI's stack usage goes through the roof, since it might need to recurse thousands of function calls deep.

```
void traverse_for_property_names(parse_node *pn) {
    for (; pn; pn = pn->next) {
        switch(pn_get_node_type(pn)) {
            case SENTENCE_NT: current_sentence = pn; break;
            case VERB_NT:
                ⟨See if this assertion creates property names with "... has ... called ..." 10⟩;
                break;
        }
        traverse_for_property_names(pn->down);
    }
}
```

§**8.** Directions are detected in sentences having the form "D is a direction."

```
void check_sentence_for_direction_creation(parse_node *pn) {
    if (pn_get_node_type(pn) != SENTENCE_NT) return;
    if ((pn->down == NULL) || (pn->down->next == NULL) || (pn->down->next->next == NULL)) return;
    if (pn_get_node_type(pn->down) != VERB_NT) return;
    if (pn_get_node_type(pn->down->next) != NOUNPHRASE_NT) return;
    if (pn_get_node_type(pn->down->next->next) != NOUNPHRASE_NT) return;
    current_sentence = pn;
    pn = pn->down->next;
    if (![[pn->next == direction]]) return;
    if (no_directions_noticed >= MAX_DIRECTIONS) {
        limit_problem(_P_(C4TooManyDirections),
            "different directions", MAX_DIRECTIONS);
        return;
    }
    direction_relations_noticed[no_directions_noticed] =
        bp_create_sketchy_mapping_direction(pn->word_ref1, pn->word_ref2);
    directions_noticed[no_directions_noticed++] = pn;
}
```

The function check_sentence_for_direction_creation is called from 4/verb.

§**9.** And to extract that sketchy BP later, for completion when possible:

```
binary_predicate *relation_noticed(int i) {
    return direction_relations_noticed[i];
}
```

The function relation_noticed is called from 9/mapbp.

§**10.** Typical patterns here are sentences in the form "X has a K called P". The trouble is that at this stage we can't verify that X is a world object or kind (they don't exist yet), nor that K is a kind of value (because nor do they). We must simply rely on the fact that assertions cannot take this form without being property declarations – with one exception:

The taking action has a number called the hazard level.

...creates not a property name but an action variable; and the same applies to activities and rulebooks. Fortunately, the names (X) of those must always end exactly in those words, so we are saved. (Unless, of course, the kind or world object for which this property name is created also ends in one of those words. Hmmm...) We therefore look for this subtree structure:

```
SENTENCE_NT "A container has a number called volume"
    VERB_NT "has"
    NOUNPHRASE_NT "container" article:indefinite
    CALLED_NT "called"
        NOUNPHRASE_NT "number" article:indefinite
        NOUNPHRASE_NT "volume"
```

...and then extract the bottom-most, rightmost noun-phrase as the name of the new property.

⟨See if this assertion creates property names with "... has ... called ..." 10⟩ ≡

```
if ((pn_int_annotation(pn, verb_id_ANNOT) == HAS_VB)
    && (pn->next)
    && (![[pn->next == ... action/activity/rulebook]])
    && (pn->next->next)
    && (pn_get_node_type(pn->next->next) == CALLED_NT)
    && (pn->next->next->down)
    && (pn->next->next->down->next))
    force_creation_of_property_name(pn->next->next->down->next);
```

This code is used in §7.

§**11.** All we really need to do is forces its creation if it doesn't already exist...

```
void force_creation_of_property_name(parse_node *pn) {
    int w1, w2;
    [[w1, w2 <-- pn]];
    internal_error_if_node_type_wrong(pn, NOUNPHRASE_NT);
    ⟨Issue problem messages for any really unfortunately chosen property name 12⟩;
    value_property_name_ref(w1, w2);                    this lookup creates a new PRN if necessary
}
```

§**12.** ...but let's also take the opportunity to pre-empt bad property names before they can do any damage:

⟨Issue problem messages for any really unfortunately chosen property name 12⟩ ≡

```
int i;
if [[w1, w2 == a/an/the/some]] {
    sentence_problem(_P_(C4PropertyCalledArticle),
        "a property name cannot consist only of an article",
        "which this one seems to. It would lead to awful ambiguities. "
        "More likely, the end of the sentence has been lost somehow?");
    return;
}
if [[w1, w2 == presence]] {
    sentence_problem(_P_(C4PropertyCalledPresence),
        "a property name cannot consist only of the word 'presence'",
        "because this would lead to ambiguities with the rule clause "
        "'...in the presence of...' (For instance, when writing something "
        "like 'Instead of eating in the presence of the Queen: ...') "
        "The best way to fix this is probably to add another word or "
        "two to the property name: 'stage presence', say, would be fine.");
    return;
}
for (i=w1; i<=w2; i++)
    if ([[word i == COMMA]] || (vocab_test_flags(w1, TEXT_MC))) {
        sentence_problem(_P_(C4PropertyNameForbidden),
            "a property name cannot contain quoted text or a comma",
            "which this one seems to. I think I must be misunderstanding: "
            "possibly you've added a subordinate clause which I can't "
            "make sense of?");
        return;
    }
```

This code is used in §11.

§**13. Traversal 2.** At this point the parse tree may contain `X_OF_Y_NT` subtrees which were formed at bad of-breaks, and that might have prevented it from forming correct ones. Any sentence which contains both worldly noun-phrases and at least one bad of-break position must therefore be considered suspect. The simplest thing to do is to throw away the existing subtree for such a sentence and build a fresh one, very probably smaller and simpler since it will not now break at what we now know to be a bad position.

(In a few cases, where for some other reason the of-break was not taken anyway, nothing will change – for instance, "On the table is a book called My point of view" does not break at the "of" whether it's a good break or a bad one, because the "called" construction takes priority. We could with some more work avoid this, but it causes no nuisance and wastes only a negligible amount of memory.)

```
void traverse_for_nonbreaking_ofs(parse_node *pn) {
    for (; pn; pn = pn->next)
        if ((pn_get_node_type(pn) == SENTENCE_NT) &&
            (pn->down) && (pn_get_node_type(pn->down) == VERB_NT)) {
            int i, vn = pn_int_annotation(pn->down, verb_id_ANNOT);
            if (((vn == ASSERT_VB) || (vn == HAS_VB) || (vn == DEFINED_BY_VB))
                && [[pn == ... of ... : i]]
                && (bad_of_break_position(i, pn->word_ref1, pn->word_ref2))) {
                current_sentence = pn;                  (just in case any problem messages are issued)
                pn->down = NULL;                        thus cutting off and forgetting its former subtree
                look_for_verb_phrase(pn);                                  ...in order to make a new one
```

```
            }
        }
}
```

§**14. Traversal 3.** Here we look for noun phrases in the form "X from Y", which have been added to the parse tree as `FROM_NT` subtrees: for instance, "northwest from the Gazebo" comes out as:

```
FROM_NT
    PROPERTYLIST_NT "Gazebo" article:definite
    NOUNPHRASE_NT "northwest"
```

We examine all such constructs to see if the subject is a direction name (because of Traversal 1, we know all those names). If so, we convert the subtree as a `RELATIONSHIP_NT` construct, since the phrase is giving spatial information. If not, we simply expunge the construct into a `NOUNPHRASE_NT`. Either way, after Traversal 3, there are no more `FROM_NT` nodes.

This is also where we finally decide which "X of Y" subtrees are to be expunged. And the answer is: all of them, except where X is one of two special pseudo-properties (possibly with articles), a property name or a direction. And even in the latter case, the construct is converted to a `RELATIONSHIP_NT` subtree. Thus, after Traversal 3, the reference child of every `X_OF_Y_NT` subtree is a property name, `specification` or `plural`.

```
void traverse_for_FROM_NT_subtrees(parse_node *pn) {
    for (; pn; pn = pn->next) {
        traverse_for_FROM_NT_subtrees(pn->down);
        switch(pn_get_node_type(pn)) {
            case SENTENCE_NT: current_sentence = pn; break;
            case FROM_NT:
                if ((pn->down) && (pn->down->next)) {
                    int direction_found = FALSE;
                    ⟨See if the word range matches a direction name found in Traversal 1 15⟩;
                    if (direction_found == FALSE) expunge_FROM_subtree(pn);
                } else internal_error("malformed FROM_NT subtree");
                break;
            case X_OF_Y_NT:
                if ((pn->down) && (pn->down->next)) {
                    int allow_this = FALSE, direction_found = FALSE, w1, w2;
                    [[w1, w2 <-- pn->down->next]];
                    if (parse_property_name(w1, w2)) allow_this = TRUE;
                    if [[w1, w2 == specification]] allow_this = TRUE;
                    else if [[w1, w2 == plural]] allow_this = TRUE;
                    else ⟨See if the word range matches a direction name found in Traversal 1 15⟩;
                    if ((allow_this == FALSE) && (direction_found == FALSE))
                        expunge_X_OF_Y_subtree(pn);
                } else internal_error("malformed X_OF_Y_NT subtree");
                break;
        }
    }
}
```

§**15.** We do not allow direction names with unexpected capital letters because we want to allow room names to contain direction names on occasion:

The fire hydrant is in West from 47th Street.

⟨See if the word range matches a direction name found in Traversal 1 15⟩ ≡

```
int i, w1, w2;
[[w1, w2 <-- pn->down->next]];
if (unexpectedly_upper_case(w1) == FALSE)
    for (i=0; i<no_directions_noticed; i++)
        if (compare_word_range(w1, w2,
                directions_noticed[i]->word_ref1, directions_noticed[i]->word_ref2))
            direction_found = TRUE;
if (direction_found) convert_clause_to_RELATIONSHIP(pn);
```

This code is used in §14.

Rule Subtrees 4/rtree

Purpose

To tidy up COMMAND_NT nodes into a list of children under the relevant ROUTINE_NT node, and so turn each rule definition into a single subtree.

4/rtree.§3-19 Unifying Block Syntaxes; §20 Basic Structural Syntax; §21 Detect Control Structures

---

Template interpreter commands

```
1   {-callv:register_recently_lexed_phrases}
20  {-callv:create_standard_csps}
```

Definitions

¶1. Initially, the phrases (COMMAND_NT) making up a rule (ROUTINE_NT) are simply listed after it in the parse tree, but we want them to become its children: this is the only thing the *A*-grammar does with rules, which otherwise wait until Chapter 12 to be dealt with.

The single routine in this section accomplishes the regrouping: after it runs, every COMMAND_NT is a child of the ROUTINE_NT header to which it belongs.

¶2. Certain phrases are "structural": otherwise, if, repeat, while and so on. These have different expectations in terms of the layout of surrounding phrases in rule or phrase definitions, and the following structure defines the relevant behaviour. (The contents are static.)

```
typedef struct control_structure_phrase {
    struct control_structure_phrase *subordinate_to;
    int indent_subblocks;
    int body_empty_except_for_subordinates;
    int suppress_RULES_ALL_text;
    int used_at_stage;
    int requires_new_syntax;
    int allow_run_on;
    MEMORY_MANAGEMENT
} control_structure_phrase;

control_structure_phrase
    *switch_CSP = NULL,
    *if_CSP = NULL,
    *repeat_CSP = NULL,
    *while_CSP = NULL,
    *otherwise_CSP = NULL,
    *otherwise_if_CSP = NULL,
    *default_case_CSP = NULL,
    *case_CSP = NULL;
```

The structure control_structure_phrase is private to this section.

---

§**1.** This routine is used whenever new material is added. Whenever it finds a childless `ROUTINE_NT` followed by a sequence of `COMMAND_NT` nodes, it joins these in sequence as children of the `ROUTINE_NT`. Since it always acts so as to leave a non-zero number of children, and since it acts only on childless nodes, it cannot ever act on the same node twice.

```
void register_recently_lexed_phrases(void) {
    parse_node *p;
    if (problem_count > 0) return;                                  for then the tree is perhaps broken anyway
    for (p = tree_root->down; p; p=p->next)
        if ((pn_get_node_type(p) == ROUTINE_NT) && (p->down == NULL)) {
            parse_node *end_def = p;
            while ((end_def->next) && (pn_get_node_type(end_def->next) == COMMAND_NT))
                end_def = end_def->next;
            if (p == end_def) continue;                          ROUTINE_NT not followed by any COMMAND_NTs
            splice so that p->next to end_def become the children of p:
            p->down = p->next;
            p->next = end_def->next;
            end_def->next = NULL;
            unify_block_syntaxes(p);
        }
    ⟨Assert that there are indeed no loose COMMAND nodes 2⟩;
}
```

The function register_recently_lexed_phrases is invoked by a command in a `.i6t` template file and called from 5/litp, 7/dti, 9/scene and 9/madj.

§**2.** And just in case:

```
⟨Assert that there are indeed no loose COMMAND nodes 2⟩ ≡
    for (p = tree_root->down; p; p=p->next)
        if (pn_get_node_type(p) == COMMAND_NT) {
            current_sentence = p;
            internal_error("loose COMMAND node outside of rule definition");
        }
```

This code is used in §1.

§**3. Unifying Block Syntaxes.** There are now two possible syntaxes to express the structural makeup of a routine: we check which is in use for this one, and unify them into a common format in the parse tree.

```
void unify_block_syntaxes(parse_node *rout) {
    parse_node *uses_colon_syntax = NULL;
    parse_node *uses_begin_end_syntax = NULL;
    parse_node *requires_colon_syntax = NULL;
    ⟨See which block syntax is used by conditionals and loops 4⟩;
    if ((uses_colon_syntax) && (uses_begin_end_syntax)) {
        current_sentence = rout;
        quote_source(1, current_sentence);
        quote_source(2, uses_colon_syntax);
        quote_source(3, uses_begin_end_syntax);
        handmade_problem(_P_(C4BothBlockSyntaxes));
        issue_problem_segment(
            "The rule or phrase definition %1 seems to use both ways of grouping "
            "phrases together into 'if', 'repeat' and 'while' blocks at once. "
```

```
            "Inform allows two alternative forms, but they cannot be mixed in "
            "the same definition. %POne way is to end the 'if', 'repeat' or "
            "'while' phrases with a 'begin', and then to match that with an "
            "'end if' or similar. ('Otherwise' or 'otherwise if' clauses are "
            "phrases like any other, and end with semicolons in this case.) "
            "You use this begin/end form here, for instance - %3. %P"
            "The other way is to end with a colon ':' and then indent the "
            "subsequent phrases underneath, using tabs. (Note that any "
            "'otherwise' or 'otherwise if' clauses also have to end with "
            "colons in this case.) You use this indented form here - %2.");
        issue_problem_end();
        return;
    }
    if ((requires_colon_syntax) && (uses_begin_end_syntax)) {
        current_sentence = rout;
        quote_source(1, current_sentence);
        quote_source(2, requires_colon_syntax);
        handmade_problem(_P_(C4NotInOldSyntax));
        issue_problem_segment(
            "The construction %2, in the rule or phrase definition %1, "
            "is only allowed if the rule is written in the 'new' format, "
            "that is, with the phrases written one to a line with "
            "indentation showing how they are grouped together, and "
            "with colons indicating the start of such a group.");
        issue_problem_end();
        return;
    }
    if (uses_colon_syntax)
        ⟨Insert begin/end markers and check that indentation is correct 5⟩;
}
```

§**4.** Traditional I7 syntax for blocks is to place them within begin/end markers: the "begin" occurring at the end of the conditional or loop header, and the "end if", "end while", etc., as a phrase of its own at the end of the block. Newer I7 syntax (March 2008) is to use Python-style colons and indentation. Both are allowed, but not in the same routine.

⟨See which block syntax is used by conditionals and loops 4⟩ ≡

```
    parse_node *p;
    for (p = rout->down; p; p = p->next) {
        control_structure_phrase *csp =
            detect_control_structure(p->word_ref1, p->word_ref2);
        if (csp) {
            int syntax_used = pn_int_annotation(p, colon_block_command_ANNOT);
            if (syntax_used == FALSE) {                          i.e., doesn't end with a colon
                don't count "if x is 1, let y be 2" – with no block – as deciding it
                if ((csp->subordinate_to == NULL) && (![[p == ... begin]]))
                    syntax_used = NOT_APPLICABLE;
            }
            if (syntax_used != NOT_APPLICABLE) {
                if (syntax_used) {
                    if (uses_colon_syntax == NULL) uses_colon_syntax = p;
                } else {
```

```
                    if (uses_begin_end_syntax == NULL) uses_begin_end_syntax = p;
                }
            }
            if (csp->suppress_RULES_ALL_text)
                pn_annotate_int(p, suppress_debug_text_ANNOT, TRUE);
            if ((csp->requires_new_syntax) && (requires_colon_syntax == NULL))
                requires_colon_syntax = p;
        }
        if ([[p == end ###]] && (uses_begin_end_syntax == NULL))
            uses_begin_end_syntax = p;
    }
```

This code is used in §3.

§**5.** In the case where the routine uses indentation, we amend the colons at the end of block phrases to the word "begin" – thus giving them the old-style syntax ready for them to be parsed – and insert suitable "end" phrases where blocks have implicitly been closed by indentation reductions.

⟨Insert begin/end markers and check that indentation is correct 5⟩ ≡

```
    parse_node *p, *prev, *run_on_at = NULL, *first_misaligned_phrase = NULL;
    int k, indent, expected_indent = 1, indent_misalign = FALSE,
        just_opened_block = FALSE;
    the blocks open stack holds blocks currently open
    parse_node *blstack_opening_phrase[10];
    control_structure_phrase *blstack_construct[10];
    int blstack_stage[10];
    int blo_sp = 0;
    for (prev = NULL, p = rout->down, k=1; p; prev = p, p = p->next, k++) {
        control_structure_phrase *csp =
            detect_control_structure(p->word_ref1, p->word_ref2);
        ⟨Determine actual indentation of this phrase 6⟩;
        ⟨Compare actual indentation to what we expect from structure so far 7⟩;
        ⟨Insert begin marker and increase expected indentation if a block begins here 9⟩;
    }
    indent = 1;
    ⟨Try closing blocks to bring expected indentation down to match 10⟩;
    if (run_on_at) ⟨Issue problem message for run-ons within phrase definition 15⟩;
    if (indent_misalign) ⟨Issue problem message for misaligned indentation 14⟩;
```

This code is used in §3.

§**6.** Here we set `indent` to the number of tab-stops in from the margin, or to `expected_indent` if the text does not appear to be at the start of its own line in the source (because it runs on from a previous phrase, in which case we set the `run_on_at` flag: except for following on from cases in switches with a non-control-structure, which is allowed, because otherwise the lines often look silly and short).

⟨Determine actual indentation of this phrase 6⟩ ≡

```
indent = expected_indent;
if (p->word_ref1 >= 0) {
    switch (lw_array[p->word_ref1].lw_break) {
        case '\n': indent = 0; break;
        case '\t': indent = 1; break;
        case '1': indent = 1; break;
        case '2': indent = 2; break;
        case '3': indent = 3; break;
        case '4': indent = 4; break;
        case '5': indent = 5; break;
        case '6': indent = 6; break;
        case '7': indent = 7; break;
        case '8': indent = 8; break;
        case '9': indent = 9; break;
        default:
            if ((prev) && (csp == NULL)) {
                control_structure_phrase *pcsp =
                    detect_control_structure(prev->word_ref1, prev->word_ref2);
                if ((pcsp) && (pcsp->allow_run_on)) break;
            }
            if (run_on_at == NULL) run_on_at = p; break;
    }
}
```

This code is used in §5.

§**7.** We now know the `indent` level of the line as read, and also the `expected_indent` given the definition so far. If they agree, fine. If they don't agree, it isn't necessarily bad news – if each line's indentation were a function of the last, there would be no information in it, after all. Roughly speaking, when `indent` is greater than we expect, that must be wrong – it means indentation has jumped inward as if to open a new block, but blocks are opened explicitly and not by simply raising the indent. But when `indent` is less than we expect, this may simply mean that the current block(s) has or have been closed, because blocks are indeed closed implicitly just by moving the indentation back in.

⟨Compare actual indentation to what we expect from structure so far 7⟩ ≡

```
if (indent == 0) {
    ⟨Record a misalignment of indentation 13⟩;
    ⟨Record a phrase within current block 11⟩;
} else {
    if ((csp) && (csp->subordinate_to)) {
        ⟨Compare actual indentation to what we expect for an intermediate phrase 8⟩;
        just_opened_block = TRUE;
    } else {
        if (expected_indent < indent) ⟨Record a misalignment of indentation 13⟩;
        if (expected_indent > indent)
            ⟨Try closing blocks to bring expected indentation down to match 10⟩;
        expected_indent = indent;
        ⟨Record a phrase within current block 11⟩;
```

```
        }
    }
    if (expected_indent < 1) expected_indent = 1;
```

This code is used in §5.

§**8.** This is a small variation used for an intermediate phrase like "otherwise". These are required to be at the same indentation as the line which opened the block, rather than being one tab step in from there: in other words they are not deemed part of the block itself. They can also occur in "stages", which is a way to enforce one intermediate phrase only being allowed after another one – for instance, "otherwise if..." is not allowed after an "otherwise" within an "if".

⟨Compare actual indentation to what we expect for an intermediate phrase 8⟩ ≡

```
    expected_indent--;
    if (expected_indent < indent) {
        ⟨Issue problem for an intermediate phrase not matching 18⟩;
    } else {
        ⟨Try closing blocks to bring expected indentation down to match 10⟩;
        if ((blo_sp == 0) ||
            (csp->subordinate_to != blstack_construct[blo_sp-1])) {
            ⟨Issue problem for an intermediate phrase not matching 18⟩;
        } else {
            if (blstack_stage[blo_sp-1] > csp->used_at_stage)
                ⟨Issue problem for an intermediate phrase out of sequence 19⟩;
            blstack_stage[blo_sp-1] = csp->used_at_stage;
        }
    }
    expected_indent++;
```

This code is used in §7.

§**9.** In colon syntax, blocks are explicitly opened; they are only implicitly closed. Here is the opening:

If `p` is a node representing a phrase beginning a block, and we're in the colon syntax, then it is followed by a word which is the colon: thus if `p` reads "if x is 2" then the word following the "2" will be ":". We replace it with the word "begin" and stretch `p` so that it now reads "if x is 2 begin", as it would if the begin/end syntax had been used.

⟨Insert begin marker and increase expected indentation if a block begins here 9⟩ ≡

```
    if ((csp) && (csp->subordinate_to == NULL) && (pn_int_annotation(p, colon_block_command_ANNOT)))
{
        p->word_ref2++;
        change_text_of_word(p->word_ref2, "begin");
        expected_indent++;
        if (csp->indent_subblocks) expected_indent++;
        blstack_construct[blo_sp] = csp;
        blstack_stage[blo_sp] = 0;
        blstack_opening_phrase[blo_sp++] = p;
        just_opened_block = TRUE;
    }
```

This code is used in §5.

§**10.** Now for the closing of colon-syntax blocks. We know that blocks must be being closed if the indentation has jumped backwards: but it may be that many blocks are being closed at once. (It may also be that the indentation has gone awry.)

⟨Try closing blocks to bring expected indentation down to match 10⟩ ≡

```
if ((just_opened_block) &&
    (blo_sp > 0) &&
    (!(blstack_construct[blo_sp-1]->body_empty_except_for_subordinates)))
    ⟨Issue problem for an empty block 16⟩;
while (indent < expected_indent) {
    parse_node *opening;
    if (blo_sp == 0) {
        ⟨Record a misalignment of indentation 13⟩;
        indent = expected_indent;
        break;
    }
    if ((blstack_construct[blo_sp-1]->body_empty_except_for_subordinates) &&
        (expected_indent - indent == 1)) {
        indent = expected_indent;
        break;
        ⟨Issue problem for non-case in a switch 17⟩;
        indent = expected_indent;
        break;
    }
    expected_indent--;
    if (blstack_construct[blo_sp-1]->indent_subblocks) expected_indent--;
    opening = blstack_opening_phrase[--blo_sp];
    ⟨Insert end marker to match the opening of the block phrase 12⟩;
}
```

This code is used in §5,7,8,5,7,8,5,7,8.

§**11.**

⟨Record a phrase within current block 11⟩ ≡

```
if ((blo_sp > 0) &&
    (blstack_stage[blo_sp-1] == 0) &&
    (blstack_construct[blo_sp-1]->body_empty_except_for_subordinates)) {
    ⟨Issue problem for non-case in a switch 17⟩;
}
just_opened_block = FALSE;
```

This code is used in §7.

§**12.** An end marker is a phrase like “end if” which matches the “if... begin” above it: here we insert such a marker at a place where the source text indentation implicitly requires it.

⟨Insert end marker to match the opening of the block phrase 12⟩ ≡

```
parse_node *implicit_end = new_node(COMMAND_NT);
implicit_end->next = prev->next; prev->next = implicit_end;
prev = implicit_end;
implicit_end->word_ref1 = lexer_wordcount;
feed_into_lexer("end ", FALSE, FALSE);
splice_words(opening->word_ref1, opening->word_ref1);
implicit_end->word_ref2 = lexer_wordcount - 1;
```

This code is used in §10.

§**13.** Here we throw what amounts to an exception...

⟨Record a misalignment of indentation 13⟩ ≡

```
indent_misalign = TRUE;
if (first_misaligned_phrase == NULL) first_misaligned_phrase = p;
```

This code is used in §7,10,7,10,7,10.

§**14.** ...and catch it with something of a catch-all message:

⟨Issue problem message for misaligned indentation 14⟩ ≡

```
current_sentence = rout;
quote_source_eliding_begin(1, current_sentence);
quote_source_eliding_begin(2, first_misaligned_phrase);
handmade_problem(_P_(C4MisalignedIndentation));
issue_problem_segment(
    "The phrase or rule definition %1 is written using the 'colon "
    "and indentation' syntax for its 'if's, 'repeat's and 'while's, "
    "where blocks of phrases grouped together are indented one "
    "tab step inward from the 'if ...:' or similar phrase to which "
    "they belong. But the tabs here seem to be misaligned, and I can't "
    "determine the structure. The first phrase going awry in the "
    "definition seems to be %2, in case that helps. %PThis sometimes "
    "happens even when the code looks about right, to the eye, if rows "
    "of spaces have been used to indent phrases instead of tabs.");
issue_problem_end();
```

This code is used in §5.

§**15.**

⟨Issue problem message for run-ons within phrase definition 15⟩ ≡

```
current_sentence = rout;
quote_source_eliding_begin(1, current_sentence);
quote_source_eliding_begin(2, run_on_at);
handmade_problem(_P_(C4RunOnsInTabbedRoutine));
issue_problem_segment(
    "The phrase or rule definition %1 is written using the 'colon "
    "and indentation' syntax for its 'if's, 'repeat's and 'while's, "
    "but that's only allowed if each phrase in the definition "
    "occurs on its own line. So phrases like %2, which follow "
    "directly on from the previous phrase, aren't allowed.");
issue_problem_end();
```

This code is used in §5.

§**16.** It's a moot point whether the following should be incorrect syntax, but it far more often happens as an accident than anything else, and it's hard to think of a sensible use.

⟨Issue problem for an empty block 16⟩ ≡

```
LOG("$T\n", rout);
current_sentence = rout;
quote_source_eliding_begin(1, current_sentence);
quote_source_eliding_begin(2, prev);
quote_source_eliding_begin(3, p);
handmade_problem(_P_(C4EmptyIndentedBlock));
issue_problem_segment(
    "The phrase or rule definition %1 is written using the 'colon "
    "and indentation' syntax for its 'if's, 'repeat's and 'while's, "
    "where blocks of phrases grouped together are indented one "
    "tab step inward from the 'if ...:' or similar phrase to which "
    "they belong. But the phrase %2, which ought to begin a block, "
    "is immediately followed by %3 at the same or a lower indentation, "
    "so the block seems to be empty - this must mean there has been "
    "a mistake in indenting the phrases.");
issue_problem_end();
```

This code is used in §10.

§**17.**

⟨Issue problem for non-case in a switch 17⟩ ≡

```
current_sentence = rout;
quote_source_eliding_begin(1, current_sentence);
quote_source_eliding_begin(2, p);
handmade_problem(_P_(C4NonCaseInIf));
issue_problem_segment(
    "In the phrase or rule definition %1, the phrase %2 came as a "
    "surprise since it was not a case in an 'if X is...' but was "
    "instead some other miscellaneous instruction.");
issue_problem_end();
```

This code is used in §10,11,10,11,10,11.

§18.

⟨Issue problem for an intermediate phrase not matching 18⟩ ≡

```
    if (indent_misalign == FALSE) {
        current_sentence = p;
        if (csp->subordinate_to == if_CSP)
            sentence_problem(_P_(C4MisalignedOtherwise),
                "this seems to be misplaced since it is not placed within an 'if'",
                "as it must be. An 'otherwise' must be vertically underneath the "
                "'if' to which it corresponds, at the same indentation.");
        if (csp->subordinate_to == switch_CSP)
            sentence_problem(_P_(C4MisalignedCase),
                "this seems to be misplaced since it is not a case within an "
                "'if X is...'",
                "as it must be. Each case must be placed one tab stop in from "
                "the 'if X is...' to which it belongs, and the instructions "
                "for what to do in that case should be one tab stop further in "
                "still.");
    }
```

This code is used in §8.

§19.

⟨Issue problem for an intermediate phrase out of sequence 19⟩ ≡

```
    if (indent_misalign == FALSE) {
        current_sentence = p;
        sentence_problem(_P_(C4MisarrangedOtherwise),
            "this seems to be misplaced since it is out of sequence within its 'if'",
            "with an 'otherwise if...' coming after the more general 'otherwise' "
            "rather than before. (Note that an 'otherwise' or 'otherwise if' must "
            "be vertically underneath the 'if' to which it corresponds, at the "
            "same indentation.");
    }
```

This code is used in §8.

§20. **Basic Structural Syntax.** The following routine is an attempt to contain information about the basic structural phrases in one place in NI, so that if future loop constructs are added, they can fairly simply be put here.

```
control_structure_phrase *csp_new(void) {
    control_structure_phrase *csp = CREATE(control_structure_phrase);
    csp->subordinate_to = NULL;
    csp->indent_subblocks = FALSE;
    csp->body_empty_except_for_subordinates = FALSE;
    csp->suppress_RULES_ALL_text = FALSE;
    csp->used_at_stage = -1;
    csp->requires_new_syntax = FALSE;
    csp->allow_run_on = FALSE;
    return csp;
}
void create_standard_csps(void) {
    switch_CSP = csp_new();
```

```
    switch_CSP->body_empty_except_for_subordinates = TRUE;
    switch_CSP->indent_subblocks = TRUE;
    switch_CSP->requires_new_syntax = TRUE;

    if_CSP = csp_new();

    repeat_CSP = csp_new();

    while_CSP = csp_new();

    otherwise_CSP = csp_new();
    otherwise_CSP->subordinate_to = if_CSP;
    otherwise_CSP->suppress_RULES_ALL_text = TRUE;
    otherwise_CSP->used_at_stage = 1;

    otherwise_if_CSP = csp_new();
    otherwise_if_CSP->subordinate_to = if_CSP;
    otherwise_if_CSP->suppress_RULES_ALL_text = TRUE;
    otherwise_if_CSP->used_at_stage = 0;

    case_CSP = csp_new();
    case_CSP->subordinate_to = switch_CSP;
    case_CSP->suppress_RULES_ALL_text = TRUE;
    case_CSP->used_at_stage = 1;
    case_CSP->requires_new_syntax = TRUE;
    case_CSP->allow_run_on = TRUE;

    default_case_CSP = csp_new();
    default_case_CSP->subordinate_to = switch_CSP;
    default_case_CSP->suppress_RULES_ALL_text = TRUE;
    default_case_CSP->used_at_stage = 2;
    default_case_CSP->requires_new_syntax = TRUE;
    default_case_CSP->allow_run_on = TRUE;
}

int is_otherwise_if(int w1, int w2) {
    if (detect_control_structure(w1, w2) == otherwise_if_CSP) return TRUE;
    return FALSE;
}
```

The function create_standard_csps is invoked by a command in a `.i6t` template file.
The function is_otherwise_if is called from 7/cmsp.

§**21. Detect Control Structures.** And here we parse the text to see which, if any, of the above control structures it might be.

```
control_structure_phrase *detect_control_structure(int w1, int w2) {
    if [[w1, w2 == if ... is begin]] return switch_CSP;                    for problem tracking only
    if [[w1, w2 == if ... is]] return switch_CSP;
    if [[w1, w2 == if/unless ...]] return if_CSP;
    if [[w1, w2 == repeat ...]] return repeat_CSP;
    if [[w1, w2 == while ...]] return while_CSP;
    if [[w1, w2 == else/otherwise]] return otherwise_CSP;
    if [[w1, w2 == else/otherwise if/unless ...]] return otherwise_if_CSP;
    if [[w1, w2 == DASHDASH otherwise]] return default_case_CSP;
    if [[w1, w2 == DASHDASH ...]] return case_CSP;
    return NULL;
}
```

The function detect_control_structure is called from 4/sent and 7/cmsp.

Verify Parse Tree 4/verif

Purpose

To check that the parse tree has been correctly constructed, in hopes of detecting bugs in the program: this check should never fail.

Template interpreter commands

```
7   {-callv:verify_parse_tree}
```

Definitions

¶1. The parse tree is a complicated structure, arbitrarily wide and deep, and containing about 30 different node types, each subject to its own rules of usage. This is both good and bad: bad because complexity is always the enemy of program correctness, good because it gives us an independent opportunity to test a great deal of what Chapter 4's code has done. If, given every source text in the `intest` suite – some correct, some with problems – Chapter 4 always constructs a well-formed tree, we must be doing something right.

We verify the parse tree at the end of the initial parsing stage whose narrative story is told by Chapters 3 and 4. (That's why this section comes last in Chapter 4.) At this time, the parse tree is the output of the *A*-grammar parser. Nodes of one type (`FROM_NT`) which were at one time present have now been eliminated; nodes of a number of other types will not appear until later, when we work further with the tree in Chapter 8. So at present, in what we call the "initial parse tree", there can be up to 20 node types in evidence. But these are not arbitrarily arranged: for instance, a `SENTENCE_NT` node cannot legally be beneath a `NOUNPHRASE_NT` one. The collection of rules like this which the tree must satisfy is called its "invariant", and is expressed in convenient numerical form by the table below.

Note that this is verification, not an attempt to correct matters. If any test fails, NI will stop with an internal error. This should never happen.

¶2. The invariant for the usage of a node type in the initial parse tree is given by a triplet of numbers $(c_{\min}, c_{\max}, w)$ and a node type t_{parent}, where it is always true that

$$0 \le c_{\min} \le c_{\max} \le \infty.$$

(In fact, we use the enormous number `INFTY` to represent ∞.) The rule to be applied at every node is that:

(1) The weight at the node $w_{\text{node}} \neq 0$;

(2) If $w_{\text{node}} > 0$ then, except at the root, we must have $w_{\text{node}} \ge \text{abs}(w_{\text{parent}})$, where $\text{abs}(x)$ is the absolute value of x;

(3) If $t_{\text{parent}} \neq -1$ then this must be the node type of the parent;

(4) The number of children c satisfies $c_{\min} \le c \le c_{\max}$.

Rules (3) and (4) speak for themselves, and rule (1) is simply a way to mark certain node types as being illegal in the initial parse tree – these are the ones which will only be added later, in Chapter 8.

The upshot of rule (2) is that heavier nodes always occur lower down in the tree than lighter ones. For instance, an `AND_NT` node (weight 6) cannot occur anywhere in the subtree beneath an `X_OF_Y_NT` node (weight 8). A negative weight, $w < 0$, allows a node of this type to occur anywhere: but it still starts a well-formed subtree on its own terms, because it behaves to its children as if it had weight $-w$.

¶3. The following structure is used only for a row in a table of what we might call metadata about node types: information on where each node type can appear, and what restrictions apply to its use. We also store textual names for the node types here, as this is convenient for logging.

The table also includes information needed for the `allow_in_assertions` check, called by the assertion-maker of Chapter 8 as it runs. If the text asserts that, say, "The cat is in the bag." then the assertion-maker will try to equate a parse subtree for "the cat" against another for "in the bag", with node types at the roots of these subtrees being `NOUNPHRASE_NT` and `RELATIONSHIP_NT` respectively. The check makes sure that inappropriate subtrees are never accidentally fed to the assertion-maker.

```
typedef struct parse_tree_node_type {
    char *node_type_name;                    text of name of type, such as "COMMAND_NT"
    int min_children;                        minimum legal number of child nodes
    int max_children;                        maximum legal number of child nodes
    int node_weight;                         where higher weights sink to the bottom
    int required_parent_node_type;           required node type of parent, or -1
    int allow_in_assertions;                 allow this on either side of an assertion?
} parse_tree_node_type;
```

The structure parse_tree_node_type is private to this section.

¶4. The actual metadata for the node types is stored in the following array. (The order of entries must match the defined values of the `_MT` constants in the Parse Tree section.)

```
parse_tree_node_type parse_tree_node_types[];
```

---

§**1.** Note that `FROM_NT` is listed as not allowed in the initial parse tree: although it did exist in the tree for part of this chapter, the tidying up done by Of And From removed every `FROM_NT` node.

define `INFTY 1000000000` *if ever a node has more than a billion children, we are in trouble anyway*

```
parse_tree_node_type parse_tree_node_types[HIGHEST_NODE_TYPE+1] = {
    the columns are: name, max and min children, weight, required parent (if any), whether allowed in assertions
    { "(zero node type)",   0, INFTY,  0,   -1,           FALSE },
    { "ROOT_NT",            0, INFTY,  1,   -1,           FALSE },
    { "BIBLIOGRAPHIC_NT",   0,  0,     2,   ROOT_NT,      FALSE },
    { "HEADING_NT",         0,  0,     2,   ROOT_NT,      FALSE },
    { "INCLUDE_NT",         0,  0,     2,   ROOT_NT,      FALSE },
    { "BEGINHERE_NT",       0,  0,     2,   ROOT_NT,      FALSE },
    { "ENDHERE_NT",         0,  0,     2,   ROOT_NT,      FALSE },
    { "SENTENCE_NT",        0, INFTY,  2,   ROOT_NT,      FALSE },
    { "ROUTINE_NT",         0, INFTY,  2,   ROOT_NT,      FALSE },
    { "INFORM6CODE_NT",     0,  0,     2,   ROOT_NT,      FALSE },
    { "TABLE_NT",           0,  0,     2,   ROOT_NT,      FALSE },
    { "EQUATION_NT",        0,  0,     2,   ROOT_NT,      FALSE },
    { "TRACE_NT",           0,  0,     2,   ROOT_NT,      FALSE },
    { "RELATIONSHIP_NT",    0,  2,    -3,   -1,           TRUE },

    { "X_OF_Y_NT",          2,  2,     8,   -1,           TRUE },
    { "VERB_NT",            0,  0,    10,   SENTENCE_NT,  FALSE },
```

```
    { "CREATED_NT",          0,  0,    10,   -1,           TRUE },
    { "NOUNPHRASE_NT",       0,  0,    10,   -1,           TRUE },
    { "PROPERTYLIST_NT",     0,  0,    10,   -1,           TRUE },
    { "FROM_NT",             2,  2,     0,   -1,           FALSE },
    { "COMMAND_NT",          0,  0,    10,   ROUTINE_NT,   FALSE },
    { "ALLOWED_NT",          1,  1,     0,   SENTENCE_NT,  TRUE },
    { "EVERY_NT",            0, INFTY,  0,   -1,           TRUE },
    { "INSTANCE_NT",         0, INFTY,  0,   -1,           TRUE },
    { "VALUE_NT",            0, INFTY,  0,   -1,           TRUE },
    { "ACTION_NT",           0, INFTY,  0,   -1,           TRUE },
    { "ADJECTIVE_NT",        0, INFTY,  0,   -1,           TRUE },
    { "PROPERTYNOUN_NT",     0, INFTY,  0,   -1,           TRUE },
    { "PROPERTYCALLED_NT",   2,  2,     4,   -1,           FALSE },
    { "TOKEN_NT",            0, INFTY,  0,   -1,           FALSE }
};
```

§**2. Logging node types.** And also making node names available to the machinery for producing internal errors when incorrect node types are encountered, though we hope this will never be used.

```
void log_node_type(int t) {
    if ((t<1) || (t>HIGHEST_NODE_TYPE)) LOG("?%d_NT", t);
    else LOG("%s", parse_tree_node_types[t].node_type_name);
}
char *pnt_get_name(int t) {
    return parse_tree_node_types[t].node_type_name;
}
```

The function log_node_type is called from 2/dl.
The function pnt_get_name is called from 2/prob3.

§**3. Checking that the tree is even a tree.** Almost always – let's say, at the end of each cycle of the `.i6t` interpreter – the main component of the parse tree is required to be a tree. (The "main component" means "all those nodes connected, directly or indirectly, from the tree root node".) It must contain no loops, and all of its `next` and `down` links must point to valid parse nodes or else to `NULL`. Finally, every node must have a valid type number.

The following routine checks that this is so for any subtree: to check it for the whole shebang, we must call `verify_integrity_of_subtree(tree_root, f)`.

```
int tree_stats_size = 0, tree_stats_depth = 0, tree_stats_width = 0;
void verify_integrity_of_subtree(parse_node *p, int worth_logging) {
    tree_stats_size = 0; tree_stats_depth = 0; tree_stats_width = 1;
    verify_tree_integrity_recursively(p->down, p, "down", 0);
    tidy_tree_after_verification(p->down);
    if (worth_logging)
        LOGIF(VERIFICATIONS, "[Initial parse tree has %d nodes, width %d and depth %d.]\n",
            tree_stats_size, tree_stats_width, tree_stats_depth);
}
```

The function verify_integrity_of_subtree is called from 4/ofs.

§**4.** To check that we never visit the same node twice (which would indicate a loop), we will mark each visited node with an imaginary cross: that way, if we visit one with a cross on it, we know this isn't a tree. We can't afford the storage to allocate an annotation for this, so the imaginary cross is actually that the node type has been increased by the following amount.

```
define OUTRAGEOUSLY_LARGE_NODE_TYPE 10000
define MARKED_WITH_CROSS(t)
    ((t >= OUTRAGEOUSLY_LARGE_NODE_TYPE + 1) &&
        (t < OUTRAGEOUSLY_LARGE_NODE_TYPE + HIGHEST_NODE_TYPE))
```

§**5.** After verification, of course, we need to erase all these crosses:

```
void tidy_tree_after_verification(parse_node *p) {
    for (; p; p = p->next) {
        int t = pn_get_node_type(p);
        if (MARKED_WITH_CROSS(t))
            pn_set_node_type(p, t - OUTRAGEOUSLY_LARGE_NODE_TYPE);
        if (p->down) tidy_tree_after_verification(p->down);
    }
}
```

§**6.** The verification traverse is a very cautious manoeuvre: we step through the tree, testing each branch with our outstretched foot in case it might be illusory or broken. At the first sign of trouble we panic.

```
void verify_tree_integrity_recursively(parse_node *p, parse_node *from, char *way,
    int depth) {
    int t, width;
    pointer_sized_int probably_an_address = (pointer_sized_int) p;
    depth++; if (depth > tree_stats_depth) tree_stats_depth = depth;
    for (width = 0; p; p = p->next, width++) {
        if ((probably_an_address == 0) || (probably_an_address == -1)) {
            LOG("Link %s broken from:\n$P", way, from);
            internal_error_tree_unsafe("Link broken in parse tree");
        }
        t = pn_get_node_type(p);
        if (MARKED_WITH_CROSS(t)) {
            LOG("Cycle found in parse tree, found %s from:\n$P", way, from);
            internal_error_tree_unsafe("Cycle found in parse tree");
        }
        if ((t >= 1) && (t < HIGHEST_NODE_TYPE)) {
            pn_set_node_type(p, t + OUTRAGEOUSLY_LARGE_NODE_TYPE);
            tree_stats_size++;
        } else {
            LOG("Invalid node type (%d) found %s from:\n$P", t, from);
            internal_error_tree_unsafe("Link broken in parse tree");
        }
        if (p->down) verify_tree_integrity_recursively(p->down, p, "down", depth);
    }
    if (width > tree_stats_width) tree_stats_width = width;
}
```

§**7. The initial parse tree invariant.** We protect ourselves by first checking that the tree is intact as a structure: once we know the tree is safe to climb over, we can wander about counting children with impunity. If there are multiple failures, we itemise them to the debugging log, and only produce a single internal error at the end.

```
int node_errors = 0;
void verify_parse_tree(void) {
    LOGIF(VERIFICATIONS, "[Verifying initial parse tree]\n");
    if (tree_root == NULL) internal_error_tree_unsafe("Root of parse tree NULL");
    if (tree_root->down) verify_integrity_of_subtree(tree_root, TRUE);
    node_errors = 0;
    verify_initial_parse_tree_invariant(tree_root, NULL, 1);
    if (node_errors > 0) {
        LOG("[Verification failed: %d node errors]\n", node_errors);
        internal_error_tree_unsafe("The initial parse tree is broken");
    }
    LOGIF(VERIFICATIONS, "[Initial parse tree correct.]\n");
}
```

The function verify_parse_tree is invoked by a command in a `.i6t` template file.

§**8.** Note that on every call to the following routine, (i) `p` is a valid parse node; (ii) either `p` is the tree root, in which case `parent` is `NULL`, or `parent` is the unique node having `p` among its children; and (iii) `current_weight` is the absolute value of $w_{\rm parent}$.

```
void verify_initial_parse_tree_invariant(parse_node *p, parse_node *parent, int current_weight) {
    parse_node *q;
    int t = pn_get_node_type(p), children_count = 0;
    int weight_here = parse_tree_node_types[t].node_weight;
    ⟨Check rule (1) of the initial parse tree invariant 9⟩;
    ⟨Check rule (2) of the initial parse tree invariant 10⟩;
    ⟨Check rule (3) of the initial parse tree invariant 11⟩;
    if (weight_here < 0) weight_here = -weight_here;
    for (q=p->down; q; q=q->next, children_count++)
        verify_initial_parse_tree_invariant(q, p, weight_here);
    ⟨Check rule (4) of the initial parse tree invariant 12⟩;
}
```

§**9.** Rule (1): $w_{\rm node} \neq 0$.

⟨Check rule (1) of the initial parse tree invariant 9⟩ ≡

```
    if (weight_here == 0) {
        LOG("N%d is %s, which is not allowed in initial tree\n",
            p->allocation_id, parse_tree_node_types[t].node_type_name);
        LOG("$P", p);
        node_errors++;
    }
```

This code is used in §8.

§**10.** Rule (2): If $w_{\text{node}} > 0$ then, except at the root, we must have $w_{\text{node}} \geq \text{abs}(w_{\text{parent}})$.

⟨Check rule (2) of the initial parse tree invariant 10⟩ ≡

```
if ((parent) && (weight_here > 0) && (weight_here < current_weight)) {
    LOG("N%d is %s (weight %d): should not be a child of %s (weight %d)\n",
        p->allocation_id,
        parse_tree_node_types[t].node_type_name,
        parse_tree_node_types[t].node_weight,
        parse_tree_node_types[pn_get_node_type(parent)].node_type_name,
        current_weight);
    node_errors++;
    if (parent == tree_root) LOG("$P", p); else LOG("$P", parent);
}
```

This code is used in §8.

§**11.** Rule (3): If $t_{\text{parent}} \neq -1$ then this must be the node type of the parent.

⟨Check rule (3) of the initial parse tree invariant 11⟩ ≡

```
if (parent) {
    int t_parent = parse_tree_node_types[t].required_parent_node_type;
    if ((t_parent != -1) && (t_parent != pn_get_node_type(parent))) {
        LOG("N%d is a %s with parent %s not %s\n",
            p->allocation_id,
            parse_tree_node_types[t].node_type_name,
            parse_tree_node_types[pn_get_node_type(parent)].node_type_name,
            parse_tree_node_types[t_parent].node_type_name);
        if (parent == tree_root) LOG("$P", p); else LOG("$P", parent);
        node_errors++;
    }
}
```

This code is used in §8.

§**12.** Rule (4): The number of children c satisfies $c_{\min} \leq c \leq c_{\max}$.

⟨Check rule (4) of the initial parse tree invariant 12⟩ ≡

```
if (children_count < parse_tree_node_types[t].min_children) {
    LOG("N%d has %d children, but min for %s is %d:\n",
        p->allocation_id,
        children_count, parse_tree_node_types[t].node_type_name,
        parse_tree_node_types[t].min_children);
    log_subtree(p, 1);
    node_errors++;
}
if (children_count > parse_tree_node_types[t].max_children) {
    LOG("N%d has %d children, but max for %s is %d:\n",
        p->allocation_id,
        children_count, parse_tree_node_types[t].node_type_name,
        parse_tree_node_types[t].max_children);
    log_subtree(p, 1);
    node_errors++;
}
```

This code is used in §8.

§**13. The assertion-maker's invariant.** Hmm: *The Assertion-Maker's Invariant* might make a good magic-realism novel, in which an enigmatic wise man of Samarkand builds an ingenious box from camphorwood in which he traps the dreams of the people, who – However. When assertions are processed in Chapter 8, the subtrees being compared will be required to be such that their head nodes each pass this test:

```
int pnt_allow_in_assertions(parse_node *subtree) {
    int t;
    verify_integrity_of_subtree(subtree, FALSE);
    t = pn_get_node_type(subtree);
    if (parse_tree_node_types[t].allow_in_assertions) return TRUE;
    return FALSE;
}
```

The function pnt_allow_in_assertions is called from 8/mass.

§**14.** And that concludes the tree checking, and with it, the narrative story told throughout Chapters 2 and 3 which take us from the start of NI's run through to the final output of the *A*-grammar parser.

5 Meanings

`5/its`: *Introduction to Semantics.w* A general introduction to the S-parser and the data structures it makes use of.

`5/det`: *Determiners and Quantifiers.w* To create the determiners found in standard English which refer to collections of things, and to create their meanings as logical quantifiers.

`5/bp`: *Binary Predicates.w* To create and manage binary predicates, which are the underlying data structures beneath Inform's relations.

`5/rel`: *Relations.w* What Inform internally calls "binary predicates", the user calls "relations". In this section, we parse definitions of new relations and create the resulting `binary_predicate` objects.

`5/conj`: *Conjugation of Verbs.w* To define verbal and prepositional forms for relations, in different tenses and numbers.

`5/aph`: *Adjectives.w* To identify the names of all adjectives used in source text, and to organise the multiple different senses each adjective might have.

`5/litp`: *Literal Patterns.w* To manage the possible notations with which literal values can be written.

`5/em`: *Excerpt Meanings.w* To register and deregister meanings for excerpts of text as nouns, adjectives, imperative phrases and other usages.

`5/unitr`: *Unicode Translations.w* To manage the names assigned to Unicode character values.

`5/ml`: *Meaning Lists.w* To build meaning lists, which despite the name are really tree structures, showing possible interpretations of a sequence of words.

`5/arch`: *Architecture of the S-Parser.w* To describe how the S-parser is organised, and to define a kit of C macros for writing its routines.

`5/parse`: *Parse Excerpts.w* Given an excerpt `(w1,w2)`, to construct a meaning list of all registered excerpt meanings which it matches.

`5/lit`: *Parse Literals.w* To decide if the text in `(w1,w2)` is a value referred to notationally rather than by name.

`5/candd`: *Constants and Descriptions.w* To parse noun phrases in constant contexts, which specify values either explicitly or by describing them more or less vaguely.

`5/tandv`: *Type Expressions and Values.w* To parse two forms of noun: a noun phrase in a sentence, and a description of what text can be written in a given situation.

`5/varc`: *Verbal and Relative Clauses.w* To break down an excerpt into NP and VP-like clauses, perhaps with a primary verb (to make a sentence), perhaps only a relative clause (to make a more complex NP).

`5/candp`: *Conditions and Phrases.w* To parse the text of To... phrases, say phrases and conditions.

`5/mlc`: *Meaning List Conversions.w* To convert meaning lists into specifications, for the use of the rest of NI.

Introduction to Semantics 5/its

Purpose

A general introduction to the S-parser and the data structures it makes use of.

---

§**1.** At this point, the text read in by NI is now a stream of words, each of which is identified by a pointer to a `vocabulary_entry` structure in its dictionary. The words are numbered upwards from 0, and we refer to any contiguous run of words as an "excerpt", often writing `(w1, w2)` to mean the text starting with word `w1` and continuing to word `w2`. The stream of words has been divided further into sentences.

Inform has two mechanisms for making sense of this text, the A-parser and the S-parser.

(A) A stands for "assertion". For instance, "Two men are in Verona." is an assertion, telling Inform that at the start of play there are to be two previously unknown men and that they begin in the room called Verona. The A-parser handles entire sentences.

(S) S stands for "semantics", the study of how already-understood meanings correspond to excerpts of text within a sentence. The S-parser handles anything from tiny excerpts like "6" through noun phrases such as "Verona" to complicated expressions like "the number of men in Verona".

There are many similarities between the A-parser and the S-parser, partly because A makes use of S, but also because they contain parallel mechanisms which handle verbs and prepositions similarly. But there are also many differences. The A-parser will accept "On the dressing table is an amber comb." even if table and comb have never been mentioned before, whereas the S-parser can only recognise meanings already defined. On the other hand, the S-parser will accept conditions like the one in "if there are fewer than 8 men in Verona, ..." whereas the A-parser would reject the assertion "There are fewer than 8 men in Verona." as being too vague to act upon. Similarly, the A-parser works only in the present tense, whereas the S-parser can handle the past and perfect tenses. (Neither can handle any future tenses, since a computer cannot either control or definitely predict the future.)

The A-parser works by applying the S-parser to text at `parse_node` structures in the parse tree. So we will build the S-parser first, which will take up Chapters 5, 6 and 7, and won't involve the parse tree at all. We will then go back to the parse tree in Chapter 8 to write the A-parser.

§**2.** The S-parser is similar to the expression parser in a regular compiler. It is in some ways simpler because natural language tends not to form complex formulae, but in other ways more complicated, because performance issues are very significant when comparing excerpts of text, and because there are many more ambiguities to resolve.

Our aim is to turn any excerpt into a `specification` structure inside Inform. This is a universal holder for both values and descriptions of values, where "value" is interpreted very broadly. It is usually too difficult to go directly from text to a `specification`, so we use a two-stage process:

(1) parse the text to a `meaning_list` which holds all possible interpretations of it, and then
(2) convert the most likely-looking interpretation(s) to a `specification`.

Thus `meaning_list` structures are private to the S-parser, and are never seen outside Chapters 5 and 6, whereas `specification` structures appear all over Inform.

Chapter 5 divides into two halves. The first half deals with how we store details of verbs, prepositions, relations, determiners and other natural language gadgets; this provides a common English grammar which will be used both by the S-grammar and the A-grammar. The second half of Chapter 5 contains the code to turn excerpts into meaning lists, and to convert the easier cases into specifications. Chapter 6 handles predicate calculus, the form of mathematical logic used by Inform to represent the meaning of complicated sentences: and this performs the remaining difficult cases of meaning list conversion. Chapter 7 then contains all of Inform's general code for handling specifications. Chapters 6 and 7 both also provide services to the rest of Inform to help make use of the `specification` and `pcalc_prop` structures which the S-parser generates.

§**3.** Consider the following contrived example.

if Mr Fitzwilliam Darcy was carrying at least three things which are in the box, increase the score by 7;

(1) There are `excerpt_meaning` structures for "Mr Fitzwilliam Darcy" and "Mr Bingham's box", which hold the wording needed to refer to these objects. In parsing the example sentence, we connect these structures to the excerpts "Mr Fitzwilliam Darcy" – an exact match – and "the box" – an abbreviated one. The `excerpt_meaning` structures contain pointers to further `world_object` structures which represent the identities of these two tangible things, that is, Darcy and his friend's box.

(2) Another `excerpt_meaning` holds the name "score" and points it to a `quantity` structure for the relevant global variable.

(3) And a further `excerpt_meaning` holds the name "things" and points it to a `world_object` structure representing the common identity shared by all things. Inform treats individual, tangible objects such as Mr Darcy and intangible categories of objects such as thing by representing both with the same structure – `world_object`. This mirrors the way that common and proper nouns are grammatically quite similar in natural language.

(4) The final noun phrase in the above example is "7". There's no `excerpt_meaning` structure for this – it would be insanely inefficient to make such things – and instead it is parsed directly as a "literal", being converted immediately into a `specification`, of which more below.

(5) Another `excerpt_meaning` structure holds the wording "if ... , ..." and is connected to a `phrase` structure for the "if" construction. Here, the wording includes flexible-sized gaps (written "...") where excerpts should appear: the S-parser will only recognise this if the excerpts make sense in themselves. The combination of a `phrase` plus the results of parsing these gaps is stored in a structure called an `invocation`.

(6) In the example, the first gap is filled by "Mr Fitzwilliam Darcy was carrying at least three things which are in the box", which the S-parser detects as being a condition. This is translated into a `pcalc_prop` structure – a predicate-calculus proposition, that is, which is a representation in mathematical logic of the meaning of this sentence.

  (a) "was carrying" is recognised as matching wording in a `verb_usage` structure. This points to an underlying relation, stored in a `binary_predicate` structure, but combines it with an indication of tense stored in a `time_period`. Here the `binary_predicate` is the carrying relation and the `time_period` is the past tense. (The term "binary predicate" comes from logic once again; an Inform author would call the same concept a "relation".)

  (b) "are in" is recognised as a usage of the verb *to be* plus "in", which matches the wording of a `preposition_usage` structure. Here the tense derives only from the *to be* part: which is "are", so the `time_period` parsed is the present tense. This makes the `preposition_usage` a simpler business than the `verb_usage` structure – it only needs to refer to the underlying meaning, which is once again a `binary_predicate` structure, the one for the containment relation.

  (c) "which" is a word introducing a relative clause. A sentence can only have one primary verb, which in this example is "was carrying". But other verbs can exist in relative clauses, and the effect of writing "X which V Y" qualifies X by saying that any noun N matching X must also satisfy "N V Y", where V is the verb. The relative-clause construction is an example of syntax built directly into the S-parser. It doesn't come from any data structures, like the meanings of "score" or "Mr Fitzwilliam Darcy".

  (d) "at least three things" is an example of a noun phrase which has a head and a tail. The head, "at least three", is recognised as matching the wording in a `determiner` structure, "at least *number*", together with the literal number 3. Once again, the `determiner` describes textual appearances; it points to another structure, a `quantifier`, to hold the meaning. This is another logical term, and Inform's debugging log would write the resulting term as `Card>=3` ("cardinality of at least 3"). Inform only uses `determiner` structures when they quantify, that is, when they talk about a possible range of objects rather than a single item. A grammar of English would probably say that the "the" in "the box" is also grammatically a determiner, but it doesn't get a `determiner` structure in Inform.

(7) The second gap in the "if ... , ..." excerpt is "increase the score by 1", which the S-parser detects as a use of yet another `phrase`, this time referred to by the `excerpt_meaning` structure for "increase ... by ...". It's worth noting that the S-parser doesn't check types, so it would have been happy to match

"increase 2 by 1" – an impossibility. The S-parser's job is to find all possible meanings at a textual level, sometimes producing a list of options: the type-checker will winnow these out later on.

So parsing the text "if Mr Fitzwilliam Darcy was carrying at least three things which are in the box, increase the score by 7" is going to result in a mass of pointers to different structures, and we need an umbrella structure to hold this mass together. This is what the `meaning_list` is for, but as explained above, it's really only an intermediate state used while the S-parser is working.

§**4.** One obvious category of word is missing: there are no adjectives in this example. Inform currently supports many sorts of adjective – either/or properties, such as "open"; values of kinds of value which coincide with properties, such as "green" as a value of a "colour"; and adjectives defined with conditions or full phrases, such as "invisible" resulting from "Definition: a thing is invisible if...".

The S-parser treats all adjectives alike – more or less just as names. This is because "open" may mean one thing for containers and another for scenes, for example. The identification of an adjective's name with its set of possible meanings is via a structure called `adjectival_phrase`.

§**5.** To sum up. If we write "text" → structure used for parsing → structure used to hold meaning, our example is parsed like so:

(1) "Mr Fitzwilliam Darcy" → `excerpt_meaning` → `world_object`

(2) "the score" → `excerpt_meaning` → `quantity`

(3) "things" → `excerpt_meaning` → `world_object`

(4) "7" → ...none... → `specification`

(5) "if Mr Fitzwilliam Darcy was carrying at least three things which are in the box, increase the score by 7" → `excerpt_meaning` → `invocation` (incorporating a `phrase`)

(6) "Mr Fitzwilliam Darcy was carrying at least three things which are in the box" → ...many... → `pcalc_prop`
   (a) "was carrying" → `verb_usage` → `binary_predicate` plus `time_period`
   (b) "are in" → `preposition_usage` → `binary_predicate` plus `time_period`
   (c) "at least three" → `determiner` → `quantifier` plus literal number

(7) "increase the score by 7" → `excerpt_meaning` → `invocation` (incorporating a `phrase`)

(8) Adjectives like the "closed" in "three closed doors" are identified by name only, with little attempt to detect which sense is meant, so they pass straight through the S-parser as pointers to `adjectival_phrase` structures.

§**6.** To sum up further still, `excerpt_meaning` structures are used to parse simple nouns and imperative phrases, whereas other specialist structures (`preposition_usage`, `determiner`, etc.) are used to parse the hinges which hold sentences together. Once parsed, individual excerpts tend to have meanings which might be pointers to a bewildering range of structures (`world_object`, `quantifier`, `binary_predicate`, `adjectival_phrase`, etc.) but these pointers are held together inside the S-parser by a single unifying construction: the `meaning_list`. And we will eventually turn the whole thing into a `specification` for the rest of Inform to use.

Determiners and Quantifiers 5/det

Purpose

To create the determiners found in standard English which refer to collections of things, and to create their meanings as logical quantifiers.

5/det.§1-3 Creating a quantifier; §4-6 Acting on quantifiers; §7 Creating a determiner; §8-9 Parsing the determiner at the head of a noun phrase; §10-15 The built-in set

Template interpreter commands

```
10   {-callv:make_built_in_determiners}
```

Definitions

¶1. In logic, a "quantifier" appears at the front of a statement which can apply to many cases, and describes the quantity of cases for which the statement is true: all of them, some of them, exactly six, and so on.

When a quantifier is used, it "ranges over a domain". The domain is the set of cases. For instance, in:

> if most of the doors are open, ...

the "most of" text is parsed into a quantifier written in the debugging log as `Proportion>50%`, and the domain is the set of all doors. We then test the inner condition ("open") for the objects in the domain.

Some quantifiers apply to a proportion of the domain, and the proportion is measured with a number we will call the T-coefficient, which is measured in tenths. Thus a quantifier talking about the entire domain ("all of the doors are open") will have $T = 10$, while the "most of" example above has $T = 5$. Other quantifiers apply to an exact number, a "cardinality" in logic jargon, rather than a proportion: for instance, "three doors are open". These quantifiers have $T = -1$.

Finally, a few quantifiers apply not to the cases in the domain which passed, but to those which didn't, and those are called "complementary" (because they describe the complement of the domain set). For instance, "all but six doors are open", where the "six" describes the number of closed doors and not the number of open ones.

¶2. These different ways to describe multiple outcomes are represented in Inform by `quantifier` structures. One exists for each different meaning supported by Inform – `ForAll`, `Exists` and so forth – except that some quantifiers take a numerical parameter, and a single `quantifier` structure represents the meaning for any value of this parameter. For instance, the cardinality quantifiers `Card=3` and `Card=17` are both represented by the same quantifier structure, whose pointer is called `exactly_quantifier` below. This is the result of parsing *exactly three* doors or *exactly 17* containers, for instance, where the parameter is 3 or 17 respectively.

```
typedef struct quantifier {
    char *operator;                          I6 operator to compare successes against the threshold
    int T_coefficient;                                                          see above
    int is_complementary;                    tests the complement of the set, not the set of matches
    int can_be_used_in_now;                                  can be asserted true or false using "now"
    int can_be_used_in_assertions;                                  can be used in assertion sentences
    struct quantifier *negated_quant;                                the logically converse determiner
    char *log_text;                          to be used in the debugging log when logging propositions
    MEMORY_MANAGEMENT
} quantifier;
```

The structure quantifier is private to this section.

¶3. The built-in set of 16 quantifiers, arranged in eight pairs, is as follows:

```
quantifier
    *for_all_quantifier = NULL,    *not_for_all_quantifier = NULL,
    *exists_quantifier = NULL,     *not_exists_quantifier = NULL,
    *all_but_quantifier = NULL,    *not_all_but_quantifier = NULL,
    *almost_all_quantifier = NULL, *almost_no_quantifier = NULL,
    *most_quantifier = NULL,       *under_half_quantifier = NULL,
    *at_least_quantifier = NULL,   *more_than_quantifier = NULL,
    *at_most_quantifier = NULL,    *less_than_quantifier = NULL,
    *exactly_quantifier = NULL,    *other_than_quantifier = NULL;
```

¶4. Whereas "quantifier" is a term from mathematical logic, "determiner" is a term from linguistics which approximately – but only approximately – means the same thing.

The determiner is the part of a noun phrase, always its head, which gives counting information to be combined with a common noun. Thus *the* clock, *seven* seals, *almost all of the* open doors, and so on. When a determiner appears to refer to a range of objects rather than a single item, NI translates it into a quantifier. Thus *the* clock is not parsed into a quantifier, but *all but three* rooms is.

The same quantifier can have several different verbal forms. For instance, *each* container and *every* container mean the same thing: both apply the `ForAll` quantifier to containers. These different verbal forms are stored in the `determiner` structure, and each one points to the `quantifier` structure which is its meaning.

```
typedef struct determiner {
    int allows_prefixed_not;                          can the word "not" come before this?
    struct vocabulary_entry *det_word1;               or null (e.g. for a bare number "N")
    struct vocabulary_entry *det_word2;                                              or null
    int takes_number;                                 does a number follow? (e.g. for "at least N"
    struct quantifier *quantifier_meant;                                  meaning of this quantifier
    char *index_text;                                 used in the Phrasebook index lexicon
    MEMORY_MANAGEMENT
} determiner;
```

The structure determiner is private to this section.

---

§**1. Creating a quantifier.** At present, there's only the built-in set, and no method exists to create new quantifiers from the source text or the template files, but what follows is written so that it would be fairly easy to add this ability.

```
quantifier *quant_new(char *op, int T, int is_comp, char *text) {
    quantifier *quant = CREATE(quantifier);
    quant->operator = op;
    quant->T_coefficient = T; quant->is_complementary = is_comp;
    quant->can_be_used_in_now = FALSE;
    quant->can_be_used_in_assertions = FALSE;
    quant->negated_quant = NULL;
    quant->log_text = text;
    return quant;
}
```

§**2.** That fills out the whole structure except for the negation pointers, and to ensure that these always occur in matched pairs, these are set here.

A little explanation may be useful about what we mean by negation. In traditional logic, the basic quantifiers "for all" and "there exists" are dual to each other in that they are related by a sort of negation: "there does not exist an open door" means the same as "all doors are closed", and so on. Thus

`Not ( ForAll x: P(x) )` is equivalent to `Exists x: Not(P(x))`

That isn't what we mean here. If Q and NQ are a quantifier and its negation in our sense, then:

`Not ( Q x: P(x) )` is equivalent to `NQ x: P(x)`

Why do we do this? There are several reasons. First, we are using a richer set of quantifiers than traditional logic provides, and most of these have natural negations which we were going to be creating anyway – so we may as well exploit that. Second, we are going to try to represent propositions using as much conjunction ("and") and as little disjunction ("or") as possible. Consider what effect de Morgan's laws have if we simplify:

```
Not ( ForAll x: closed(x) and locked(x) and lockable(x) )
```

in the traditional way: we obtain

```
Exists x: Not(closed(x)) or Not(locked(x)) or Not(lockable(x))
```

which introduces disjunction ("or") in just the way we don't want. By simply regarding `NotAll` as a quantifier in its own right, we obtain something much easier to handle:

```
NotAll x: closed(x) and locked(x) and lockable(x)
```

This is why we will be creating quantifiers `NotAll` and `DoesNotExist` – the negations of `ForAll` and `ThereExists` – even though they might seem puzzlingly redundant from a traditional logic point of view.

```
void quants_negate_each_other(quantifier *qx, quantifier *qy) {
    qx->negated_quant = qy; qy->negated_quant = qx;
}
quantifier *quant_get_negation(quantifier *quant) {
    return quant->negated_quant;
}
```

The function quant_get_negation is called from 6/simp.

§**3.** Logging a quantifier:

```
void log_quantifier(quantifier *quant, int parameter) {
    if (quant == NULL) { LOG("<NULL-QUANTIFIER>"); return; }
    LOG(quant->log_text, parameter);
}
```

The function log_quantifier is called from 5/ml and 6/aprop.

§**4. Acting on quantifiers.** When compiling code to test a proposition which includes a quantifier, we need to test the cases in the domain set to see how many of them qualify and how many do not. These counts are stored in local variables called `qcy_0`, `qcn_0` and so on: `qcn` means "quantifier count number" and is the size of the domain set, while `qcy` is the number of "yes" cases. Thus if the original source text read:

> if most of the closed doors are locked, ...

`qcy_0` will be the number of closed doors which turned out to be locked and `qcn_0` the total number of closed doors. (The indices `_0`, `_1`, ..., are used because the same routine may have to compile code to test several quantifiers.)

The following routine compiles an I6 condition to test whether the tallies are acceptable for the given quantifier. In the example above, the quantifier is `Proportion>50%`, and compiles to the test:

```
qcy_0 > 5*qcn_0/10
```

(It looks a little wasteful to multiply by 5 and then divide by 10, but I6 will fold that out in eventual code generation. When the proportion is 0/10ths or 10/10ths, though, we do generate simpler code, mostly so that the resulting I6 is more legible.)

```
void quant_compile_test(OUTPUT_STREAM, quantifier *quant, int index,
    int quantification_parameter) {
    int TC = quant->T_coefficient;
    switch (TC) {
        case -1:
            if (quant->is_complementary)
                WRITE("qcy_%d %s qcn_%d-%d",
                    index, quant->operator, index, quantification_parameter);
            else
                WRITE("qcy_%d %s %d",
                    index, quant->operator, quantification_parameter);
            break;
        case 10:
            WRITE("qcy_%d %s qcn_%d", index, quant->operator, index);
            break;
        case 0:
            WRITE("qcy_%d %s 0", index, quant->operator);
            break;
        default:
            WRITE("qcy_%d %s %d*qcn_%d/10", index, quant->operator, TC, index);
            break;
    }
}
```

The function quant_compile_test is called from 6/cdefp.

§**5.** "Now" is the Inform way to assert that a proposition should now be made true. Many quantifiers obstruct this, by introducing too much vagueness. For instance, "now three doors are open" is dangerously vague because it doesn't say which doors are to be made open; similarly "now most of the coins are in the box". On the other hand, "now all the coins are in the box" is fine, because there's no ambiguity. The `can_be_used_in_now` flag for a quantifier shows whether it can be asserted in "now" like this.

```
int quant_is_now_assertable(quantifier *quant) {
    return quant->can_be_used_in_now;
}
```

The function quant_is_now_assertable is called from 6/aprop.

§**6.** Not every proposition can be used in assertion sentences, either, and again it's the quantifiers which cause the trouble. For instance, "Not every room is dark." gives Inform too little to act on. Which room(s) should it make lighted?

```
int quant_can_be_used_in_assertions(quantifier *quant) {
    return quant->can_be_used_in_assertions;
}
```

The function quant_can_be_used_in_assertions is called from 8/refpt.

§**7. Creating a determiner.** Again, at present there's only the built-in set, but we want to keep our options open.

```
determiner *det_new(int not, vocabulary_entry *ve1, vocabulary_entry *ve2,
    int num, quantifier *quant, char *text) {
    determiner *det = CREATE(determiner);
    det->det_word1 = ve1; det->det_word2 = ve2;
    det->takes_number = num;
    det->allows_prefixed_not = not;
    det->quantifier_meant = quant;
    if (quant == NULL) internal_error("created meaningless quantifier");
    det->index_text = text;
    if (text)
        lexicon_new_entry_with_details(
            -1, -1, MISCELLANEOUS_LEXE, ve1, ve2, "determiner", text);
    return det;
}
```

§**8. Parsing the determiner at the head of a noun phrase.** We run through the possible determiners in creation order, choosing the first which matches. The following returns -1 if nothing was found, or else the first word number after the determiner words, and in that case it also writes a pointer to the quantifier meant to `*which_quant` and the parameter value to `*which_P`.

```
int quant_parse_against_text(int w1, int w2, int *which_P, quantifier **which_quant) {
    determiner *det;
    int not_flag = FALSE;
    if [[w1, w2 == not ... --> w1, w2]] not_flag = TRUE;
    *which_P = -1; *which_quant = NULL;
    LOOP_OVER(det, determiner) {
        int x1;
        if ((not_flag) && (det->allows_prefixed_not == FALSE)) continue;
        x1 = det_parse_against_text(w1, w2, det, which_P);
        if (x1 < 0) continue;
        if (not_flag) *which_quant = det->quantifier_meant->negated_quant;
        else *which_quant = det->quantifier_meant;
        [[x1, w2 == the ... --> x1, w2]];
        return x1;
    }
    return -1;
}
```

The function quant_parse_against_text is called from 5/candd.

§**9.** We attempt to see if the word range begins with (or consists of) text which refers to the given determiner, returning the first word past this text and also (where appropriate) setting the number specified. For instance, for "at least three doors are open" and the `at_least_determiner` we would return the word "doors" and set `which_P` to 3.

Note that "of", if used, must be followed by "the". Thus "three of the doors are open" will work, but "three of doors are open" will not. This reduces misunderstandings when objects have names like "three of clubs", meaning a single playing card.

```
int det_parse_against_text(int x1, int w2, determiner *det, int *which_P) {
    int parameter = -1;
    if (x1 < 0) return -1;
    if (det->det_word1) {
        if (compare_word(x1++, det->det_word1) == FALSE) return -1;
        if (x1 > w2) return -1;
    }
    if (det->det_word2) {
        if (compare_word(x1++, det->det_word2) == FALSE) return -1;
        if (x1 > w2) return -1;
    }
    if (det->takes_number) {
        if ((is_a_cardinal(x1, x1) == FALSE) || (unexpectedly_upper_case(x1))) return -1;
        x1++;
        if (x1 > w2) return -1;
        parameter = last_literal_evaluated;
    }
    if [[x1, w2 == of ...]] {
        if (compare_word(x1+1, the_V)) x1++;
        else return -1;
    }
    *which_P = parameter;
    return x1;
}
```

§**10. The built-in set.** We now construct both the tidy logical world of 16 quantifiers in matched pairs, and also a higgledy-piggledy world of 20 English-language determiners referring to them. There are four broad families which we take in turn.

```
void make_built_in_determiners(void) {
    ⟨Make traditional quantification determiners 11⟩;
    ⟨Make complement comparison determiners 12⟩;
    ⟨Make proportion determiners 13⟩;
    ⟨Make cardinality quantification determiners 14⟩;
}
```

The function make_built_in_determiners is invoked by a command in a `.i6t` template file.

§11. As discussed above, the two traditional quantifiers in logic are "for all" and "there exists", usually written in mathematical notation as ∀ and ∃, but we also need to create their negation quantifiers. So we end up with four: `ForAll`, `NotAll`, `Exists` and `DoesNotExist`.

The for-all quantifier can be used in assertions for a slightly oddball reason: it's how the source text makes assemblies. For instance,

> A nose is part of every person.

The "every" is parsed as a use of `ForAll`. Strictly speaking this sentence should be read as creating a single nose which would be shared by all of the people. But the presence of a `ForAll` quantifier in an assertion causes the A-parser to interpret the sentence differently, and to create a fresh nose for each person. (There are some restrictions on the use of `ForAll` in this way, but they are enforced in the A-parser: our part here is simply to authorise `ForAll` in assertions.)

Something which English allows, but Inform does not, is the use of "all" in a way which also specifies a cardinality. For instance, the following condition:

> if all six doors are open, ...

is an attempt to use a determiner which Inform does not possess – "all" plus number. We don't allow this because if there happen to be eight doors, say, the condition would be meaningless.

It's an example of the irregularity of English that you can say "not every door is open" but would never say "not each door is open". In all other respects "each" and "every" are synonymous in the S-parser.

⟨Make traditional quantification determiners 11⟩ ≡

```
for_all_quantifier     = quant_new("==", 10, FALSE, "ForAll");
not_for_all_quantifier = quant_new("<", 10, FALSE, "NotAll");
exists_quantifier      = quant_new(">", 0, FALSE, "Exists");
not_exists_quantifier  = quant_new("==", 0, FALSE, "DoesNotExist");

for_all_quantifier->can_be_used_in_now = TRUE;
for_all_quantifier->can_be_used_in_assertions = TRUE;
not_exists_quantifier->can_be_used_in_now = TRUE;

quants_negate_each_other(for_all_quantifier, not_for_all_quantifier);
quants_negate_each_other(exists_quantifier, not_exists_quantifier);

det_new(TRUE, all_V, NULL, FALSE, for_all_quantifier,
    "used in conditions: 'if all of the doors are open'");
det_new(FALSE, each_V, NULL, FALSE, for_all_quantifier,
    "- see </i>all<i>");
det_new(TRUE, every_V, NULL, FALSE, for_all_quantifier,
    "- see </i>all<i>, and can also be used in generalisations such as "
    "'A nose is part of every person.'");
det_new(FALSE, no_V, NULL, FALSE, not_exists_quantifier,
    "opposite of 'all': 'if no door is open...'");
det_new(FALSE, none_V, NULL, FALSE, not_exists_quantifier,
    "opposite of 'all of': 'if none of the doors is open...'");
det_new(FALSE, some_V, NULL, FALSE, exists_quantifier, NULL);
```

This code is used in §10.

§**12.** Here $T = -1$, because we are counting actual numbers of matches rather than a proportion of matches. But these quantifiers count downwards from the total: thus "all but six" means there have to be exactly $S - 6$ matching items, where S is the total available. The only logical negation for this quantifier would be "other than $S - 6$", which is too unnatural a construction to have any natural English paraphrase, so we do not make a `determiner *` structure pointing to it. But we create it in order that the built-in quantifiers all occur in negation pairs.

⟨Make complement comparison determiners 12⟩ ≡

```
all_but_quantifier     = quant_new("==", -1, TRUE, "AllBut%d");
not_all_but_quantifier = quant_new("~=", -1, TRUE, "NotAllBut%d");

quants_negate_each_other(all_but_quantifier, not_all_but_quantifier);

det_new(FALSE, all_V, but_V, TRUE, all_but_quantifier,
    "used to count things: 'all but three containers'");
det_new(FALSE, all_V, except_V, TRUE, all_but_quantifier,
    "- see </i>all except<i>");
```

This code is used in §10.

§**13.** Here the T-coefficient, measuring the proportion needed, has $0 < T < 10$.

We don't support the determiner "half", as in, "if half the doors are open", because it's ambiguous as to whether it means exactly half or half-or-more.

⟨Make proportion determiners 13⟩ ≡

```
almost_all_quantifier  = quant_new(">=", 8, FALSE, "Proportion>=80%%");
almost_no_quantifier   = quant_new("<",  2, FALSE, "Proportion<20%%");
most_quantifier        = quant_new(">",  5, FALSE, "Proportion>50%%");
under_half_quantifier  = quant_new("<=", 5, FALSE, "Proportion<=50%%");

quants_negate_each_other(almost_all_quantifier, almost_no_quantifier);
quants_negate_each_other(most_quantifier, under_half_quantifier);

det_new(FALSE, almost_V, all_V, FALSE, almost_all_quantifier,
    "used in conditions: true if 80 percent or more possibilities work");
det_new(FALSE, almost_V, no_V, FALSE, almost_no_quantifier,
    "used in conditions: true if fewer than 20 percent of possibilities work");
det_new(FALSE, most_V, NULL, FALSE, most_quantifier,
    "used in conditions: true if a simple majority of possibilities work");
det_new(FALSE, under_V, half_V, FALSE, under_half_quantifier,
    "used in conditions: true if fewer than half of possibilities work");
```

This code is used in §10.

§**14.** The usefulness of cardinality quantifiers in logic as applied to linguistics seems to be an observation due to Barwise and Cooper. They are a natural generalisation of the for-all and there-exists quantifiers, and again come in matched pairs.

The bare number determiner, as in "six doors are open", is perhaps a little ambiguous in English. We read it as "at least six doors are open", in distinction to "exactly six doors are open". This is why the at-least quantifier is allowed in assertions: the assertion sentence "Four coins are in the strongbox." is read as containing the `Card>=4` quantifier, not `Card=4` one. The advantage of this is that two assertions in a row, such as

> Four coins are in the strongbox. Two coins are in the strongbox.

can combine to put six coins in the strongbox, rather than having to be read as contradictory. (It may look improbable that anyone would ever write that, but of course the two assertions need not be adjacent in the source text. One might be in an extension, for instance.)

⟨Make cardinality quantification determiners 14⟩ ≡

```
    at_least_quantifier    = quant_new(">=", -1, FALSE, "Card>=%d");
    at_most_quantifier     = quant_new("<=", -1, FALSE, "Card<=%d");
    exactly_quantifier     = quant_new("==", -1, FALSE, "Card=%d");
    less_than_quantifier   = quant_new("<",  -1, FALSE, "Card<%d");
    more_than_quantifier   = quant_new(">",  -1, FALSE, "Card>%d");
    other_than_quantifier  = quant_new("~=", -1, FALSE, "Card~=%d");

    at_least_quantifier->can_be_used_in_assertions = TRUE;

    quants_negate_each_other(at_least_quantifier, less_than_quantifier);
    quants_negate_each_other(at_most_quantifier, more_than_quantifier);
    quants_negate_each_other(exactly_quantifier, other_than_quantifier);

    det_new(FALSE, at_V, least_V, TRUE, at_least_quantifier,
        "used to count things: 'at least five doors'");
    det_new(FALSE, at_V, most_V, TRUE, at_most_quantifier,
        "- see </i>at least<i>");
    det_new(FALSE, exactly_V, NULL, TRUE, exactly_quantifier,
        "whereas 'if two doors are open' implicitly means 'if at least two "
        "doors are open', 'if exactly two...' makes the count precise");
    det_new(TRUE, fewer_V, than_V, TRUE, less_than_quantifier,
        "pedantic way to say </i>less than<i> when counting");
    det_new(TRUE, less_V, than_V, TRUE, less_than_quantifier,
        "- see </i>more than<i>");
    det_new(TRUE, more_V, than_V, TRUE, more_than_quantifier,
        "used to count things: 'more than three rooms'");
    det_new(FALSE, other_V, than_V, TRUE, other_than_quantifier, NULL);

    det_new(FALSE, NULL, NULL, TRUE, at_least_quantifier, NULL);
```

This code is used in §10.

§**15.** The following question is relevant when simplifying propositions:

```
int quant_requires_at_least_one_true_case(quantifier *quant, int parameter) {
    if (quant == exists_quantifier) return TRUE;
    if (((quant == exactly_quantifier) || (quant == at_least_quantifier)) &&
        (parameter > 0)) return TRUE;
    if ((quant == more_than_quantifier) && (parameter >= 0)) return TRUE;
    if ((quant == other_than_quantifier) && (parameter == 0)) return TRUE;
    return FALSE;
}
```

Binary Predicates 5/bp

Purpose

To create and manage binary predicates, which are the underlying data structures beneath Inform's relations.

Template interpreter commands

```
24  {-callv:make_built_in_relations}
25  {-callv:make_further_built_in_relations}
```

Definitions

¶1. A "binary predicate" (the term comes from logic) is a property B such that for any combination x and y, and at any given moment at run-time, $B(x, y)$ is either true or false.

Examples used in Inform include equality, where $EQ(x, y)$ is true if and only if $x = y$, and containment, where $C(x, y)$ is true if and only if the thing x is inside the room or container y. (EQ does not change during play, but C does.) A fairly large set of binary predicates is built into Inform, and the user is allowed to create more with sentences like

> Lock-fitting relates one thing (called the matching key) to various things.

In the Inform documentation, binary predicates are called "relations". The code to parse "relates" sentences and construct the binary predicate implied can be found in the next section, "Relations.w".

Binary predicates are of central importance because they allow complex sentences to be written which talk about more than one thing at a time, with some connection between them. In excerpts like "an animal inside something" or "a man who wears the top hat", the meanings of the two connecting pieces of text – "inside" and "who wears" – are (pointers to) binary predicates: the containment relation and the wearing relation.

Inform is rich in ways to create relations, and consequently the BPs are many and varied. They turn up in one-off examples but also in whole families. Still, despite the variation, what they share in common is greater yet, and so a single `binary_predicate` structure is used to represent them all.

¶2. The values x and y to which a binary predicate B can apply are called its "terms". For some relations, the source text gives these names:

> Lock-fitting relates one thing (called the matching key) to various things.

Here the x term has the name "matching key", whereas the y term is anonymous. (More often, both are anonymous.) Internally the terms are not named but are numbered 0 and 1: so we should really write $B(x_0, x_1)$ rather than $B(x, y)$.

¶3. Different BPs apply to different sorts of terms: for instance, the numerical less-than comparison applies to numbers, whereas containment applies to things. The two terms need not have the same domain: the "wearing" relation, as seen in

```
Harry Smythe wears the tweed waistcoat.
```

is a binary predicate $W(x_0, x_1)$ such that x_0 ranges across people and x_1 ranges across things.

Inform represents this by allowing each BP to have *either* a designated kind of object, *or* a designated kind of value, *or* no restriction at all, for each term. (In practice, even the unrestricted terms have limitations, but which are enforced by special code in the type-checker to handle special predicates such as equality. For instance, $EQ(x, y)$ can be tested for any values x and y of the same kind, so the two terms in effect constrain each other.)

In the S-parser, type-checking is used to make sure the source text doesn't try to test or assert $B(x, y)$ for any x or y which don't fit, so that

```
if 1 wears "Hello there", ...
```

will be rejected. Whereas in the A-parser, these restrictions are used to infer information about otherwise unknown quantities: so writing

```
Harry Smythe wears the tweed waistcoat.
```

causes the A-parser to force the Harry Smythe object to be of kind "person", and the tweed waistcoat of kind "thing".

¶4. Some BPs are such that $B(x, y)$ can be true for more or less any combination of x and y. Those can take a lot of storage and it is difficult to perform any reasoning about them, because knowing that $B(x, y)$ is true doesn't give you any information about $B(x, z)$. For instance, the BP created by

```
Suspicion relates various people to various people.
```

is stored at run-time in a bitmap of P^2 bits, where P is the number of people, and searching it ("if anyone suspects Harry") requires exhaustive loops, which incur some speed overhead as well.

But other BPs have special properties restricting the circumstances in which they are true, and in those cases we want to capitalise on that. "Contains" is an example of this. A single thing y can be (directly) inside only one other thing x at a time, so that if we know $C(x, y)$ and $C(w, y)$ then we can deduce that $x = w$. We write this common value as $f_0(y)$, the only possible value for term 0 given that term 1 is y. Another way to say this is that the only possible pairs making C true have the form $C(f_0(y), y)$.

And similarly for term 1. If we write T for the "on top of" relation then it turns out that there is a function f_1 such that the only cases where T is true have the form $T(x, f_1(x))$. Here $f_1(x)$ is the thing which directly supports x.

Containment has an f_0 but not an f_1 function; "on top of" has an f_1 but not an f_0. Many BPs (like "suspicion" above) have neither.

Note that if B does have an f_0 function then its reversal R has an identical f_1 function, and vice versa.

¶5. We never in fact need to calculate the value of $f_0(y)$ from y during compilation – only at run-time. So we store the function $f_0(y)$ as what is called an "I6 schema", basically a piece of I6 source code with a place-holder where y is to be inserted. In the case of containment, the schema is written

$$f_0(*1) = \texttt{ContainerOf}(*1)$$

and what this means is that we can calculate $f_0(y)$ from an object y at run-time by calling the `ContainerOf` function, which tells us what container (if any) is at present directly containing y.

¶6. To sum up, each term of a BP can specify: a name, a kind of object or a kind of value, and an f_i function. Every one of these details is optional. They are gathered together in a sub-structure called `bp_term_details`.

The `kind_when_ready` field is needed temporarily because of a timing constraint, the details of which are gone into below.

```
typedef struct bp_term_details {
    int word_ref1, word_ref2;                    "(called...)" name, if any exists
    struct world_object *implies_kind;           terms necessarily of a given kind?
    int kind_when_ready;                         temp. version of implies_kind used before kind creation
    struct kind_of_value *implies_kov;           terms necessarily of a given data type?
    struct i6_schema *function_of_other;         the function f_0 or f_1 as above
} bp_term_details;
```

The structure bp_term_details is shared with 9/vpbp and 10/libp.

¶7. Given any binary predicate B, we may wish to do some or all of the following at run-time:

(a) Test whether or not $B(x, y)$ is true at run-time. Here Inform needs to compile an I6 condition.

(b) Assert that $B(x, y)$ is true in the assertion sentences of the source text. Inform will need to remember all pairs x, y for which B has been asserted so that it can compile this information as the original state of the I6 data structure containing the current state of B.

(c) Set $B(x, y)$ true, or false, at run-time. Here Inform needs to compile I6 code which will modify that data structure.

Some BPs provide an I6 schema to achieve (a), others provide (a) and (b), while a happy few provide all of (a), (b), (c).

The variety of BPs is such that different BPs use very different run-time mechanisms. Some relations compile elaborate routines to test (a), some look at parents or chidren in the I6 object tree, some look at I6 property values, others look inside bitmaps. The actual work is often done by routines in the I6 template, which are called by code generated by the I6 schema for (a); and similarly for (b) and (c).

¶8. Each BP has a partner which we call its "reversal". If B is the original and R is its reversal, then $B(x, y)$ is true if and only if $R(y, x)$ is true. Reversals sometimes occur quite naturally in English language. "To wear" is the reversal of "to be worn by". "Contains" is the reversal of being "inside". (Though not every BP has an interesting reversal. The reversal of "is" – equality – looks much the same as the original, because $x = y$ if and only if $y = x$.)

The following sentences express the same fact:

> The ball is inside the trophy case.
>
> The trophy case contains the ball.

...but when we parse them into their meanings, we could easily lose sight that they are saying the same thing, because they involve different BPs:

> `inside(ball, trophy case)` and `contains(trophy case, ball)`

It's usually a bad idea for any computer program to represent the same conceptual idea in more than one way. So for every pair of BPs X and Y which are each other's reversal, Inform designates one as being "the right way round" and the other as being "the wrong way round". Whenever a sentence's meaning involves a BP which is "the wrong way round", Inform swaps over the terms and replaces the BP by its reversal, which is "the right way round". That makes it much easier to recognise when pairs of sentences like the one above are duplicating each other's meanings.

This is purely an internal implementation trick. There's no natural sense in language or mathematics in which "contains" is the right way round and "inside" the wrong way round.

¶9. We can finally now declare the epic BP structure.

```
typedef struct binary_predicate {
    int relation_family;                                    one of the *_KBP constants defined below
    int form_of_relation;                                   one of the Relation_* constants defined below
    struct vocabulary_entry *relation_name;                 (if any): must be one single word
    struct parse_node *bp_created_at;                       where declared in the source text
    char debugging_log_name[MAX_WORD_LENGTH+10];            used when printing propositions to the debug log
    struct bp_term_details term_details[2];                 term 0 is the left term, 1 is the right
    struct binary_predicate *reversal;                      the R such that R(x,y) iff B(y,x)
    int right_way_round;                                    was this BP created directly? or is it a reversal of another?
    how to compile code which tests or forces this BP to be true or false:
    struct i6_schema *test_function;                        I6 schema for (a) testing B(x,y)...
    int condition_defn_w1, condition_defn_w2;                ...unless this I7 condition is used instead
    struct i6_schema *make_true_function;                   I6 schema for (b) "now B(x,y)"
    struct i6_schema *make_false_function;                  I6 schema for (c) "now not(B(x,y))"
    for use in the A-parser:
    int arbitrary;                                          allow source to assert B(x,y) for any arbitrary pairs x,y
    struct property_name *set_property;                     asserting B(x,v) sets this prop. of x to v
    int property_pending_w1, property_pending_w2;           temp. version used until props created
    int set_inference;                                      unless -1, asserting B in the A-parser makes an inference of this type
    int relates_values_not_objects;                         true if either term is necessarily a value...
    struct inference *knowledge_about_bp;                   ...and if so, here's the list of known assertions
    for optimisation of run-time code:
    struct property_name *i6_storage_property;              provides run-time storage
    int allow_function_simplification;                      allow Inform to make use of any f_i functions?
    int fast_route_finding;                                 use fast rather than slow route-finding algorithm?
    char *loop_parent_optimisation_proviso;                 if not NULL, optimise loops using object tree
    char *loop_parent_optimisation_ranger;                  if not NULL, routine iterating through contents
    details, filled in for right-way-round BPs only, for particular kinds of BP:
    int a_listed_in_predicate;                              (if right way) was this generated from a table column?
    struct property_name *same_property;                    (if right way) if a "same property as..."
    struct property_name *comparative_property;             (if right way) if a comparative adjective
    int comparison_sign;                                    ...and +1 or -1 according to sign of definition
    int *equivalence_partition;                             (if right way) partition array of equivalence classes
    struct world_object *direction_object;                  (if right way) if spatial between rooms
    MEMORY_MANAGEMENT
} binary_predicate;
```

The structure binary_predicate is shared with 5/rel, 9/spabp, 9/mapbp, 9/cmpbp, 9/vpbp and 10/libp.

¶10. This seems a good point to lay out a classification of all of the BPs existing within Inform. Broadly, they divide into two: the ones explicitly created by the source text, in sentences like

Admiration relates various people to various people.

These are called "explicit". The others are "implicit" and are either created automatically soon after Inform starts up, or else are created as a consequence of something else being created by the source text, such as

Definition: A woman is tall if her height is 68 or more.

which implicitly creates a "taller than" relation. All explicit BPs are constructed in the "Relations.w" section of the source code.

define `EQUALITY_KBP 1` *there is exactly one of these: the $x = y$ predicate*
define `QUASINUMERIC_KBP 2` *the inequality comparison $\leq$, $<$ and so on*
define `SPATIAL_KBP 3` *a relation associated with a map connection*
define `MAP_CONNECTING_KBP 4` *a relation associated with a map connection*
define `PROPERTY_SETTING_KBP 5` *a relation associated with a value property*
define `PROPERTY_SAME_KBP 6` *another relation associated with a value property*
define `PROPERTY_COMPARISON_KBP 7` *another relation associated with a value property*
define `LISTED_IN_KBP 8` *a relation for indirect table lookups, one for each column name*
define `PROVISION_KBP 9` *a relation for specifying which objects provide which properties*
define `EXPLICIT_KBP 100` *defined explicitly in the source text; the others are all implicit*

¶11. The following constants are used to identify the "form" of a BP (in that the `form_of_relation` field of any BP always equals one of these and never changes). These constant names (and values) exactly match a set of constants compiled into every I6 program created by Inform, so they can be used freely both in the Inform source code and also in the I6 template layer.

define `Relation_Implicit -1` *all implicit BPs have this form, and all others are explicit*
define `Relation_OtoO 1` *one to one: "R relates one K to one K"*
define `Relation_OtoV 2` *one to various: "R relates one K to various K"*
define `Relation_VtoO 3` *various to one: "R relates various K to one K"*
define `Relation_VtoV 4` *various to various: "R relates various K to various K"*
define `Relation_Sym_OtoO 5` *symmetric one to one: "R relates one K to another"*
define `Relation_Sym_VtoV 6` *symmetric various to various: "R relates K to each other"*
define `Relation_Equiv 7` *equivalence relation: "R relates K to each other in groups"*
define `Relation_ByRoutine 8` *relation tested by a routine: "R relates K to L when (some condition)"*

¶12. That completes the catalogue of the one-off cases, and we can move on to the five families of implicit relations which correspond to other structures in the source text.

¶13. The second family of implicit relations corresponds to any property which has been given as the meaning of a verb, as in the example

The verb to weigh (it weighs, they weigh, it is weighing) implies the weight property.

This implicitly constructs a relation $W(p, w)$ where p is a thing and w a weight.

¶14. The third family corresponds to defined adjectives which perform a numerical comparison in a particular way, as here:

Definition: A woman is tall if her height is 68 or more.

This implicitly constructs a relation $T(x, y)$ which is true if and only if woman x is taller than woman y.

¶15. The fourth family corresponds to value properties, so that

A door has a number called street number.

implicitly constructs a relation $SN(d_1, d_2)$ which is true if and only if doors d_1 and d_2 have the same street number.

¶16. The fifth family corresponds to names of table columns. If any table includes a column headed "eggs per clutch" then that will implicitly construct a relation $LEPC(n, T)$ which is true if and only if the number n is listed as one of the eggs-per-clutch entries in the table T, where T has to be one of the tables which has a column of this name.

---

§**1. Creating term details.** Five, count them, five ways to set up the details of a term in a BP. The first is `bptd_blank()`, which gives Inform no information at all about what a term signifies.

```
bp_term_details bptd_blank(void) {
    bp_term_details bptd;
    bptd.word_ref1 = -1; bptd.word_ref2 = -1;
    bptd.kind_when_ready = -1;
    bptd.implies_kind = NULL; bptd.implies_kov = NULL;
    bptd.function_of_other = NULL;
    return bptd;
}
```

The function bptd_blank is called from 9/spabp, 9/mapbp, 9/provr, 9/cmpbp, 9/vpbp and 10/libp.

§**2.** `bptd_new()` is for general use once Inform's initialisation is finished:

```
bp_term_details bptd_new(world_object *k, kind_of_value *kov) {
    bp_term_details bptd = bptd_blank();
    if ((k == NULL) && (kov == NULL)) internal_error("BP term without domain");
    if ((k != NULL) && (kov != NULL)) internal_error("BP term with ambiguous domain");
    bptd.implies_kind = k; bptd.implies_kov = kov;
    return bptd;
}
```

The function bptd_new is called from 10/qnbp and 10/libp.

§**3.** And there is also a fuller version:

```
bp_term_details bptd_full_new(world_object *k, kind_of_value *kov, int c1, int c2, i6_schema *f) {
    bp_term_details bptd = bptd_new(k, kov);
    bptd.word_ref1 = c1; bptd.word_ref2 = c2;
    bptd.function_of_other = f;
    return bptd;
}
```

The function bptd_full_new is called from 5/rel.

§**4.** `bptd_early_new()` is for use early on in Inform's run. We potentially have a vicious circle, because
(a) we need fundamental kinds like "thing" and "room" in order to specify the domains for built-in relations like "containment",
(b) we need built-in relations like "containment" in order to specify the meanings of prepositional usages like "to be inside",
(c) we need to have defined usages like "to be inside" in order to break up sentences in the parse tree and identify their primary verbs and noun phrases, but
(d) we need a parse tree already in place before we can act on sentences like "A room is a kind of object." which create the fundamental kinds.

We break the deadlock at (a) by specifying the domains of the built-in relations using the following constants written into the `kind_when_ready` field. These amount to promisory notes that we will copy in pointers to the actual kinds later on, at some point after stage (d) when they exist.

```
define kind_thing_WR 1
define kind_supporter_WR 2
define kind_person_WR 3
define kind_room_WR 4
```

```
bp_term_details bptd_early_new(int kwr, i6_schema *fn) {
    bp_term_details bptd = bptd_blank();
    bptd.kind_when_ready = kwr;
    bptd.function_of_other = fn;
    return bptd;
}
```

The function bptd_early_new is called from 9/spabp.

§**5.** Lastly, a catch-all way to define a "this must be a thing" term: it works whether the kind "thing" exists yet, or not.

```
bp_term_details bptd_thing(void) {
    bp_term_details bptd = bptd_blank();
    bptd.kind_when_ready = kind_thing_WR;
    bptd.implies_kind = kind_thing;                    which might still be equal to NULL at this point
    return bptd;
}
```

The function bptd_thing is called from 9/vpbp.

§**6.** And here is where we redeem those "when ready" IOU notes. This catches everything, because the only `bp_term_details` structures in existence (well, other than as local variables in routines in this section) are the ones inside `binary_predicate` structures.

```
void write_kind_references_into_BPs(void) {
    binary_predicate *bp;
    LOOP_OVER(bp, binary_predicate) {
        int i;
        for (i=0; i<2; i++) {
            switch(bp->term_details[i].kind_when_ready) {
                case kind_thing_WR:     bp->term_details[i].implies_kind = kind_thing; break;
                case kind_supporter_WR: bp->term_details[i].implies_kind = kind_supporter; break;
                case kind_person_WR:    bp->term_details[i].implies_kind = kind_person; break;
                case kind_room_WR:      bp->term_details[i].implies_kind = kind_room; break;
            }
        }
    }
}
```

The function write_kind_references_into_BPs is called from 9/wo.

§**7.** The table of relations in the index needs this. All those IOUs will be redeemed long since.

```
void bp_term_details_index(bp_term_details *bptd) {
    if (bptd->implies_kind) {
        print_text_to_file(bptd->implies_kind->word_ref1,
            bptd->implies_kind->word_ref2, ifl);
    } else if (bptd->implies_kov) {
        char term_name_buffer[500];
        copy_kov_to_string(bptd->implies_kov, term_name_buffer, FALSE);
        INDEX("%s", term_name_buffer);
    } else INDEX("--");
}
```

The function bp_term_details_index is called from 5/rel.

§**8.** The following routine adds the given BP term as a call parameter to the routine currently being compiled, deciding that something is an object if its kind indications are all blank, but verifying that the value supplied matches the specific necessary kind of object if there is one.

```
void bptd_add_as_call_parameter(OUTPUT_STREAM, ph_stack_frame *phsf, bp_term_details bptd) {
    int nv;
    kind_of_value *kov = kova(OBJECT_TY);
    if (bptd.implies_kov) kov = bptd.implies_kov;
    nv = phsf_add_call_parameter(phsf, bptd.word_ref1, bptd.word_ref2, kov);
    if (bptd.implies_kind)
        WRITE("  if (~~(t_%d ofclass %s)) rfalse;\n",
            nv, wo_get_I6_representation(bptd.implies_kind));
}
```

The function bptd_add_as_call_parameter is called from 12/phsf.

§**9. Making the equality relation.** As we shall see below, BPs are almost always created in matched pairs. There is one and only one exception to this rule: the equality predicate where $EQ(x, y)$ if $x = y$. Equality plays a special role in the system of logic we'll be using in Chapter 6. Since $x = y$ and $y = x$ are exactly equivalent, it is safe to make EQ its own reversal; this makes it impossible for equality to occur "the wrong way round" in any proposition, even one which is not yet fully simplified.

There is no fixed domain to which x and y belong: equality can be used whenever x and y belong to the same domain. Thus "if the score is 12" and "if the location is the Pantheon" are both valid uses of EQ, where x and y are numbers in the former case and rooms in the latter. It will take special handling in the type-checker (Chapter 7) to achieve this effect. For now, we give EQ entirely blank term details.

```
binary_predicate *make_equality(void) {
    binary_predicate *bp = make_single_BP(EQUALITY_KBP,
        bptd_blank(), bptd_blank(),
        "is", 0, NULL, NULL, NULL, equality_V);
    bp->reversal = bp; bp->right_way_round = TRUE;
    return bp;
}
```

The function make_equality is called from 6/equal.

§**10. Making a pair of relations.** Every other BP belongs to a matched pair, in which each is the reversal of the other, but only one is designated as being "the right way round". The left-hand term of one behaves like the right-hand term of the other, and vice versa.

The BP which is the wrong way round is never used in compilation, because it will long before that have been reversed, so we only fill in details of how to compile the BP for the one which is the right way round.

```
binary_predicate *make_pair_of_BPs(int family,
    bp_term_details left_term, bp_term_details right_term,
    char *name, char *namer, int inference_type, property_name *pn,
    i6_schema *mtf, i6_schema *tf, vocabulary_entry *word) {
    binary_predicate *bp, *bpr;
    char namer_constructed[MAX_WORD_LENGTH+10];
    if (name == NULL) name = "nameless";
    if (namer == NULL) { sprintf(namer_constructed, "%s-r", name); namer = namer_constructed; }
    bp  = make_single_BP(family, left_term, right_term, name, inference_type, pn, mtf, tf, word);
    bpr = make_single_BP(family, right_term, left_term, namer, inference_type, NULL, NULL, NULL, NULL);
    bp->reversal = bpr; bpr->reversal = bp;
    bp->right_way_round = TRUE; bpr->right_way_round = FALSE;
    if (word)
        register_reworded_meaning(MISCELLANEOUS_MC, RELATION_SMC, word, relation_V, -1, -1, 0,
            STORE_POINTER_binary_predicate(bp));
    return bp;
}
```

The function make_pair_of_BPs is called from 9/spabp, 9/mapbp, 9/provr, 9/cmpbp, 9/vpbp, 10/qnbp and 10/libp.

§**11.** When the source text declares new relations, it turns out to be convenient to make their BPs in a two-stage process: to make sketchy, mostly-blank BP structures for them early on – but getting their names registered – and then fill in the correct details later. This is where such sketchy pairs are made:

```
void make_sketchy_pair_of_BPs(vocabulary_entry *ve, int f) {
    char *name = vocab_get_exemplar(ve, FALSE);
    binary_predicate *bp =
        make_pair_of_BPs(EXPLICIT_KBP,
        bptd_blank(), bptd_blank(), name, NULL, -1, NULL, NULL, NULL, ve);
    bp->form_of_relation = f;
    bp->reversal->form_of_relation = f;
}
```

The function make_sketchy_pair_of_BPs is called from 5/rel.

§**12. BP construction.** The following routine should only ever be called from the two above: provided we stick to that, we ensure the golden rule that *every BP has a reversal and a BP equals its reversal if and only if it is the equality relation.*

It looks a little asymmetric that the "make true function" schema `mtf` is an argument here, but the "make false function" isn't. That's because it happens that the implicit relations defined in this section of code generally do support making-true, but don't support making-false, so that such an argument would always be `NULL` in practice.

```
binary_predicate *make_single_BP(int family,
    bp_term_details left_term, bp_term_details right_term,
    char *name, int inference_type, property_name *pn,
    i6_schema *mtf, i6_schema *tf, vocabulary_entry *word) {
    binary_predicate *bp = CREATE(binary_predicate);
    bp->relation_family = family;
    bp->form_of_relation = Relation_Implicit;
    bp->relation_name = word;
    bp->bp_created_at = current_sentence;
    truncated_strcpy(bp->debugging_log_name, name, MAX_WORD_LENGTH+10);
    bp->term_details[0] = left_term; bp->term_details[1] = right_term;
    the reversal and the right_way_round field must be set by the caller
    for use in code compilation
    bp->test_function = tf;
    bp->condition_defn_w1 = -1; bp->condition_defn_w2 = -1;
    bp->make_true_function = mtf;
    bp->make_false_function = NULL;
    for use by the A-parser
    bp->arbitrary = FALSE;
    bp->set_property = NULL;
    bp->property_pending_w1 = -1; bp->property_pending_w2 = -1;
    bp->set_inference = inference_type;
    bp->relates_values_not_objects = FALSE;
    bp->knowledge_about_bp = NULL;
    for optimisation of run-time code
    bp->i6_storage_property = pn;
    bp->allow_function_simplification = TRUE;
    bp->fast_route_finding = FALSE;
    bp->loop_parent_optimisation_proviso = NULL;
```

```
    bp->loop_parent_optimisation_ranger = NULL;
    details for particular kinds of relation
    bp->a_listed_in_predicate = FALSE;
    bp->same_property = NULL;
    bp->comparative_property = NULL;
    bp->comparison_sign = 0;
    bp->equivalence_partition = NULL;
    bp->direction_object = NULL;
    return bp;
}
```

§13. BP and term logging.

```
void log_bp_term_details(bp_term_details *bptd, int i) {
    LOG("  function(%d): $i\n", i, bptd->function_of_other);
    if (bptd->word_ref1 >= 0) LOG("  term %d is '$W'\n", i, bptd->word_ref1, bptd->word_ref2);
    if (bptd->implies_kind) LOG("  term %d implies kind $O\n", i, bptd->implies_kind);
    if (bptd->implies_kov) LOG("  term %d implies KOV $u\n", i, bptd->implies_kov);
}
void log_binary_predicate(binary_predicate *bp) {
    int i;
    if (bp == NULL) { LOG("<null-BP>\n"); return; }
    LOG("BP%d <%s> - %s way round - %s\n",
        bp->allocation_id, bp->debugging_log_name, bp->right_way_round?"right":"wrong",
        bp_form_to_text(bp));
    for (i=0; i<2; i++) log_bp_term_details(&bp->term_details[i], i);
    LOG("  test: $i\n", bp->test_function);
    LOG("  make true: $i\n", bp->make_true_function);
    LOG("  make false: $i\n", bp->make_false_function);
    LOG("  storage property: $Y\n", bp->i6_storage_property);
}
```

The function log_binary_predicate is called from 2/dl.

§14. Relation names. A useful little routine to spot the names of relations. This is only used when there is good reason to suspect that the word in question is the name of a relation, so its relative inefficiency does not matter.

```
binary_predicate *parse_relation_name(int w1) {
    binary_predicate *bp;
    LOOP_OVER(bp, binary_predicate)
        if (compare_word(w1, bp->relation_name))
            return bp;
    return NULL;
}
char *bp_get_log_name(binary_predicate *bp) {
    return bp->debugging_log_name;
}
```

The function parse_relation_name is called from 5/rel, 5/conj and 13/gtok.
The function bp_get_log_name is called from 5/rel, 5/conj, 6/aprop and 8/refpt.

§15. Miscellaneous access routines.

```
int bp_get_form_of_relation(binary_predicate *bp) {
    return bp->form_of_relation;
}
int bp_is_explicit_with_runtime_storage(binary_predicate *bp) {
    if (bp->right_way_round == FALSE) bp = bp->reversal;
    if (bp->form_of_relation == Relation_Implicit) return FALSE;
    if (bp->form_of_relation == Relation_ByRoutine) return FALSE;
    return TRUE;
}
char *bp_form_to_text(binary_predicate *bp) {
    switch(bp->form_of_relation) {
        case Relation_Implicit: return "Relation_Implicit";
        case Relation_OtoO: return "Relation_OtoO";
        case Relation_OtoV: return "Relation_OtoV";
        case Relation_VtoO: return "Relation_VtoO";
        case Relation_VtoV: return "Relation_VtoV";
        case Relation_Sym_OtoO: return "Relation_Sym_OtoO";
        case Relation_Sym_VtoV: return "Relation_Sym_VtoV";
        case Relation_Equiv: return "Relation_Equiv";
        case Relation_ByRoutine: return "Relation_ByRoutine";
        default: return "formless-BP";
    }
}
```

The function bp_get_form_of_relation is called from 9/exrel and 13/gtok.
The function bp_is_explicit_with_runtime_storage is called from 9/exrel.
The function bp_form_to_text is called from 5/rel.

§16. Details of the terms:

```
world_object *bp_term_kind(binary_predicate *bp, int t) {
    return bp->term_details[t].implies_kind;
}
kind_of_value *bp_term_kind_of_value(binary_predicate *bp, int t) {
    return bp->term_details[t].implies_kov;
}
i6_schema *bp_get_term_as_function_of_other(binary_predicate *bp, int t) {
    return bp->term_details[t].function_of_other;
}
```

The function bp_term_kind is called from 5/rel, 6/simp, 6/tcpr, 6/asp, 8/creat and 13/gtok.
The function bp_term_kind_of_value is called from 5/rel, 6/sconv, 6/simp, 6/tcpr, 8/creat, 9/exrel and 13/gtok.
The function bp_get_term_as_function_of_other is called from 6/term, 6/simp and 6/cind.

§**17.** Reversing:

```
binary_predicate *bp_get_reversal(binary_predicate *bp) {
    return bp->reversal;
}
int bp_is_the_wrong_way_round(binary_predicate *bp) {
    if (bp->right_way_round == FALSE) return TRUE;
    return FALSE;
}
```

The function bp_get_reversal is called from 4/verb, 4/noun, 5/conj, 6/simp, 8/refpt, 8/relv, 9/prop and 13/gtok.
The function bp_is_the_wrong_way_round is called from 6/simp, 6/tcpr, 8/relv and 13/gtok.

§**18.** For compiling code from conditions:

```
i6_schema *bp_get_test_function(binary_predicate *bp) {
    return bp->test_function;
}
int bp_can_be_made_true_at_runtime(binary_predicate *bp) {
    if ((bp->make_true_function) ||
        (bp->reversal->make_true_function)) return TRUE;
    return FALSE;
}
```

The function bp_get_test_function is called from 13/gtok.
The function bp_can_be_made_true_at_runtime is called from 9/spabp and 9/exrel.

§**19.** For the A-parser. The real code is all elsewhere; note that the `assertions` field, which is used only for relations between values rather than objects, is a linked list. (Information about objects is stored in linked lists pointed to from the `world_object` structure in question; that can't be done if an assertion is about values, so they are stored under the relation itself.)

```
int bp_allow_arbitrary_assertions(binary_predicate *bp) {
    return bp->arbitrary;
}
int bp_get_kind_of_inference(binary_predicate *bp) {
    return bp->set_inference;
}
int bp_relates_values_not_objects(binary_predicate *bp) {
    return bp->relates_values_not_objects;
}
inference **bp_get_inferences(binary_predicate *bp) {
    return &(bp->knowledge_about_bp);
}
```

The function bp_allow_arbitrary_assertions is called from 9/exrel and 9/prop.
The function bp_get_kind_of_inference is called from 9/spabp.
The function bp_relates_values_not_objects is called from 5/rel, 8/mass and 8/relv.
The function bp_get_inferences is called from 9/inf.

§**20.** For use when optimising code.

```
property_name *bp_get_i6_storage_property(binary_predicate *bp) {
    return bp->i6_storage_property;
}
int bp_allows_function_simplification(binary_predicate *bp) {
    return bp->allow_function_simplification;
}
```

The function bp_get_i6_storage_property is called from 9/exrel and 13/gtok.
The function bp_allows_function_simplification is called from 6/simp.

§**21.** The predicate-calculus engine (Chapter 6) compiles much better loops if we can help it by providing an I6 schema of a loop header solving the following problem:

Loop a variable v (in the schema, `*1`) over all possible x such that $R(x, t)$, for some fixed t (in the schema, `*1`).

If we can't do this, it will still manage, but by the brute force method of looping over all x in the left domain of R and testing every possible $R(x, t)$.

```
int bp_write_optimised_loop_schema(i6_schema *sch, binary_predicate *bp) {
    if (bp == NULL) return FALSE;
    ⟨Try loop ranger optimisation 22⟩;
    ⟨Try loop parent optimisation subject to a proviso 23⟩;
    return FALSE;
}
```

The function bp_write_optimised_loop_schema is called from 6/cdefp.

§**22.** Some relations R provide a "ranger" routine, `R`, which is such that `R(t)` supplies the first "child" of t and `R(t, n)` supplies the next "child" after n. Thus `R` iterates through some linked list of all the objects x such that $R(x, t)$.

⟨Try loop ranger optimisation 22⟩ ≡

```
    if (bp->loop_parent_optimisation_ranger) {
        sch_write_to_existing_2s(sch,
            "for (*1=%s(*2): *1: *1=%s(*2,*1))",
            bp->loop_parent_optimisation_ranger,
            bp->loop_parent_optimisation_ranger);
        return TRUE;
    }
```

This code is used in §21.

§**23.** Other relations make use of the I6 object tree, in cases where $R(x, t)$ is true if and only if t is an object which is the parent of x in the I6 object tree *and* some routine associated with R, called its proviso `P`, is such that `P(x) == t`. For example, $worn - by(x, t)$ is true iff t is the parent of x and `WearerOf(x) == t`. The proviso ensures that we don't falsely pick up, say, items carried by t which aren't being worn, or aren't even clothing.

⟨Try loop parent optimisation subject to a proviso 23⟩ ≡

```
if (bp->loop_parent_optimisation_proviso) {
    sch_write_to_existing_1s(sch,
        "objectloop (*1 in *2) if (%s(*1)==parent(*1))",
        bp->loop_parent_optimisation_proviso);
    return TRUE;
}
```

This code is used in §21.

§**24. The built-in BPs.** Here we create spatial relationships, numerical comparisons and a few others: all of the BPs in the "exceptional one-off cases" part of the classification above. This happens very early in compilation.

```
void make_built_in_relations(void) {
    EQUALITY_KBP_create_initial_stock();
    PROVISION_KBP_create_initial_stock();
    QUASINUMERIC_KBP_create_initial_stock();
    SPATIAL_KBP_create_initial_stock();
    MAP_CONNECTING_KBP_create_initial_stock();
    PROPERTY_SETTING_KBP_create_initial_stock();
    PROPERTY_SAME_KBP_create_initial_stock();
    PROPERTY_COMPARISON_KBP_create_initial_stock();
    LISTED_IN_KBP_create_initial_stock();
    EXPLICIT_KBP_create_initial_stock();
}
```

The function make_built_in_relations is invoked by a command in a `.i6t` template file.

§**25. Other property-based relations.**

```
void make_further_built_in_relations(void) {
    EQUALITY_KBP_create_second_stock();
    PROVISION_KBP_create_second_stock();
    QUASINUMERIC_KBP_create_second_stock();
    SPATIAL_KBP_create_second_stock();
    MAP_CONNECTING_KBP_create_second_stock();
    PROPERTY_SETTING_KBP_create_second_stock();
    PROPERTY_SAME_KBP_create_second_stock();
    PROPERTY_COMPARISON_KBP_create_second_stock();
    LISTED_IN_KBP_create_second_stock();
    EXPLICIT_KBP_create_second_stock();
}
```

The function make_further_built_in_relations is invoked by a command in a `.i6t` template file.

§**26.**

define DECLINE_TO_MATCH 1000 *not one of the three legal* *_MATCH *values*
define NEVER_MATCH_SAYING_WHY_NOT 1001 *not one of the three legal* *_MATCH *values*

```

Relations 5/rel

Purpose

What Inform internally calls "binary predicates", the user calls "relations". In this section, we parse definitions of new relations and create the resulting `binary_predicate` objects.

Template interpreter commands

```
25  {-array:relation_metadata}
29  {-callv:compile_runtime_relation_storage}
42  {-callv:compile_defined_relations}
```

---

§1. Creation, Stage I. The creation of relations happens in two stages. First, when the parse tree is being organised into sentences, we call the following routine the moment a relation definition has been found. (This is important because it may affect the parsing of subsequent sentences in the source text.) The predicate we make is initially sketchy: but by existing, and having a name, it can be used in subsequent verb definitions, and then subsequent sentences using those newly defined verbs can be properly parsed all during the same run-through of the parse tree.

```
void parse_new_relation(parse_node *PN) {
    int rw1 = PN->down->next->word_ref1;
    if (parse_relation_name(rw1)) {
        sentence_problem(_P_(C5RelationExists),
            "that relation already exists",
            "and cannot have its definition amended now.");
        return;
    }
    make_sketchy_pair_of_BPs(lw_array[rw1].lw_identity, Relation_OtoO);
}
```

The function parse_new_relation is called from 4/verb.

§2. Creation, Stage II. In the second stage, which is reached during the first traverse of sentences to work through the assertions, we parse the specification of the relation properly and complete the BP structure. (In the interim period, the name of the BP is really the only thing that has been used.)

Altogether, the Inform user is allowed to define some eight different forms of relation. The code below is an attempt to find whatever common ground can be found from these different outcomes, but inevitably ends up splitting into cases.

```
sentence_handler NEW_RELATION_SH_handler =
    { SENTENCE_NT, NEW_RELATION_VB, 1, parse_new_relation_further };

void parse_new_relation_further(parse_node *PN) {
    int rw = PN->down->next->word_ref1;                                  word number of relation name
    binary_predicate *bp = parse_relation_name(rw), *bpr = bp->reversal;
    property_name *prn = NULL;                                  used for run-time storage of this relation
    char *i6_prn_name = NULL;                                          the I6 identifier for this property
    world_object *storage_k = NULL;                          what kind of object, if any, might be stored in it
    int left_unique = NOT_APPLICABLE,                                  TRUE for one, FALSE for various,
        right_unique = NOT_APPLICABLE,                                 ...or NOT_APPLICABLE for unspecified
        condition_w1 = -1, condition_w2 = -1,                                text of test condition if any
        symmetric = FALSE,                                                        a symmetric relation?
        equivalence = FALSE,                                    an equivalence ("in groups") relation?
        rvno = FALSE,                                                      relate values not objects?
        frf = FALSE;                                                          use fast route-finding?
    if (bp == NULL) internal_error("BP in relation not initially parsed");
    ⟨Parse the classification variables and use them to fill in the BP term details 3⟩;
    if (rvno) { bp->relates_values_not_objects = TRUE; bpr->relates_values_not_objects = TRUE; }
    if (frf) { bp->fast_route_finding = TRUE; bpr->fast_route_finding = TRUE; }
    if (prn) { bp->i6_storage_property = prn; bpr->i6_storage_property = prn; }
    if (condition_w1 >= 0) ⟨Complete as a relation-by-routine BP 22⟩
    else if (equivalence) ⟨Complete as an equivalence-relation BP 21⟩
    else if (left_unique) {
        if (right_unique) {
            if (symmetric) ⟨Complete as a symmetric one-to-one BP 19⟩
            else ⟨Complete as an asymmetric one-to-one BP 15⟩;
        } else ⟨Complete as a one-to-various BP 16⟩;
    } else {
        if (right_unique) ⟨Complete as a various-to-one BP 17⟩
        else if (symmetric) ⟨Complete as a symmetric various-to-various BP 20⟩
        else ⟨Complete as an asymmetric various-to-various BP 18⟩;
    }
    bpr->form_of_relation = bp->form_of_relation;
    LOGIF(RELATION_DEFINITIONS, "Defined the binary predicate:\n$2\n", bp);
}
```

§**3. The parsing phase.** Our aims here are:

(i) to decide if the definition is valid, and reject it with a suitable problem message if not, returning from the current routine;
(ii) to fill in the classification variables `left_unique`, `symmetric`, etc., as defined above;
(iii) to choose a property which will provide run-time storage for this relation, if it needs any; and
(iii) to set `bp->term_details[0]` and `...[1]` with the kinds, names and logical properties of the two terms of the BP being defined.

⟨Parse the classification variables and use them to fill in the BP term details 3⟩ ≡

```
int f1 = PN->down->next->word_ref1 + 2;                    left term declaration, before "to"
int f2 = PN->down->next->word_ref2;
int s1 = PN->down->next->next->word_ref1;                  right term declaration, after "to"
int s2 = PN->down->next->next->word_ref2;
world_object *left_k = NULL, *right_k = NULL;                              kind requirement
kind_of_value *left_kov = NULL, *right_kov = NULL;                  kind of value requirement
int left_cw1 = -1, left_cw2 = -1,                                    left term "calling" name
    right_cw1 = -1, right_cw2 = -1;                                 right term "calling" name
LOGIF(RELATION_DEFINITIONS,
    "Relation definition of $W: left term: '$W', right term: '$W'\n",
        rw, rw, f1, f2, s1, s2);
⟨Find term multiplicities and use of fast route-finding 5⟩;
⟨Detect use of a condition for a test-only relation 6⟩;
⟨Detect callings for the terms of the relation 7⟩;
⟨Detect use of symmetry in definition of second term 8⟩;
⟨Vet the use of callings for the terms of the relation 9⟩;
⟨Work out the kinds of the terms in the relation 10⟩;
if (left_unique == NOT_APPLICABLE) left_unique = FALSE;
if (right_unique == NOT_APPLICABLE) right_unique = FALSE;
if (condition_w1 == -1) {
    ⟨Police restrictions on some combinations 11⟩;
    ⟨Determine property used for run-time storage 12⟩;
}
⟨Fill in the BP term details based on the left- and right- variables 4⟩;
```

This code is used in §2.

§**4.** The left- and right- local variables above provide us with convenient aliases for the entries which will end up in the `bp_term_details` structures attached to the BP: this is where we put them back.

For the meaning of functions f_0 and f_1, see "Binary Predicates.w". The idea here is this: suppose we have a relation of objects where the only true outcomes have the form $B(f_0(y), y)$. At run-time we store the identity of the counterpart object $f_0(y)$ in the `prn` property of the original object y.

And we similarly construct an f_1 function if the only true outcomes have the form $B(x, f_1(x))$.

⟨Fill in the BP term details based on the left- and right- variables 4⟩ ≡

```
i6_schema *f0 = NULL, *f1 = NULL;
bp_term_details left_bptd, right_bptd;
if (i6_prn_name) {
    if (left_unique) f0 = sch_new_1("(*1.%s)", i6_prn_name);
    else if (right_unique) f1 = sch_new_1("(*1.%s)", i6_prn_name);
}
left_bptd = bptd_full_new(left_k, left_kov, left_cw1, left_cw2, f0);
right_bptd = bptd_full_new(right_k, right_kov, right_cw1, right_cw2, f1);
```

```
    bp->term_details[0] = left_bptd; bp->term_details[1] = right_bptd;
    bpr->term_details[0] = right_bptd; bpr->term_details[1] = left_bptd;
```

This code is used in §3.

§**5.** We set word ranges for the condition (if any) and the callings (if any), whittling down the word ranges for the left and right specifications if these are clipped away, and also look at the multiplicities.

⟨Find term multiplicities and use of fast route-finding 5⟩ ≡

```
    if [[s1, s2 == ... with fast route_finding --> s1, s2]] frf = TRUE;
    if [[f1, f2 == one ... --> f1, f2]]     left_unique = TRUE;
    if [[f1, f2 == various ... --> f1, f2]] left_unique = FALSE;
    if [[s1, s2 == one ... --> s1, s2]]     right_unique = TRUE;
    if [[s1, s2 == various ... --> s1, s2]] right_unique = FALSE;
    if (frf && (left_unique != FALSE) && (right_unique != FALSE)) {
        sentence_problem(_P_(C5FRFUnavailable),
            "fast route-finding is only possible with various-to-various "
            "relations",
            "though this doesn't matter because with other relations the "
            "standard route-finding algorithm is efficient already.");
        return;
    }
```

This code is used in §3.

§**6.** When a relation is said to hold depending on a condition to be tested at run-time, it is meaningless to tell Inform anything about the uniqueness of terms in the domain: a relation might be one-to-one at the start of play but become various-to-various later on, as the outcomes of these tests change. So we reject any such misleading syntax.

⟨Detect use of a condition for a test-only relation 6⟩ ≡

```
    int i;
    if [[s1, s2 == ... when ... : i --> s1, s2 ... condition_w1, condition_w2]] {
        if ((left_unique != NOT_APPLICABLE) || (right_unique != NOT_APPLICABLE)) {
            sentence_problem(_P_(C5OneOrVariousWithWhen),
                "this relation is a mixture of different syntaxes",
                "and must be simplified. If it is going to specify 'one' or "
                "'various' then it cannot also say 'when' the relation holds.");
            return;
        }
    }
```

This code is used in §3.

§**7.** Callings are used to give names to the terms on each side of the relation, e.g.,

Lock-fitting relates one thing (called the matching key) to various things.

⟨Detect callings for the terms of the relation 7⟩ ≡

```
if (word_range_ends_with_calling(f1, f2, &f1, &f2, &left_cw1, &left_cw2)) {
    if (brackets_unbalanced(left_cw1, left_cw2))
        ⟨Issue problem message for malformed relation definition 13⟩;
}
if (word_range_ends_with_calling(s1, s2, &s1, &s2, &right_cw1, &right_cw2)) {
    if (brackets_unbalanced(right_cw1, right_cw2))
        ⟨Issue problem message for malformed relation definition 13⟩;
}
```

This code is used in §3.

§**8.** The second term can be given in several special ways to indicate symmetry between the two terms. This is more than a declaration that the left and right terms belong to the same domain set (though that is true): it says that $R(x, y)$ is true if and only if $R(y, x)$ is true.

⟨Detect use of symmetry in definition of second term 8⟩ ≡

```
int specified_one = left_unique;
if [[s1, s2 == another]] {
    symmetric = TRUE; left_unique = TRUE; right_unique = TRUE;
}
if [[s1, s2 == each other]] {
    symmetric = TRUE; left_unique = FALSE; right_unique = FALSE;
}
if [[s1, s2 == each other in groups]] {
    symmetric = TRUE; left_unique = FALSE; right_unique = FALSE; equivalence = TRUE;
}
if ((specified_one == TRUE) && (left_unique == FALSE)) {
    sentence_problem(_P_(C5BothOneAndMany),
        "the left-hand term in this relation seems to be both 'one' thing "
        "and also many things",
        "given the mention of 'each other'. Try removing the 'one'.");
    return;
}
```

This code is used in §3.

§**9.** To give a name to one term implies some degree of uniqueness about it. But that only makes sense if there is indeed some uniqueness involved, because otherwise it is unclear what the name refers to. Who is "the greeter of the Queen of Sheba" given the following definition?

> Acquaintance relates various people (called the greeter) to various people.

Because of that, callings are only allowed in certain circumstances. An exception is made – that is, they are always allowed – where the relation tests a given condition, because then the names identify the terms, e.g.,

> Divisibility relates a number (called N) to a number (called M) when the remainder after dividing M by N is 0.

Here the names "N" and "M" unambiguously refer to the terms being tested at this moment, and have no currency beyond that context.

⟨Vet the use of callings for the terms of the relation 9⟩ ≡

```
if (condition_w1 == -1) {
    if ((left_unique == FALSE) && (left_cw1 >= 0)) {
        sentence_problem(_P_(C5CantCallLeft),
            "the left-hand term of this relation is not unique",
            "so you cannot assign a name to it using 'called'.");
        return;
    }
    if ((right_unique == FALSE) && (right_cw1 >= 0)) {
        sentence_problem(_P_(C5CantCallRight),
            "the right-hand term of this relation is not unique",
            "so you cannot assign a name to it using 'called'.");
        return;
    }
    if ((left_cw1 >= 0) && (right_cw1 >= 0)) {
        sentence_problem(_P_(C5CantCallBoth),
            "the relation has to have the same name on both sides",
            "so it should be 'called' something even-handed: for instance, "
            "'Marriage relates one person to another (called the spouse).' "
            "rather than 'Marriage relates one man (called the husband) to "
            "one woman (called the wife).'");
        return;
    }
    if ((symmetric == FALSE) && (left_unique) && (right_unique) && (right_cw1 >= 0)) {
        sentence_problem(_P_(C5OneToOneMiscalled),
            "with a one-to-one relation which is not symmetrical "
            "only the left-hand item can be given a name using 'called'",
            "so this needs rephrasing to name the left in terms of the right "
            "rather than vice versa. For instance, 'Transmission relates "
            "one remote to one gadget (called the target).' should be "
            "rephrased as 'Transmission relates one gadget (called the "
            "target) to one remote.' It will then be possible to talk about "
            "'the gadget of' any given remote.");
        return;
    }
}
```

This code is used in §3.

§**10.** At the end of this paragraph of code, on each side either the `k` or the `kov` is set to a non-NULL pointer, but not both. In the event of a KOV, it is an enumerated KOV with a known finite domain. (If a relation will involve run-time storage, then it must have a fixed-size and fairly small domain set for its terms: relating a number to a number would be impossible. A relation defined in terms of a condition, which is test-only, doesn't suffer from this restriction.)

⟨Work out the kinds of the terms in the relation 10⟩ ≡

```
if (parse_relation_term_type(f1, f2, &left_k, &left_kov, "left") == FALSE) return;
if (symmetric) {
    right_k = left_k; right_kov = left_kov;
} else {
    if (parse_relation_term_type(s1, s2, &right_k, &right_kov, "right") == FALSE) return;
}
if ((left_kov) || (right_kov)) rvno = TRUE;
if (condition_w1 == -1) {
    if ((left_kov) &&
        (check_finite_range(left_kov) == FALSE)) return;
    if ((right_kov) && (symmetric == FALSE) &&
        (check_finite_range(right_kov) == FALSE)) return;
}
```

This code is used in §3.

§**11.** Not everything permitted by the grammar of these declarations is actually allowed: there are a number of pragmatic restrictions.

⟨Police restrictions on some combinations 11⟩ ≡

```
if ((left_k == NULL) || (right_k == NULL))
    if ((left_unique) || (right_unique)) {
        sentence_problem(_P_(C5ValueRelationNotV2V),
            "at present relations among values must be various-to-various",
            "so for instance 'Shading relates various things to various colours' "
            "is allowed, but not 'Shading relates various things to one colour'. "
            "(The latter would be better done with a property anyhow.)");
        return;
    }
if (equivalence) {
    if (left_k == NULL) {
        sentence_problem(_P_(C5ValueRelationInGroups),
            "at present relations in groups are restricted to objects",
            "such as things or rooms, and not values.");
        return;
    }
}
```

This code is used in §3.

§**12.** All forms of relation we can produce from here use an I6 property for run-time storage (though different forms of relation use it differently). We use the calling, if any, to name this property: if there are no callings, then it gets a name like "concealment relates", and is omitted from the index.

⟨Determine property used for run-time storage 12⟩ ≡
```
if (left_cw1 >= 0) {
    prn = typed_property_name_ref(left_cw1, left_cw2, left_kov);
    if (prn == NULL) return;
} else if (right_cw1 >= 0) {
    prn = typed_property_name_ref(right_cw1, right_cw2, right_kov);
    if (prn == NULL) return;
} else {
    if (brackets_unbalanced(rw, rw+1))
        ⟨Issue problem message for malformed relation definition 13⟩;
    prn = typed_property_name_ref(rw, rw+1, kova(OBJECT_TY));
    if (prn == NULL) return;
    prn_exclude_from_index(prn);
}
i6_prn_name = prn_get_i6_identifier(prn);
storage_k = left_k;
if (left_unique) storage_k = right_k;
else if (right_unique) storage_k = left_k;
```

This code is used in §3.

§**13.** Something of a catch-all problem message:

⟨Issue problem message for malformed relation definition 13⟩ ≡
```
sentence_problem(_P_(C5RelMalformed),
    "this relation's definition is malformed",
    "and should follow these models: 'Concealment relates "
    "one thing to various things' or 'Knowledge relates "
    "various people to various things'.");
return;
```

This code is used in §7,12,7,12,7,12.

§**14. The completion phase.** At this point the BP is filled in except for: its form; the schemas for testing, asserting true and asserting false; the run-time storage property to be used, if any; and any fields which are specific to the form in question. Anyway, there are eight possible forms of explicit BP, so here are eight paragraphs creating them.

§**15.** The `Relation_OtoO` case, or one to one: "R relates one K to one K".

Such a relation consumes run-time storage of $5D$ bytes on the Z-machine and $14D$ bytes on Glulx, where D is the size of the domain...

⟨Complete as an asymmetric one-to-one BP 15⟩ ≡
```
bp->form_of_relation = Relation_OtoO;
prop_true_in_world_model_about(prop_to_provide_property(prn), storage_k, NULL);
prn_now_stores_1to1_relation(prn);
bp->make_true_function = sch_new_1("Relation_Now1to1(*2,%s,*1)", i6_prn_name);
bp->make_false_function = sch_new_1("Relation_NowN1toV(*2,%s,*1)", i6_prn_name);
```

This code is used in §2.

§**16.** The `Relation_OtoV` case, or one to various: "R relates one K to various K".

⟨Complete as a one-to-various BP 16⟩ ≡
```
bp->form_of_relation = Relation_OtoV;
prop_true_in_world_model_about(prop_to_provide_property(prn), storage_k, NULL);
bp->make_true_function = sch_new_1("*2.%s = *1", i6_prn_name);
bp->make_false_function = sch_new_1("Relation_NowN1toV(*2,%s,*1)", i6_prn_name);
```
This code is used in §2.

§**17.** The `Relation_VtoO` case, or various to one: "R relates various K to one K".

⟨Complete as a various-to-one BP 17⟩ ≡
```
bp->form_of_relation = Relation_VtoO;
prop_true_in_world_model_about(prop_to_provide_property(prn), storage_k, NULL);
bp->make_true_function = sch_new_1("*1.%s = *2", i6_prn_name);
bp->make_false_function = sch_new_1("Relation_NowN1toV(*1,%s,*2)", i6_prn_name);
```
This code is used in §2.

§**18.** The `Relation_VtoV` case, or various to various: "R relates various K to various K".

⟨Complete as an asymmetric various-to-various BP 18⟩ ≡
```
bp->form_of_relation = Relation_VtoV;
bp->arbitrary = TRUE;
bp->test_function = sch_new_1d("(Relation_TestVtoV(*1,V2V_Bitmap_%d,*2,false))",
    bp->allocation_id);
bp->make_true_function = sch_new_1d("(Relation_NowVtoV(*1,V2V_Bitmap_%d,*2,false))",
    bp->allocation_id);
bp->make_false_function = sch_new_1d("(Relation_NowNVtoV(*1,V2V_Bitmap_%d,*2,false))",
    bp->allocation_id);
```
This code is used in §2.

§**19.** The `Relation_Sym_OtoO` case, or symmetric one to one: "R relates one K to another".

⟨Complete as a symmetric one-to-one BP 19⟩ ≡
```
bp->form_of_relation = Relation_Sym_OtoO;
prop_true_in_world_model_about(prop_to_provide_property(prn), storage_k, NULL);
prn_now_stores_1to1_relation(prn);
bp->make_true_function = sch_new_1("Relation_NowS1to1(*2,%s,*1)", i6_prn_name);
bp->make_false_function = sch_new_1("Relation_NowSN1to1(*2,%s,*1)", i6_prn_name);
```
This code is used in §2.

§**20.** The `Relation_Sym_VtoV` case, or symmetric various to various: "R relates K to each other".

⟨Complete as a symmetric various-to-various BP 20⟩ ≡
```
bp->form_of_relation = Relation_Sym_VtoV;
bp->arbitrary = TRUE;
bp->test_function = sch_new_1d("(Relation_TestVtoV(*1,V2V_Bitmap_%d,*2,true))",
    bp->allocation_id);
bp->make_true_function = sch_new_1d("(Relation_NowVtoV(*1,V2V_Bitmap_%d,*2,true))",
    bp->allocation_id);
bp->make_false_function = sch_new_1d("(Relation_NowNVtoV(*1,V2V_Bitmap_%d,*2,true))",
    bp->allocation_id);
```
This code is used in §2.

§**21.** The `Relation_Equiv` case, or equivalence relation: "R relates K to each other in groups".

⟨Complete as an equivalence-relation BP 21⟩ ≡

```
bp->form_of_relation = Relation_Equiv;
bp->arbitrary = TRUE;
prop_true_in_world_model_about(prop_to_provide_property(prn), storage_k, NULL);
bp->test_function = sch_new_2("(*1.%s == *2.%s)", i6_prn_name, i6_prn_name);
bp->make_true_function = sch_new_1("Relation_NowEquiv(*1,%s,*2)", i6_prn_name);
bp->make_false_function = sch_new_1("Relation_NowNEquiv(*1,%s,*2)", i6_prn_name);
```

This code is used in §2.

§**22.** The `Relation_ByRoutine` case, or relation tested by a routine: "R relates K to L when (some condition)".

⟨Complete as a relation-by-routine BP 22⟩ ≡

```
bp->form_of_relation = Relation_ByRoutine;
bp->test_function = sch_new_1d("(Relation_%d(*1,*2))", bp->allocation_id);
bp->condition_defn_w1 = condition_w1; bp->condition_defn_w2 = condition_w2;
```

This code is used in §2.

§**23. Parsing utilities.** A term is specified either as a kind, or as the name of a kind of value.

```
int parse_relation_term_type(int w1, int w2, world_object **k, kind_of_value **kov, char *side) {
    specification *spec;
    *k = parse_world_object(w1, w2, TRUE); *kov = NULL;
    if (*k) return TRUE;
    spec = parse_expression(w1, w2, TYPE_EXPCON);
    if (spec_is_generic_CONSTANT(spec)) {
        *kov = spec_get_kind_of_value(spec);
        return TRUE;
    }
    quote_source(1, current_sentence);
    quote_words(2, w1, w2);
    quote_text(3, side);
    handmade_problem(_P_(C5RelatedKindsUnknown));
    issue_problem_segment(
        "In the relation definition %1, I am unable to understand the %3-hand "
        "side -- I was expecting that %2 would be either the name of a kind, "
        "or the name of a kind of value, but it wasn't either of those.");
    issue_problem_end();
    return FALSE;
}
```

§**24.** A modest utility, to check for a case we forbid because of the prohibitive (or anyway unpredictable) run-time storage it would imply.

```
int check_finite_range(kind_of_value *kov) {
    if (kov_is_an_enumeration(kov)) return TRUE;
    if (kov == NULL) return TRUE;                                    to recover from earlier problems
    if ((is_kova(kov, OBJECT_TY)) || (is_kova(kov, ANY_VALUE_TY)))
    sentence_problem(_P_(C5RangeOverlyBroad),
        "relations aren't allowed to range over all 'objects' or all 'values'",
        "as these are too broad. A relation has to be between two kinds of "
        "object, or kinds of value. So 'Taming relates various people to "
        "various animals' is fine, because 'people' and 'animals' both mean "
        "kinds of object, but 'Wanting relates various objects to various "
        "values' is not allowed.");
    else sentence_problem(_P_(C5ValueRangeInfinite),
        "relations involving values can only be used with new kinds of value "
        "having a known set of possible values (unless they are defined using "
        "a condition)",
        "so for instance 'Tallying relates various things to various numbers.' "
        "is disallowed because 'number' is a kind of value with an unlimited "
        "range of possible values; but 'Colour is a kind of value. The colours "
        "are red, blue and green. Painting relates various things to various "
        "colours.' is allowed. (And if we use a condition, anything goes: "
        "for instance, 'Divisibility relates a number (called N) to a number "
        "(called M) when remainder after dividing M by N is 0.' defines a "
        "relation between numbers.)");
    return FALSE;
}
```

§**25. The relation metadata array at run-time.** The template layer needs to be able to tell, given a value of KOV "abstract-relation", what form of relation it represents, where its run-time storage lives in memory and so on. This information is wrapped up in the `relation_metadata` array, which consists of three-word records plus a `NULL` terminator. An "abstract-relation" value at run-time is the allocation ID number of the `binary_predicate` structure representing the relation: it follows that data on abstract-relation `R` can be found at the I6 location

```
relation_metadata-->(3*R)
```

Field 0 depends on the form of the relation (see below). Field 1 is the form number. Field 2 is the text of the sentence used to define the relation – this is so that the RELATIONS testing command can generate legible output.

```
void compile_relation_metadata_array(OUTPUT_STREAM) {
    binary_predicate *bp;
    WRITE("Array relation_metadata -->\n"); INDENT;
    LOOP_OVER(bp, binary_predicate) {
        ⟨Write the storage field of the relation metadata array 26⟩;
        if (bp->right_way_round == FALSE) WRITE(" (%d) \"", Relation_Implicit);
        else WRITE(" %s \"", bp_form_to_text(bp));
        if (bp->form_of_relation == Relation_Implicit) WRITE("%s", bp_get_log_name(bp));
        else print_raw_text_to_file(bp->bp_created_at->word_ref1,
            bp->bp_created_at->word_ref2, OUT);
        WRITE("\"\n");
    }
```

```
    WRITE("NULL;\n");
    OUTDENT;
}
```

The function compile_relation_metadata_array is invoked by a command in a `.i6t` template file.

§**26.** Field 0 has different meanings for different families of BPs:

⟨Write the storage field of the relation metadata array 26⟩ ≡

```
    binary_predicate *dbp = bp;
    if (bp->right_way_round == FALSE) dbp = bp->reversal;
    switch(dbp->form_of_relation) {
        case Relation_Implicit:                                    Field 0 is not used
            WRITE("0");                                  which is not the same as NULL, unlike in C
            break;
        case Relation_OtoO:
        case Relation_OtoV:
        case Relation_VtoO:
        case Relation_Sym_OtoO:
        case Relation_Equiv:                          Field 0 is the property used for run-time storage
            WRITE("%s", prn_get_i6_identifier(dbp->i6_storage_property));
            break;
        case Relation_VtoV:
        case Relation_Sym_VtoV:                  Field 0 is the bitmap array used for run-time storage
            WRITE("V2V_Bitmap_%d", dbp->allocation_id);
            break;
        case Relation_ByRoutine:                      Field 0 is the routine used to test the relation
            WRITE("Relation_%d", dbp->allocation_id);
            break;
        default:
            internal_error("Binary predicate with unknown structural type");
    }
```

This code is used in §25.

§**27. The bitmap for various-to-various relations.** It is unavoidable that a general V-to-V relation will take at least LR bits of storage, where L is the size of the left domain and R the size of the right domain. (A symmetric V-to-V relation needs only a little over $LR/2$ bits, though in practice we don't want the nuisance of this memory saving.) Cheaper implementations would only be possible if we could guarantee that the relation would have some regularity, or would be sparse, but we can't guarantee any of that. Our strategy will therefore be to store these LR bits in the most direct way possible, with as little overhead as possible: in a bitmap.

§**28.** The following code compiles a stream of bits into a sequence of 16-bit I6 constants written in hexadecimal, padding out with 0s to fill any incomplete word left at the end. The first bit of the stream becomes the least significant bit of the first word of the output.

```
int word_compiled = 0, bit_counter = 0, words_compiled;

void begin_bit_stream(OUTPUT_STREAM) {
    word_compiled = 0; bit_counter = 0; words_compiled = 0;
}

void compile_bit(OUTPUT_STREAM, int b) {
    word_compiled += (b << bit_counter);
    bit_counter++;
    if (bit_counter == 16) {
        WRITE("$%04x ", word_compiled);
        words_compiled++;
        word_compiled = 0; bit_counter = 0;
    }
}

void end_bit_stream(OUTPUT_STREAM) {
    while (bit_counter != 0) compile_bit(OUT, 0);
}
```

§**29.** As was implied above, the run-time storage for a various to various relation whose BP has allocation ID number `X` is an I6 word array called `V2V_Bitmap_X`. This begins with a header of 8 words and is then followed by a bitmap.

```
define MAX_RIGHT_DOMAIN_SIZE 10000

void compile_runtime_relation_storage(OUTPUT_STREAM) {
    binary_predicate *bp;
    LOOP_OVER(bp, binary_predicate)
        if ((bp->right_way_round) &&
            ((bp->form_of_relation == Relation_VtoV) ||
                (bp->form_of_relation == Relation_Sym_VtoV))) {
            int left_count = 0, right_count = 0, words_used = 0, bytes_used = 0;
            ⟨Index the left and right domains and calculate their sizes 30⟩;
            WRITE("Array V2V_Bitmap_%d --> ", bp->allocation_id);
            ⟨Compile header information in the V-to-V structure 31⟩;
            if ((left_count > 0) && (right_count > 0))
                ⟨Compile bitmap pre-initialised to the V-to-V relation at start of play 34⟩;
            WRITE(";\n");
            if ((left_count > 0) && (right_count > 0))
                ⟨Allocate a zeroed-out memory cache for relations with fast route-finding 32⟩;
            note_VM_usage("relation",
                bp->bp_created_at->word_ref1, -1,
                vocab_get_exemplar(bp->relation_name, FALSE),
                words_used, bytes_used, FALSE);
        }
}
```

The function compile_runtime_relation_storage is invoked by a command in a `.i6t` template file.

§**30.** We calculate numbers L and R, and index the items being related, so that the possible left values are indexed $0, 1, 2, ..., L-1$ and the possible right values $0, 1, 2, ..., R-1$. Note that in a relation such as

Roominess relates various things to various containers.

the same object (if a container) might be in both the left and right domains, and be indexed differently on each side: it might be thing number 11 but container number 6, for instance.

L and R are stored in the variables `left_count` and `right_count`. If the left domain contains objects, the index of a member `wo` is stored in `wo->relation_indices[0]`; if the right domain does, then in `wo->relation_indices[1]`. If the domain set is an enumerated kind of value, no index needs to be stored, because the values are already enumerated $1, 2, 3, ..., N$ for some N. The actual work in this is done by the routine `relation_range` (below).

⟨Index the left and right domains and calculate their sizes 30⟩ ≡

```
left_count = relation_range(bp, 0);
right_count = relation_range(bp, 1);
if (right_count >= MAX_RIGHT_DOMAIN_SIZE) internal_error("Far too many relatees");
```

This code is used in §29.

§**31.** See "Relations.i6t" in the template layer for details.

⟨Compile header information in the V-to-V structure 31⟩ ≡

```
if ((bp_term_kind(bp, 0)) && (left_count > 0))
    WRITE("IK_%d ", bp_term_kind(bp, 0)->allocation_id);
else WRITE("0 ");
if ((bp_term_kind(bp, 1)) && (right_count > 0))
    WRITE("IK_%d ", bp_term_kind(bp, 1)->allocation_id);
else WRITE("0 ");
WRITE("\n  %d ! Number of left instances\n", left_count);
WRITE("  %d ! Number of right instances\n  ", right_count);
WRITE("  %s ! To print left instances\n",
    (bp_term_kind(bp, 0))?"PrintShortName":
        (kov_get_name_of_printing_rule(bp_term_kind_of_value(bp, 0))));
WRITE("  %s ! To print right instances\n  ",
    (bp_term_kind(bp, 1))?"PrintShortName":
        (kov_get_name_of_printing_rule(bp_term_kind_of_value(bp, 1))));
WRITE("  true ! Cache broken flag\n");
if ((left_count > 0) && (right_count > 0))
    WRITE("  V2V_Route_Cache_%d ! Cache array (if any)\n", bp->allocation_id);
else
    WRITE("  0 ! No cache array needed\n");
words_used += 8;
```

This code is used in §29.

§**32.** Fast route finding is available only where the left and right domains are equal, and even then, only when the user asked for it. If so, we allocate LR bytes as a cache if $L = R < 256$, and LR words otherwise. The cache is initialised to all-zeros, which saves an inordinate amount of nuisance, and this is why the "cache broken" flag is initially set in the header above: it forces the template layer to generate the cache when first used.

⟨Allocate a zeroed-out memory cache for relations with fast route-finding 32⟩ ≡

```
if ((bp->fast_route_finding) &&
    ((bp_term_kind(bp, 0) == bp_term_kind(bp, 1)) && (left_count == right_count))) {
    if (left_count < 256) {
        WRITE("Array V2V_Route_Cache_%d -> %d;\n",
            bp->allocation_id, 2*left_count*left_count);
        bytes_used += 2*left_count*left_count;
    } else {
        WRITE("Array V2V_Route_Cache_%d --> %d;\n",
            bp->allocation_id, 2*left_count*left_count);
        words_used += 2*left_count*left_count;
    }
} else {
    WRITE("Constant V2V_Route_Cache_%d = 0;\n", bp->allocation_id);
}
```

This code is used in §29.

§**33.** The following macro `wo` conveniently iterates through the objects in domain `i` of the relation defined by `bp`: it should only be used if the relevant domain set does indeed contain objects.

```
define LOOP_OVER_BP_DOMAIN(wo, bp, i)
    LOOP_OVER(wo, world_object)
        if ((wo->kind_flag == FALSE) && (wo_of_kind(wo, bp_term_kind(bp, i))))
```

§**34.** Now to assemble the bitmap. We do this by calling out to the world-model code to ask it what pairs (x, y) are such that assertions have declared that $B(x, y)$ must be true. Because the world-model code stores inferences about objects differently from those about values, we call one department when x and y are both objects, but another if either one is a value.

It would be convenient if the world-model code could feed us the necessary information in exactly the right order, but life is not that kind. On the other hand it would save the world model code some trouble if we built the entire bitmap in memory, so that it could send the pairs (x, y) in any order at all, but that's a little wasteful. We compromise and build the bitmap one row at a time, requiring us to store a whole row, but allowing the world-model code to send the pairs in that row in any order. We do this by first calling either `begin_collating_vpairs` or `begin_collating_wopairs`, and then calling either `send_vpairs_in_row` or `send_wopairs_in_row` for each row (i.e., each x value) in turn. The world-model code then calls `send_related_index` for every y it knows of where $B(x, y)$ is true.

⟨Compile bitmap pre-initialised to the V-to-V relation at start of play 34⟩ ≡

```
char row_flags[MAX_RIGHT_DOMAIN_SIZE];
if (bp_relates_values_not_objects(bp))
    begin_collating_vpairs(bp, left_count, right_count);
else
    begin_collating_wopairs(bp, left_count, right_count);
begin_bit_stream(OUT);
if (bp_relates_values_not_objects(bp)) {
    int i, j;
    for (i=0; i<left_count; i++) {
```

```
            for (j=0; j<right_count; j++) row_flags[j] = 0;
            send_vpairs_in_row(bp, i, row_flags);
            for (j=0; j<right_count; j++) compile_bit(OUT, row_flags[j]);
        }
    } else {
        world_object *wo; int j;
        ⟨Include some comments to make the bitmap slightly easier for humans to decipher 36⟩;
        LOOP_OVER_BP_DOMAIN(wo, bp, 0) {
            for (j=0; j<right_count; j++) row_flags[j] = 0;
            send_wopairs_in_row(bp, wo, row_flags);
            for (j=0; j<right_count; j++) compile_bit(OUT, row_flags[j]);
        }
    }
    end_bit_stream(OUT);
    words_used += words_compiled;
```

This code is used in §29.

§**35.** See above. (The world-model code does nothing with `row_flags`, simply passing it back on to us as a pointer.)

```
void send_related_index(binary_predicate *bp, int i, char *row_flags) {
    row_flags[i] = 1;
}
```

The function send_related_index is called from 9/cot.

§**36.** The following does nothing functional.

⟨Include some comments to make the bitmap slightly easier for humans to decipher 36⟩ ≡

```
    LOOP_OVER_BP_DOMAIN(wo, bp, 0)
        WRITE("  ! Left-count %d = %s\n",
            wo->relation_indices[0], wo_get_I6_representation(wo));
    LOOP_OVER_BP_DOMAIN(wo, bp, 1)
        WRITE("  ! Right-count %d = %s\n",
            wo->relation_indices[1], wo_get_I6_representation(wo));
```

This code is used in §34.

§**37.** Lastly on this: the way we count and index the left (`index=0`) or right (1) domain. If the domain set is an enumerated kind of value, there's no indexing required, because the values at run-time are already $1, 2, 3, ..., N$, where N is the result of calling `kov_get_highest_valid_value_as_integer`.

But if the domain set is a kind of object, there's no regularity in the values at run-time, and so we assign each object an index in the domain set, counting upwards from 0 (in order of creation).

```
int relation_range(binary_predicate *bp, int index) {
    int t = 0;
    if (bp_term_kind(bp, index)) {
        world_object *wo;
        LOOP_OVER(wo, world_object)
            wo->relation_indices[index] = -1;
        LOOP_OVER_BP_DOMAIN(wo, bp, index) {
            wo->relation_indices[index] = t++;
        }
    } else {
        kind_of_value *kov = bp_term_kind_of_value(bp, index);
        if (kov_has_named_constant_values(kov) == FALSE) return -1;
        t = kov_get_highest_valid_value_as_integer(kov);
    }
    return t;
}
```

§**38. The partition for an equivalence relation.** An equivalence relation E is such that $E(x, x)$ for all x, such that $E(x, y)$ if and only if $E(y, x)$, and such that $E(x, y)$ and $E(y, z)$ together imply $E(x, z)$: the properties of being reflexive, symmetric and transitive. The relation constructed by a sentence like

Alliance relates people to each other in groups.

is to be an equivalence relation. This means we need to ensure first that the original state of the relation, resulting from assertions such as...

The verb to be allied to implies the alliance relation. Louis is allied to Otto. Otto is allied to Helene.

...satisfies the reflexive, symmetric and transitive properties; and then also that these properties are maintained at run-time when the situation changes as a result of executing phrases such as

now Louis is allied to Gustav;

We use the same solution both in the compiler and at run-time, which is to exploit an elementary theorem about ERs. Let E be an equivalence relation on the members of a set S (say, the set of people in Central Europe). Then there is a unique way to divide up S into a "partition" of subsets called "equivalence classes" such that:

(a) every member of S is in exactly one of the classes,
(b) none of the classes is empty, and
(c) $E(x, y)$ is true if and only if x and y belong to the same class.

Conversely, given any partition of S (i.e., satisfying (a) and (b)), there is a unique equivalence relation E such that (c) is true. In short: possible states of an equivalence relation on a set correspond exactly to possible ways to divide it up into non-empty, non-overlapping pieces.

We therefore store the current state not as some list of which pairs (x, y) for which $E(x, y)$ is true, but instead as a partition of the set S. We store this as a function $p : S \to \{1, 2, 3, ...\}$ such that x and y belong in the same class – or to put it another way, such that $E(x, y)$ is true – if and only if $p(x) = p(y)$. When we are assembling the initial state, the function p is an array of integers whose address is stored in the `bp->equivalence_partition` field of the BP structure. It is then compiled into the storage properties of the I6 objects concerned. For instance, if we have `p44_alliance` as the storage property for the "alliance"

relation, then `O31_Louis.p44_alliance` and `O32_Otto.p44_alliance` will be set to the same partition number. The template routines which set and remove alliance then maintain the collective values of the `p44_alliance` property, keeping it always a valid partition function for the relation.

§**39.** We calculate the initial partition by starting with the sparsest possible equivalence relation, $E(x, y)$ if and only if $x = y$, where each member is related only to itself. (This is the equality relation.) The partition function here is given by $p(x)$ equals the allocation ID number for object x, plus 1. Since all objects have distinct IDs, $p(x) = p(y)$ if and only if $x = y$, which is what we want. But note that the objects in S may well not have contiguous ID numbers. This doesn't matter to us, but it means p may look less tidy than we expect.

For instance, suppose there are five people: Sophie, Ryan, Daisy, Owen and the player, with a "helping" equivalence relation. We might then generate the initial partition:

$$p(P) = 12, p(S) = 23, p(R) = 25, p(D) = 26, p(O) = 31.$$

```
void equivalence_relations_make_singleton_partitions(int domain_size) {
    binary_predicate *bp;
    LOOP_OVER(bp, binary_predicate)
        if ((bp->form_of_relation == Relation_Equiv) && (bp->right_way_round)) {
            int i;
            int *partition_array = I7_calloc(domain_size, sizeof(int), PARTITION_MREASON);
            for (i=0; i<domain_size; i++) partition_array[i] = i+1;
            bp->equivalence_partition = partition_array;
        }
}
```

The function equivalence_relations_make_singleton_partitions is called from 9/cot.

§**40.** The A-parser, over in Chapter 9, has meanwhile been reading in facts about the helping relation:

> Sophie helps Ryan. Daisy helps Ryan. Owen helps the player.

And it feeds these facts to us one at a time. It tells us that $A(S, R)$ has to be true by calling the routine below for the helping relation with the ID numbers of Sophie and Ryan as arguments. Sophie is currently in class number 23, Ryan in class 25. We merge these two classes so that anybody whose class number is 25 is moved down to have class number 23, and so:

$$p(P) = 12, p(S) = 23, p(R) = 23, p(D) = 26, p(O) = 31.$$

Similarly we now merge Daisy's class with Ryan's:

$$p(P) = 12, p(S) = 23, p(R) = 23, p(D) = 23, p(O) = 31.$$

And Owen's with the player's:

$$p(P) = 12, p(S) = 23, p(R) = 23, p(D) = 23, p(O) = 12.$$

This leaves us with the final partition where the two equivalence classes are

$$\{\text{player}, \text{Owen}\} \quad \{\text{Sophie}, \text{Daisy}, \text{Ryan}\}.$$

As mentioned above, it might seem "tidy" to renumber these classes 1 and 2 rather than 12 and 23, but there's really no need and we don't bother.

Note that the A-parser does not allow negative assertions about equivalence relations to be made:

Daisy does not help Ryan.

While we could try to accommodate this (using the same method we use at run-time to handle "now Daisy does not help Ryan"), it would only invite users to set up these relations in a stylistically poor way.

```
void equivalence_relation_merge_classes(binary_predicate *bp,
    int domain_size, int ix1, int ix2) {
    if (bp->form_of_relation != Relation_Equiv)
        internal_error("attempt to merge classes for a non-equivalence relation");
    if (bp->right_way_round == FALSE) bp = bp->reversal;
    int *partition_array = bp->equivalence_partition;
    if (partition_array == NULL)
        internal_error("attempt to use null equivalence partition array");
    int little, big;                                                    or, The Fairies' Parliament
    big = partition_array[ix1]; little = partition_array[ix2];
    if (big == little) return;
    if (big < little) { int swap = little; little = big; big = swap; }
    int i;
    for (i=0; i<domain_size; i++)
        if (partition_array[i] == big)
            partition_array[i] = little;
}
```

The function equivalence_relation_merge_classes is called from 9/cot.

§**41.** Once that process has completed, the code in Chapter 9 which compiles the initial state of the I6 object tree calls the following routine to ask it to fill in the (let's say) `p63_helping` property for each person in turn.

```
void equivalence_relations_add_properties(OUTPUT_STREAM, world_object *wo) {
    binary_predicate *bp;
    LOOP_OVER(bp, binary_predicate)
        if ((bp->form_of_relation == Relation_Equiv) && (bp->right_way_round) &&
            (wo->kind_flag == FALSE) && (wo_of_kind(wo, bp_term_kind(bp, 1))))
            WRITE(" with %s %d\n",
                prn_get_i6_identifier(bp->i6_storage_property),
                equivalence_relation_get_class(bp, wo->allocation_id));
}
int equivalence_relation_get_class(binary_predicate *bp, int ix) {
    if (bp->form_of_relation != Relation_Equiv)
        internal_error("attempt to merge classes for a non-equivalence relation");
    if (bp->right_way_round == FALSE) bp = bp->reversal;
    int *partition_array = bp->equivalence_partition;
    if (partition_array == NULL)
        internal_error("attempt to use null equivalence partition array");
    return partition_array[ix];
}
```

The function equivalence_relations_add_properties is called from 9/cot.

§42. Generating routines to test relations by condition. When a relation has to be tested as a condition, we can't simply embed that condition as the I6 schema for "test relation": it might very well need local variables, the table row-choosing variables, etc., to evaluate. It has to be tested in its own context. So we generate a routine called `Relation_X`, where `X` is the allocation ID number of the BP, which takes two parameters `t_0` and `t_1` and returns true or false according to whether or not $R(\texttt{t\_0}, \texttt{t\_1})$.

This is where those routines are compiled.

```
void compile_defined_relations(OUTPUT_STREAM) {
    binary_predicate *bp;
    LOOP_OVER(bp, binary_predicate)
        if ((bp->form_of_relation == Relation_ByRoutine) && (bp->right_way_round)) {
            char rname[32];
            sprintf(rname, "Relation_%d", bp->allocation_id);
            current_sentence = bp->bp_created_at;
            WRITE("! Routine to decide if %s(t_0, t_1)\n", bp_get_log_name(bp));
            compile_condition_routine(OUT, rname,
                bp->condition_defn_w1, bp->condition_defn_w2,
                bp->term_details[0], bp->term_details[1]);
        }
}
```

The function compile_defined_relations is invoked by a command in a `.i6t` template file.

§43. Indexing relations. A brief table of relations appears on the Phrasebook Index page.

```
void index_table_of_relations(void) {
    binary_predicate *bp;
    begin_plain_html_table(ifl);
    LOOP_OVER(bp, binary_predicate)
        if (bp->right_way_round) {
            char *type = NULL, *left = NULL, *right = NULL;
            switch (bp->relation_family) {
                case EQUALITY_KBP: type = "equality"; left = "<i>any</i>"; right = left; break;
                case QUASINUMERIC_KBP: type = "numeric"; break;
                case SPATIAL_KBP: type = "spatial"; break;
                case MAP_CONNECTING_KBP: type = "map"; left = "room/door"; right = left; break;
                case PROVISION_KBP: type = "provision"; left = "<i>any</i>"; right = "property"; break;
                case EXPLICIT_KBP:
                    switch (bp->form_of_relation) {
                        case Relation_OtoO: type = "one-to-one"; break;
                        case Relation_OtoV: type = "one-to-various"; break;
                        case Relation_VtoO: type = "various-to-one"; break;
                        case Relation_VtoV: type = "various-to-various"; break;
                        case Relation_Sym_OtoO: type = "one-to-another"; break;
                        case Relation_Sym_VtoV: type = "various-to-each-other"; break;
                        case Relation_Equiv: type = "in groups"; break;
                        case Relation_ByRoutine: type = "defined"; break;
                    }
                    break;
            }
            if ((type == NULL) || (bp->relation_name == NULL)) continue;
            first_html_column(ifl, 0);
            INDEX("%s", vocab_get_exemplar(bp->relation_name, FALSE));
```

```
            if (bp->bp_created_at) index_link(lw_array[bp->bp_created_at->word_ref1].lw_source);
            next_html_column(ifl, 0);
            if (type) INDEX("%s", type); else INDEX("--");
            next_html_column(ifl, 0);
            if (left) INDEX("%s", left);
            else bp_term_details_index(&(bp->term_details[0]));
            next_html_column(ifl, 0);
            if (right) INDEX("%s", right);
            else bp_term_details_index(&(bp->term_details[1]));
            end_html_row(ifl);
        }
    end_html_table(ifl);
}
```

The function index_table_of_relations is called from 2/lexi.

Conjugation of Verbs 5/conj

Purpose

To define verbal and prepositional forms for relations, in different tenses and numbers.

5/conj.§1-3 Verb usages; §4-6 Preposition usages; §7-8 Parsing source text against verb and preposition usages; §9 Debug log; §10 Index tabulation; §11 The built-in verbs and prepositions; §12 Registration of to be; §13-17 Registration of regular verbs; §18-21 Registration of to be able to; §22 Late registration of prepositions comparing properties; §23 Parsing new verb declarations; §24-26 I: Semantics; §27-33 IIa: Syntax of a new verb usage; §34-39 IIb: Syntax of a new prepositional usage

---

Template interpreter commands

```
9   {-callv:debug_verbs}
11   {-callv:make_built_in_verbs}
```

Definitions

¶1. A single English verb, such as "to contain", produces numerous `verb_usage` objects, since we have one for each combination of tense, number and negation – "contains", "had not contained", etc.

```
define MAX_WORDS_IN_USAGE 5

typedef struct verb_usage {
    struct vocabulary_entry *vu_text[MAX_WORDS_IN_USAGE];      some may be null
    int negated_form_of_verb;                                  is this a negated form?
    int tensed;                                                one of the four tense values
    struct binary_predicate *vu_meaning;                       the BP is the root meaning of the verb
    struct lexicon_entry *under_main_verb;                     for use when indexing
    struct parse_node *where_vu_created;                       for use if problem messages needed
    MEMORY_MANAGEMENT
} verb_usage;

verb_usage *regular_to_be = NULL;                              "is"
verb_usage *negated_to_be = NULL;                              "is not"
verb_usage *negated_plural_to_be = NULL;                       "are not"
```

The structure verb_usage is private to this section.

¶2. We use the term "preposition" pretty loosely here: for instance, "in" counts (which is fair enough) but so does "contained by". Essentially, these are forms of words which, when modifying the verb "to be", assert a relationship. (Thus "had not been contained by" couples "to be" in a particular tense with "contained by".)

Ordinarily a preposition, coupled with "to be", overly asserts a binary predicate. "X is carried by Y", for instance, clearly asserts a relationship between two things, X and Y. But in some cases the past participle of a verb can be used adjectivally with the second term, Y, left unspoken: for instance, "X is carried". The `implies_player` flag below asserts that given form is allowable adjectivally with Y filled in as the player.

```
typedef struct preposition_usage {
    struct vocabulary_entry *pu_text[MAX_WORDS_IN_USAGE];          some may be null
    int implies_player;                                  for prepositions used adjectivally
    struct property_name *is_same_property_as;              for "is the same P as" preps
    struct binary_predicate *pu_meaning;                          again, the root meaning
    struct parse_node *where_pu_created;                 for use if problem messages needed
    int negated_sense;                    if the sense of the sentence is implicitly negated
    int allow_unexpected_upper_case;                    for preps like "in Cahoots With"
    int implicitly_behave_as_noun;                                for preps like "part of"
    MEMORY_MANAGEMENT
} preposition_usage;
```

The structure preposition_usage is private to this section.

---

§**1. Verb usages.** The meaning of a verb, or of *to be* plus a preposition, is more complicated than a simple relation $R(a, b)$. It is R together with an indication of when R needs to be true (the *tense* of the verb), and of whether it in fact needs to be false (or *negated*). Each combination, and each possible wording, can have its own `verb_usage` structure. For instance, some 14 `verb_usage` structures exist which all ultimately correspond to the same equality predicate.

```
parse_node *set_where_created = NULL;
verb_usage *register_vu(vocabulary_entry *ve1, vocabulary_entry *ve2,
    vocabulary_entry *ve3, vocabulary_entry *ve4, vocabulary_entry *ve5,
    int negated, int tensed, binary_predicate *root) {
    verb_usage *vu = CREATE(verb_usage);
    vu->vu_text[0] = ve1; vu->vu_text[1] = ve2; vu->vu_text[2] = ve3;
    vu->vu_text[3] = ve4; vu->vu_text[4] = ve5;
    vu->negated_form_of_verb = negated; vu->tensed = tensed;
    vu->vu_meaning = root;
    vu->under_main_verb = current_main_verb;
    vu->where_vu_created = set_where_created;
    vocab_set_flags(ve1, CVERB_MC);
    return vu;
}
```

§**2.** The following is not especially fast, but is only a convenience used when creating verbs, so it runs only a handful of times in Inform's run.

```
verb_usage *find_vu(vocabulary_entry *ve1, vocabulary_entry *ve2,
    vocabulary_entry *ve3, vocabulary_entry *ve4, vocabulary_entry *ve5) {
    verb_usage *vu;
    LOOP_OVER(vu, verb_usage) {
        if (vu->vu_text[0] != ve1) continue;
        if (vu->vu_text[1] != ve2) continue;
        if (vu->vu_text[2] != ve3) continue;
        if (vu->vu_text[3] != ve4) continue;
        if (vu->vu_text[4] != ve5) continue;
        return vu;
    }
    return NULL;
}
```

§**3.** And some access routines:

```
binary_predicate *vu_get_meaning(verb_usage *vu) {
    return vu->vu_meaning;
}
int vu_get_tense_used(verb_usage *vu) {
    return vu->tensed;
}
int vu_is_used_negatively(verb_usage *vu) {
    return vu->negated_form_of_verb;
}
```

The function vu_get_meaning is called from 4/verb, 5/varc, 5/mlc and 6/sconv.
The function vu_get_tense_used is called from 2/prob3, 4/verb, 5/mlc and 6/sconv.
The function vu_is_used_negatively is called from 4/verb and 6/sconv.

§**4. Preposition usages.** And now almost the same code again as for verb usages.

```
preposition_usage *register_pu(vocabulary_entry *ve1, vocabulary_entry *ve2,
    vocabulary_entry *ve3, vocabulary_entry *ve4, vocabulary_entry *ve5,
    int assumes_player, binary_predicate *root) {
    preposition_usage *pu = CREATE(preposition_usage);
    pu->pu_text[0] = ve1; pu->pu_text[1] = ve2; pu->pu_text[2] = ve3;
    pu->pu_text[3] = ve4; pu->pu_text[4] = ve5;
    pu->pu_meaning = root; pu->implies_player = assumes_player;
    pu->is_same_property_as = NULL;
    pu->where_pu_created = set_where_created;
    pu->negated_sense = FALSE;
    pu->allow_unexpected_upper_case = FALSE;
    pu->implicitly_behave_as_noun = FALSE;
    vocab_set_flags(ve1, PREPOSITION_MC);
    return pu;
}
```

The function register_pu is called from 9/mapbp.

§**5.** And once again a slowish but rarely-needed search.

```
preposition_usage *find_pu(vocabulary_entry *ve1, vocabulary_entry *ve2,
    vocabulary_entry *ve3, vocabulary_entry *ve4, vocabulary_entry *ve5) {
    preposition_usage *pu;
    LOOP_OVER(pu, preposition_usage) {
        if (pu->pu_text[0] != ve1) continue;
        if (pu->pu_text[1] != ve2) continue;
        if (pu->pu_text[2] != ve3) continue;
        if (pu->pu_text[3] != ve4) continue;
        if (pu->pu_text[4] != ve5) continue;
        return pu;
    }
    return NULL;
}
```

§**6.** And again some access routines:

```
int pu_implies_player(preposition_usage *pu) {
    return pu->implies_player;
}
int pu_implicitly_negates(preposition_usage *pu) {
    return pu->negated_sense;
}
binary_predicate *pu_get_meaning(preposition_usage *pu) {
    return pu->pu_meaning;
}
int pu_implicitly_behaves_as_noun(preposition_usage *pu) {
    return pu->implicitly_behave_as_noun;
}
```

The function pu_implies_player is called from 5/varc.
The function pu_implicitly_negates is called from 6/sconv.
The function pu_get_meaning is called from 4/verb, 4/noun and 6/sconv.
The function pu_implicitly_behaves_as_noun is called from 5/varc.

§**7. Parsing source text against verb and preposition usages.** Given a particular VU, and a word range `w1` to `w2`, we test whether the range begins with but does not consist only of the text of the VU. We return the first word after the VU text if it does (which will therefore be a word number still inside the range), or −1 if it doesn't.

```
int vu_parse_text_against(int w1, int w2, verb_usage *vu) {
    int k, i;
    for (i=0, k=w1; i<MAX_WORDS_IN_USAGE; i++)
        if (vu->vu_text[i]) {
            if ((k==w2) || (vu->vu_text[i] != lw_array[k].lw_identity)) return -1;
            k++;
        }
    return k;
}
```

The function vu_parse_text_against is called from 2/prob3, 4/verb and 5/varc.

§**8.** More complicatedly, the same test for a prepositional usage. Sometimes we allow prepositions like "the same weight as", which refer to properties, and sometimes we don't. If we do, the bogus word `STROKE_V` is used to mark where the property name should appear in the text of the usage; this value is chosen since it can't ever occur in a preposition written by the user, being used otherwise only to mark paragraph breaks.

Note that, unlike the corresponding test for VUs, this one allows the usage to exactly fill the text `w1` to `w2` supplied, and in that case we return `w2+1`. This is needed because of prepositional usages which behave as if adjectives, like "carried", where the second term is missing because it is understood as meaning the player: "The briefcase is carried."

```
int pu_parse_text_against(int w1, int w2, preposition_usage *pu,
    int allow_sap) {
    int k, i;
    if ((pu->is_same_property_as) && (allow_sap == FALSE)) return -1;
    for (i=0, k=w1; i<MAX_WORDS_IN_USAGE; i++)
        if (pu->pu_text[i] == STROKE_V) {
            int pw1 = pu->is_same_property_as->word_ref1;
            int pw2 = pu->is_same_property_as->word_ref2;
            if (k + pw2 - pw1 > w2) return -1;
            if (compare_word_range(pw1, pw2, k, k+pw2-pw1) == FALSE) return -1;
            k += pw2 - pw1 + 1;
        } else if (pu->pu_text[i]) {
            if ((k > w2) || (pu->pu_text[i] != lw_array[k].lw_identity)) return -1;
            if ((pu->allow_unexpected_upper_case == FALSE) &&
                (unexpectedly_upper_case(k))) return -1;
            k++;
        }
    if ((k > w2) && (pu->implies_player == FALSE)) return -1;
    return k;
}
```

The function pu_parse_text_against is called from 4/verb, 4/noun and 5/varc.

§**9. Debug log.** The following dumps the entire stock of registered verb and preposition usages to the debugging log.

```
void log_verb_usage(verb_usage *vu) {
    int i;
    LOG("VU: ");
    for (i=0; i<MAX_WORDS_IN_USAGE; i++)
        if (vu->vu_text[i]) LOG("%s ", vocab_get_exemplar(vu->vu_text[i], FALSE));
    if (vu->negated_form_of_verb) LOG("(negated) ");
    log_tense_number(vu->tensed);
    LOG(" -> %s", bp_get_log_name(vu->vu_meaning));
}
void log_preposition_usage(preposition_usage *pu) {
    int i;
    LOG("PU: ");
    for (i=0; i<MAX_WORDS_IN_USAGE; i++)
        if (pu->pu_text[i]) LOG("%s ", vocab_get_exemplar(pu->pu_text[i], FALSE));
    if (pu->implies_player) LOG("(implies player) ");
    if (pu->is_same_property_as) LOG("(same $Y) ", pu->is_same_property_as);
    LOG("-> %s", bp_get_log_name(pu->pu_meaning));
}
void debug_verbs(void) {
    verb_usage *vu;
    preposition_usage *pu;
    LOG("The current S-grammar has the following verb and preposition usages:\n");
    LOOP_OVER(vu, verb_usage) {
        log_verb_usage(vu);
        LOG("\n");
    }
    LOOP_OVER(pu, preposition_usage) {
        log_preposition_usage(pu);
        LOG("\n");
    }
}
```

The function log_verb_usage is called from 5/ml.

The function log_preposition_usage is called from 5/ml.

The function debug_verbs is invoked by a command in a `.i6t` template file.

§10. Index tabulation. The following produces the table of verbs in the Phrasebook Index page.

```
void tabulate_verb(lexicon_entry *lex, int tense, char *tensename) {
    verb_usage *vu; int f = TRUE;
    LOOP_OVER(vu, verb_usage)
        if ((vu->under_main_verb == lex) && (vu_is_used_negatively(vu) == FALSE)
            && (vu_get_tense_used(vu) == tense)) {
            vocabulary_entry *lastword = vu->vu_text[4];
            if (lastword == NULL) lastword = vu->vu_text[3];
            if (lastword == NULL) lastword = vu->vu_text[2];
            if (lastword == NULL) lastword = vu->vu_text[1];
            if (lastword == NULL) lastword = vu->vu_text[0];
            if (f) INDEX("<p class=\"hang\">  <i>%s:</i> ",
                tensename);
            else INDEX("; ");
            f = FALSE;
            if (lastword == by_V) INDEX("B "); else INDEX("A ");
            if (vu->vu_text[0]) INDEX("%s ", vocab_get_exemplar(vu->vu_text[0], FALSE));
            if (vu->vu_text[1]) INDEX("%s ", vocab_get_exemplar(vu->vu_text[1], FALSE));
            if (vu->vu_text[2]) INDEX("%s ", vocab_get_exemplar(vu->vu_text[2], FALSE));
            if (vu->vu_text[3]) INDEX("%s ", vocab_get_exemplar(vu->vu_text[3], FALSE));
            if (vu->vu_text[4]) INDEX("%s ", vocab_get_exemplar(vu->vu_text[4], FALSE));
            if (lastword == by_V) INDEX("A"); else INDEX("B");
        }
    if (f == FALSE) INDEX("</p>\n");
}
```

The function tabulate_verb is called from 2/lexi.

§11. The built-in verbs and prepositions. Although we have created numerous built-in relations, very few verbs and prepositions are built in: those are created, instead, early on in the Standard Rules. (See Appendix A.) To justify the exceptions:

(a) "To be" is both grammatically irregular and also plays a special role in terms of having as its meaning the equality predicate, which behaves unlike all others. The syntax available to the Standard Rules can't construct this.

(b) "To have" is more surprising, given that there's nothing grammatically irregular about it. It's defined here just in order to come before the definition of "to be", because definition order occasionally breaks ties in parsing ambiguous sentences. (Because "to have" is sometimes used as an auxiliary verb, we can indeed find both in the same sentence – "Fred has been in the hut".) So although the Standard Rules could create "to have", they couldn't create it before the creation of "to be".

(c) Note that numerical comparisons are handled by two methods. Verbally, they are prepositions: "less than", for instance, is combined with "to be", giving us "A is less than B" and similar forms. These wordy forms are therefore defined as prepositional usages and created as such in the Standard Rules. But we also permit the use of the familiar mathematical symbols `<`, `>`, `<=` and `>=`. Inform treats these as verbs without tense, so registers them as verb usages, but without the full conjugation given to a conventional verb; and they are also excluded from the lexicon in the Phrasebook index, being notation rather than words. (This is why the variable `current_main_verb` is cleared.)

```
void make_built_in_verbs(void) {
    set_where_created = NULL;
    register_regular_verb(has_V, have_V, had_V, had_V, NULL, a_has_b_predicate, FALSE);
    register_to_be();
```

```
    current_main_verb = NULL;
    register_vu(LT_V, 0, 0, 0, 0, FALSE, IS_TENSE, a_lt_b_predicate);
    register_vu(GT_V, 0, 0, 0, 0, FALSE, IS_TENSE, a_gt_b_predicate);
    register_vu(LE_V, 0, 0, 0, 0, FALSE, IS_TENSE, a_le_b_predicate);
    register_vu(GE_V, 0, 0, 0, 0, FALSE, IS_TENSE, a_ge_b_predicate);
}
```

The function make_built_in_verbs is invoked by a command in a `.i6t` template file.

§**12. Registration of to be.** The English verb *to be* is the only one irregular enough to need its own special code to be created.

```
void register_to_be(void) {
    lexicon_new_main_verb(be_V, VERB_LEXE);
    negated_to_be = register_vu(is_V, not_V, 0, 0, 0, TRUE, IS_TENSE, a_is_b_predicate);
    regular_to_be = register_vu(is_V, 0, 0, 0, 0, FALSE, IS_TENSE, a_is_b_predicate);
    negated_plural_to_be = register_vu(are_V, not_V, 0, 0, 0, TRUE, IS_TENSE, a_is_b_predicate);
    register_vu(are_V, 0, 0, 0, 0, FALSE, IS_TENSE, a_is_b_predicate);
    register_vu(was_V, not_V, 0, 0, 0, TRUE, WAS_TENSE, a_is_b_predicate);
    register_vu(was_V, 0, 0, 0, 0, FALSE, WAS_TENSE, a_is_b_predicate);
    register_vu(were_V, not_V, 0, 0, 0, TRUE, WAS_TENSE, a_is_b_predicate);
    register_vu(were_V, 0, 0, 0, 0, FALSE, WAS_TENSE, a_is_b_predicate);
    register_vu(has_V, not_V, been_V, 0, 0, TRUE, HASBEEN_TENSE, a_is_b_predicate);
    register_vu(has_V, been_V, 0, 0, 0, FALSE, HASBEEN_TENSE, a_is_b_predicate);
    register_vu(have_V, not_V, been_V, 0, 0, TRUE, HASBEEN_TENSE, a_is_b_predicate);
    register_vu(have_V, been_V, 0, 0, 0, FALSE, HASBEEN_TENSE, a_is_b_predicate);
    register_vu(had_V, not_V, been_V, 0, 0, TRUE, HADBEEN_TENSE, a_is_b_predicate);
    register_vu(had_V, been_V, 0, 0, 0, FALSE, HADBEEN_TENSE, a_is_b_predicate);
}
```

§**13. Registration of regular verbs.** English forms verbs with reasonable regularity, and the following routine takes the standard conjugation of a verb (he likes, they like, etc.) and forms all its possible usages, both alone and in combination with the auxiliary verbs *to have* and *to do*. (*To have* also exists as a verb in its own right, and indeed can be used as its own auxiliary: "they had had...". As a primary verb, it is defined by the Standard Rules.)

```
void register_regular_verb(vocabulary_entry *present_singular,
    vocabulary_entry *present_plural, vocabulary_entry *past,
    vocabulary_entry *past_participle, vocabulary_entry *participle,
    binary_predicate *root, int participle_adjectival) {
    lexicon_new_main_verb(present_plural, VERB_LEXE);
    if (past_participle)
        ⟨To have plus past participle makes present and past perfect forms 14⟩;
    if (present_plural)
        ⟨To do plus infinitive makes auxiliary forms 15⟩;
    if (present_singular) register_vu(present_singular, 0, 0, 0, 0, FALSE, IS_TENSE, root);
    if (present_plural) register_vu(present_plural, 0, 0, 0, 0, FALSE, IS_TENSE, root);
    if (past) register_vu(past, 0, 0, 0, 0, FALSE, WAS_TENSE, root);
    if (past_participle)
        ⟨Make prepositional usages arising from past participle 16⟩;
    if (participle)
        ⟨Make prepositional usage arising from participle 17⟩;
}
```

§**14.** English forms the perfect tenses using *to have* as an auxiliary verb. (For instance, "has not fetched", "had fetched".)

⟨To have plus past participle makes present and past perfect forms 14⟩ ≡

```
register_vu(has_V, not_V, past_participle, 0, 0, TRUE, HASBEEN_TENSE, root);
register_vu(have_V, not_V, past_participle, 0, 0, TRUE, HASBEEN_TENSE, root);
register_vu(had_V, not_V, past_participle, 0, 0, TRUE, HADBEEN_TENSE, root);
register_vu(has_V, past_participle, 0, 0, 0, FALSE, HASBEEN_TENSE, root);
register_vu(have_V, past_participle, 0, 0, 0, FALSE, HASBEEN_TENSE, root);
register_vu(had_V, past_participle, 0, 0, 0, FALSE, HADBEEN_TENSE, root);
```

This code is used in §13.

§**15.** Because the verb is regular, its present plural is the same as its infinitive. (So the word "fetch" is the same in "They fetch" and "to fetch".)

⟨To do plus infinitive makes auxiliary forms 15⟩ ≡

```
register_vu(do_V, not_V, present_plural, 0, 0, TRUE, IS_TENSE, root);
register_vu(does_V, not_V, present_plural, 0, 0, TRUE, IS_TENSE, root);
register_vu(did_V, not_V, present_plural, 0, 0, TRUE, WAS_TENSE, root);
register_vu(do_V, present_plural, 0, 0, 0, FALSE, IS_TENSE, root);
register_vu(does_V, present_plural, 0, 0, 0, FALSE, IS_TENSE, root);
register_vu(did_V, present_plural, 0, 0, 0, FALSE, WAS_TENSE, root);
```

This code is used in §13.

§**16.** These prepositional usages reverse the sense of the relation. For instance, "to be fetched by" means the reversal of "to fetch". For a few verbs, the participle can also be used adjectivally with the implied understanding that the player is the missing term in the relation: for instance, "The hat is carried" is understood as if it were "The hat is carried by the player."

⟨Make prepositional usages arising from past participle 16⟩ ≡

```
binary_predicate *bpr = bp_get_reversal(root);
register_pu(past_participle, by_V, 0, 0, 0, FALSE, bpr);
if (participle_adjectival) register_pu(past_participle, 0, 0, 0, 0, TRUE, bpr);
```

This code is used in §13.

§**17.** With the present participle the meaning is back the right way around: for instance, "to be fetching" has the same meaning as "to fetch". At any rate, Inform's linguistic model is not subtle enough to distinguish the difference, in terms of a continuous rather than instantaneous process, which a human reader might be aware of.

⟨Make prepositional usage arising from participle 17⟩ ≡

```
register_pu(participle, 0, 0, 0, 0, FALSE, root);
```

This code is used in §13.

§**18. Registration of to be able to.** Finally, verbs taking the auxiliary *to be able to*: for instance, "to be able to follow".

```
void register_to_be_able_to_verb(vocabulary_entry *infinitive,
    vocabulary_entry *past_participle, binary_predicate *root) {
    if (infinitive == NULL) internal_error("Registered verb without infinitive");
    lexicon_new_main_verb(infinitive, ABLE_VERB_LEXE);
    if (past_participle)
        ⟨Have ever plus past participle for additional perfect forms 19⟩;
    if (past_participle)
        ⟨Can be plus past participle for imperfect forms 20⟩;
    register_vu(cannot_V, infinitive, 0, 0, 0, TRUE, IS_TENSE, root);
    register_vu(can_V, infinitive, 0, 0, 0, FALSE, IS_TENSE, root);
    register_vu(can_V, not_V, infinitive, 0, 0, TRUE, IS_TENSE, root);
    register_vu(could_V, not_V, infinitive, 0, 0, TRUE, WAS_TENSE, root);
    register_vu(could_V, infinitive, 0, 0, 0, FALSE, WAS_TENSE, root);
    ⟨Able or unable to plus infinitive or past participle for prepositional forms 21⟩;
}
```

§**19.** The following looks slightly questionable. After all, the past perfect form for "to be able to grasp" ought to be "had not been able to grasp", not "had never grasped". But "had not been able to grasp" is already created by the prepositional usage "able to grasp" made below; this one is an extra. It's here primarily because of "to be able to see", which is a curiosity of English. Seeing is so instantaneous that being able to see something and actually seeing it are more or less the same thing, and language takes note of this. So while "had never grasped" seems different in meaning from "had not been able to grasp", "had never seen" and "had not been able to see" are much closer.

⟨Have ever plus past participle for additional perfect forms 19⟩ ≡

```
    register_vu(has_V, never_V, past_participle, 0, 0, TRUE, HASBEEN_TENSE, root);
    register_vu(have_V, never_V, past_participle, 0, 0, TRUE, HASBEEN_TENSE, root);
    register_vu(had_V, never_V, past_participle, 0, 0, TRUE, HADBEEN_TENSE, root);
    register_vu(has_V, ever_V, past_participle, 0, 0, FALSE, HASBEEN_TENSE, root);
    register_vu(have_V, ever_V, past_participle, 0, 0, FALSE, HASBEEN_TENSE, root);
    register_vu(had_V, ever_V, past_participle, 0, 0, FALSE, HADBEEN_TENSE, root);
```

This code is used in §18.

§**20.** For instance, "cannot be seen by", which reverses the relation: "X cannot be seen by Y" has the same meaning as "Y cannot see X".

⟨Can be plus past participle for imperfect forms 20⟩ ≡

```
    binary_predicate *bpr = bp_get_reversal(root);
    register_vu(cannot_V, be_V, past_participle, by_V, 0, TRUE, IS_TENSE, bpr);
    register_vu(can_V, not_V, be_V, past_participle, by_V, TRUE, IS_TENSE, bpr);
    register_vu(can_V, be_V, past_participle, by_V, 0, FALSE, IS_TENSE, bpr);
    register_vu(could_V, not_V, be_V, past_participle, by_V, TRUE, WAS_TENSE, bpr);
    register_vu(could_V, be_V, past_participle, by_V, 0, FALSE, WAS_TENSE, bpr);
```

This code is used in §18.

§**21.** "To be able to see", "to be unable to see", "to be able to be seen by", "to be unable to be seen by".

⟨Able or unable to plus infinitive or past participle for prepositional forms 21⟩ ≡

```
register_pu(able_V, to_V, infinitive, 0, 0, FALSE, root);
register_pu(unable_V, to_V, infinitive, 0, 0, FALSE, root)->negated_sense = TRUE;
if (past_participle) {
    binary_predicate *bpr = bp_get_reversal(root);
    register_pu(able_V, to_V, be_V, past_participle, by_V, FALSE, bpr);
    register_pu(unable_V, to_V, be_V, past_participle, by_V, FALSE, bpr)
        ->negated_sense = TRUE;
}
```

This code is used in §18.

§**22. Late registration of prepositions comparing properties.** The following routines, used only when all the properties have been created, make suitable comparatives ("bigger than", etc.) and prepositional usages to test property-equality ("the same height as").

```
void register_comparative_preposition(int wn, binary_predicate *root) {
    set_where_created = current_sentence;
    register_pu(lw_array[wn].lw_identity, than_V, 0, 0, 0, FALSE, root);
}
void register_same_property_as_preposition(binary_predicate *root) {
    set_where_created = current_sentence;
    preposition_usage *pu =
        register_pu(the_V, same_V, STROKE_V, as_V, 0, FALSE, root);
    pu->is_same_property_as = bp_get_same_as_property(root);
}
```

The function register_comparative_preposition is called from 9/cmpbp.
The function register_same_property_as_preposition is called from 9/vpbp.

§**23. Parsing new verb declarations.** In addition to the built-in stock, new verbs can be declared from the source text. This is where such text is parsed and acted upon. Before we get here, the sentence is known to have the form:

> The verb to ... implies ...

and the parse node has two children, for the text before and after the primary verb "implies".

```
void parse_new_verb(parse_node *PN) {
    int w1, w2, rw1, rw2, parts1, parts2, i;
    binary_predicate *bp = NULL;
    int to_be_able_to = FALSE;
    set_where_created = current_sentence;
    [[rw1, rw2 <-- PN->down->next->next]];
    ⟨Find the underlying relation of the new verb or preposition 24⟩;
    [[w1, w2 <-- PN->down->next]];
    [[w1, w2 == the verb ... --> w1, w2]];
    parts1 = -1; parts2 = -1;
    if [[w1, w2 == ... OPENBRACKET ... CLOSEBRACKET : i --> w1, w2 ... parts1, parts2]] ;
    if [[w1, w2 == to be]] {
        sentence_problem(_P_(C5VerbRedefinesBe),
            "the verb 'to be' cannot be defined again",
```

```
            "though prepositional forms of it can ('The verb to be alongside ...').");
        return;
    } else if [[w1, w2 == to be able to ...]] {
        w1 = w1 + 3;                                    to skip over the words "to be able"
        to_be_able_to = TRUE;
        ⟨Definition makes a new verb usage 27⟩;
    } else if [[w1, w2 == to be ... --> w1, w2]] {
        ⟨Definition makes a new prepositional usage 34⟩;
    } else if [[w1, w2 == to ...]] {
        to_be_able_to = FALSE;
        ⟨Definition makes a new verb usage 27⟩;
    } else internal_error("Verb without infinitive");
}
```

The function parse_new_verb is called from 4/verb.

§24. I: Semantics.

⟨Find the underlying relation of the new verb or preposition 24⟩ ≡

```
    int reversal_flag = FALSE;
    [[rw1, rw2 == the ... --> rw1, rw2]];
    if [[rw1, rw2 == relation]] {
        sentence_problem(_P_(C5VerbRelationVague),
            "that's too vague",
            "calling a relation simply 'relation'.");
        return;
    }
    if [[rw1, rw2 == ... property --> rw1, rw2]]
        ⟨Find the BP corresponding to setting this property 25⟩
    else if [[rw1, rw2 == ... relation --> rw1, rw2]]
        ⟨Find the BP corresponding to this named relation 26⟩
    else {
        sentence_problem(_P_(C5VerbUnknownMeaning),
            "new verbs can only be defined in terms of existing properties "
            "or relations",
            "so the last word should be 'property' or 'relation': thus "
            "'...implies the possession relation' is an example of a valid "
            "definition, this being one of the relations built into Inform.");
        return;
    }
```

This code is used in §23.

§25. The following perhaps looks odd. Why do we delegate to `make_set_property_BP` the business of parsing the property name? What happens if the user typed

> The verb to be mystified by implies the arfle barfle gloop property.

when there is no property of that name? The answer is that we can't check this yet, because verb definitions are read long before properties come into existence. The check will be made later on, and the BP generated by the following call is really only provisional until it is. So for now absolutely any non-empty word range is accepted as the property name.

⟨Find the BP corresponding to setting this property 25⟩ ≡

```
    bp = make_set_property_BP(rw1, rw2);
```

This code is used in §24.

§26.

⟨Find the BP corresponding to this named relation 26⟩ ≡
```
if [[rw1, rw2 == reversed ... --> rw1, rw2]] reversal_flag = TRUE;
if (rw2 > rw1) {
    sentence_problem(_P_(C5VerbRelationLong),
        "that's too long for a relation",
        "whose name has to be a single word followed by 'relation'.");
    return;
}
bp = parse_relation_name(rw1);
if (bp == NULL) {
    sentence_problem(_P_(C5VerbRelationUnknown),
        "new verbs can only be defined in terms of existing relations",
        "all of which have names ending 'relation': thus '...implies the "
        "possession relation' is an example of a valid definition, this "
        "being one of the relations built into Inform.");
    return;
}
if (reversal_flag) bp = bp_get_reversal(bp);
```

This code is used in §24.

§27. IIa: Syntax of a new verb usage.

⟨Definition makes a new verb usage 27⟩ ≡
```
int can_be_used_adjectivally = FALSE;
vocabulary_entry *infinitive = lw_array[w1+1].lw_identity;
vocabulary_entry *present_singular = NULL;
vocabulary_entry *present_plural = NULL;
vocabulary_entry *past = NULL;
vocabulary_entry *past_participle = NULL;
vocabulary_entry *participle = NULL;
⟨Reject with a problem message if verb has no auxiliary and is not conjugated 28⟩;
⟨Parse the parts of speech supplied for the verb 29⟩;
⟨Reject with a problem message if this verb has been defined before 32⟩;
⟨Register the new verb 33⟩;
```

This code is used in §23.

§28.

⟨Reject with a problem message if verb has no auxiliary and is not conjugated 28⟩ ≡
```
if ((parts1 < 0) && (to_be_able_to == FALSE)) {
    sentence_problem(_P_(C5VerbWithoutParts),
        "new verbs can't be defined with infinitive alone",
        "and should have all parts supplied: for instance, 'The verb "
        "to sport (he sports, they sport, he sported, it is sported, "
        "he is sporting) ...'");
    return;
}
```

This code is used in §27.

§**29.** We read the parts of speech as a comma-separated list of individual parts (but we don't allow "and" or "or" to divide this list: only commas).

At the end, if no present plural is supplied, we may as well use the infinitive for that – the two are the same in most regular English verbs ("to sleep", "they sleep") even if not irregular ones ("to be", "they are").

⟨Parse the parts of speech supplied for the verb 29⟩ ≡

```
int more_to_read = TRUE;
while (more_to_read) {
    int c1 = parts1, c2 = parts2, i;
    if [[c1, c2 == ... COMMA ... : i --> c1, c2 ... parts1, parts2]]
        more_to_read = TRUE;
    else
        more_to_read = FALSE;
    ⟨Parse the part of speech in this clause 30⟩;
}
if (present_plural == NULL) present_plural = infinitive;
```

This code is used in §27.

§**30.** Note that the suffix "-ing" is used to distinguish the present participle ("he is grabbing") from the past ("he is grabbed").

⟨Parse the part of speech in this clause 30⟩ ≡

```
int number = 0;
if [[c1, c2 == he/she/it ... --> c1, c2]] number = 1;
else if [[c1, c2 == they ... --> c1, c2]] number = 2;
else ⟨Give up on verb definition as malformed 31⟩;
int is_a_participle = FALSE;
if [[c1, c2 == is ... --> c1, c2]] is_a_participle = TRUE;
if [[c1, c2 == ... OPENBRACKET adjectival CLOSEBRACKET --> c1, c2]]
    can_be_used_adjectivally = TRUE;
if (c1 != c2) ⟨Give up on verb definition as malformed 31⟩;
if (is_a_participle) {
    if (vocab_test_flags(c1, ING_MC)) participle = lw_array[c1].lw_identity;
    else past_participle = lw_array[c1].lw_identity;
} else {
    if (number == 2) {
        if (present_plural) {
            sentence_problem(_P_(C5PresentPluralTwice),
                "the present plural has been given twice",
                "since two of the principal parts of this verb begin "
                "with 'they'.");
        }
        present_plural = lw_array[c1].lw_identity;
    } else {
        if (present_singular) past = lw_array[c1].lw_identity;
        else present_singular = lw_array[c1].lw_identity;
    }
}
```

This code is used in §29.

§**31.** A catch-all problem message:

⟨Give up on verb definition as malformed 31⟩ ≡
```
sentence_problem(_P_(C5VerbMalformed),
    "this verb's definition is malformed",
    "and should have its principal parts supplied like so: 'The verb "
    "to sport (he sports, they sport, he sported, it is sported, "
    "he is sporting) ...' As in this example, the verb must be a "
    "single word, so 'to sport' is allowed but not 'to run over'.");
return;
```

This code is used in §30.

§**32.** As the slightly evasive wording of these problem messages suggests, it's not so much a matter of the new verb coinciding with an old one as overlapping with it. We possibly reject more than we need to, but it seems wise to be cautious.

⟨Reject with a problem message if this verb has been defined before 32⟩ ≡
```
verb_usage *duplicate_vu = NULL;
if (to_be_able_to)
    duplicate_vu = find_vu(able_V, to_V, infinitive, 0, 0);
else
    duplicate_vu = find_vu(present_singular, 0, 0, 0, 0);
if (duplicate_vu) {
    if (duplicate_vu->where_vu_created)
        two_sentences_problem(_P_(C5DuplicateVerbs1),
            duplicate_vu->where_vu_created,
            "this gives us two definitions of what appears to be the same verb",
            "or at least has the same infinitive form.");
    else
        sentence_problem(_P_(C5DuplicateVerbs2),
            "this verb definition appears to clash with a built-in verb",
            "a table of which can be seen on the Phrasebook index.");
    return;
}
```

This code is used in §27.

§**33.** And the happy ending:

⟨Register the new verb 33⟩ ≡
```
if (to_be_able_to)
    register_to_be_able_to_verb(infinitive, past_participle, bp);
else
    register_regular_verb(present_singular, present_plural, past,
        past_participle, participle, bp, can_be_used_adjectivally);
```

This code is used in §27.

§34. IIb: Syntax of a new prepositional usage. This runs along much the same lines.

⟨Definition makes a new prepositional usage 34⟩ ≡
```
int unexpected_upper_casing_used = FALSE, noun_like = FALSE;
vocabulary_entry *word_one = NULL, *word_two = NULL, *word_three = NULL;
⟨Reject with a problem message if preposition is conjugated 35⟩;
⟨Find the one to three words making up the preposition 36⟩;
⟨Determine if unexpected upper casing is used in preposition 37⟩;
⟨Reject with a problem message if this preposition has been defined before 38⟩;
⟨Register the new preposition 39⟩;
```

This code is used in §23.

§35. This funny little problem message is the price we pay for blurring grammar in the syntax provided for users. They shouldn't really use the same sentence form to define prepositions as they do to define verbs: but it's easy to remember, and convenient, and no alternative seems better, so we go along with it, and allow

The verb to be beneath implies ...

even though this is not the definition of a verb at all, and it is only "beneath" which is being defined. Prepositions do not inflect in English when used in different tenses or when negated, so there's no conjugation involved, and we need to reject any attempt – even though it would be perfectly valid if a verb were being defined.

⟨Reject with a problem message if preposition is conjugated 35⟩ ≡
```
if (parts1 >= 0) {
    sentence_problem(_P_(C5PrepositionConjugated),
        "the principal parts of 'to be' are known already",
        "so should not be spelled out again as part of the instructions "
        "for this new preposition.");
    return;
}
```

This code is used in §34.

§36.

⟨Find the one to three words making up the preposition 36⟩ ≡
```
if (w2>w1+2) {
    sentence_problem(_P_(C5PrepositionLong),
        "prepositions can only be up to three words long",
        "so 'to be very roughly alongside' is allowed, but 'to be "
        "frankly far away from' is not.");
    return;
}
if [[w1, w2 == part/parts of]] noun_like = TRUE;
word_one = lw_array[w1].lw_identity;
if (w2>w1) word_two = lw_array[w1+1].lw_identity;
if (w2>w1+1) word_three = lw_array[w1+2].lw_identity;
```

This code is used in §34.

§**37.** Casing problems are acutely problematic with prepositions, because so many locations have names which begin with them – "Under Milkwood", "Inside the Machine", "On Top of Old Smoky". Our best way to avoid confusion is to read prepositions as such only when they do not unexpectedly jump into upper case, i.e., to distinguish between the meanings of

X is in Bahrain. Y is In Bahrain.

according to the unexpected capital I in the second "In". But just occasionally people do want to define prepositions which genuinely involve an unexpected upper-case letter; and those we flag for special treatment, since otherwise they could never be parsed successfully.

⟨Determine if unexpected upper casing is used in preposition 37⟩ ≡

```
if (unexpectedly_upper_case(w1)) unexpected_upper_casing_used = TRUE;
if ((w2>w1) && (unexpectedly_upper_case(w1+1))) unexpected_upper_casing_used = TRUE;
if ((w2>w1+1) && (unexpectedly_upper_case(w1+2))) unexpected_upper_casing_used = TRUE;
```

This code is used in §34.

§**38.** And once again:

⟨Reject with a problem message if this preposition has been defined before 38⟩ ≡

```
preposition_usage *duplicate_pu = NULL;
duplicate_pu = find_pu(word_one, word_two, word_three, 0, 0);
if (duplicate_pu) {
    if (duplicate_pu->where_pu_created)
        two_sentences_problem(_P_(C5DuplicateVerbs3),
            duplicate_pu->where_pu_created,
            "this gives us two definitions of what appears to be the "
            "same prepositional form",
            "or at least has the same words in.");
    else
        sentence_problem(_P_(BelievedImpossible),                    none are built in nowadays
            "this definition appears to clash with a built-in "
            "prepositional form",
            "a list of which can be seen on the Phrasebook index.");
    return;
}
```

This code is used in §34.

§**39.** And the happy ending:

⟨Register the new preposition 39⟩ ≡

```
preposition_usage *pu = register_pu(word_one, word_two, word_three, 0, 0, FALSE, bp);
pu->allow_unexpected_upper_case = unexpected_upper_casing_used;
pu->implicitly_behave_as_noun = noun_like;
```

This code is used in §34.

Adjectives 5/aph

Purpose

To identify the names of all adjectives used in source text, and to organise the multiple different senses each adjective might have.

Definitions

¶1. Chapter 5's tour of linguistic categories has already taken in determiners, verbs and prepositions. Next we cover adjectives, which will turn out to be simpler; subsequent sections will cover nouns, which will turn out not to be so easy.

Adjectives are simpler than verbs since they define unary rather than binary predicates. The word "open" applies to only one term – logically, we regard it as *open*(x), whereas a verb like "suspects" would appear in formulae as *suspects*(x, y).

But they are more complicated than verbs in that Inform allows multiple definitions of the same adjective. For instance, two of the senses of "empty" in the Standard Rules are:

> Definition: a text is empty rather than non-empty if it is "".
>
> Definition: a table-name is empty rather than non-empty if the number of filled rows in it is 0.

(Which also defines two of the senses of "non-empty", another adjective.) The clause *empty*(x) can be fully understood only when we know what kind of value x has; for a text, the first sense applies, and for a table-name, the second.

Instances of the `adjectival_phrase` structure correspond exactly to names of adjectives. Thus a single `adjectival_phrase` exists for "empty", and another for "non-empty". The structure records just one thing: a linked list of `adjective_meaning` structures, of which there is one for each sense. (In all, the Standard Rules define six senses of "empty", each one getting its own `adjective_meaning` structure.)

We eventually need to sort this list of definitions into logical priority order – so that a definition applying to just Count Dracula precedes one applying to men, which in turn precedes one applying to things. (Priority order is irrelevant when two senses apply to domains with no overlap, as in the case of texts and table-names.) It's convenient and costs little memory to keep the sorted list as a second linked list.

```
typedef struct adjectival_phrase {
    int word_ref1, word_ref2;                                  text of what is defined
    struct adjective_meaning *possible_meanings;               list of definitions in order given
    struct adjective_meaning *sorted_meanings;                 the same list sorted into logical order
    MEMORY_MANAGEMENT
} adjectival_phrase;
```

The structure adjectival_phrase is private to this section.

¶2. Each individual sense of an adjective, then, has its own `adjective_meaning` structure, which we define next. It consists of some logistical data to keep its place in the linked lists (see above), some data to specify its domain (see below), some indexing data which is not very important, and then the crucial part: its "detailed meaning".

The general model is that adjective meanings come in different "kinds", for which specific code is scattered across Inform. In each case, the `detailed_meaning` points to an appropriate data structure, and specialised routines are called to create and use the adjective.

We can also specify that the meaning implied by this pointer is to be understood reversely: that the adjective is the negation of the one specified. This enables "non-empty" for texts (say) to be defined identically with "empty" for texts, but with the `meaning_parity` flag set to `FALSE` rather than `TRUE`.

```
define CONDITION_KADJ 1                                  defined by a condition in I7 source text
define PHRASE_KADJ 2                                     defined by an explicit but nameless rule
define I6_ROUTINE_KADJ 3                                 defined by a named I6 routine
define I6_CONDITION_KADJ 4                               defined by an explicit I6 schema
define MEASUREMENT_KADJ 5                                defined by numerical comparison with a property value
define ENUMERATIVE_KADJ 6                                defined by a property like "colour" with named values
define EORP_KADJ 7                                       defined by an either/or property like "closed"

typedef struct adjective_meaning {
    int index_w1, index_w2;                              text to use in the Phrasebook index
    struct parse_node *defined_at;                       from what sentence this came (if it did)
    struct adjectival_phrase *owning_adjective;          of which this is a definition
    struct adjective_meaning *next_meaning;              next in order of definition
    struct adjective_meaning *next_sorted;               next in logically sorted order
    int definition_domain_w1, definition_domain_w2;      domain to which defn applies
    struct kind_of_value *domain_kov;                    resolved into a KOV
    struct world_object *domain_wo;                      used only for specific objects as domain
    int problems_thrown;                                 complaining about the domain of this adjective
    int meaning_parity;                                  meaning understood positively?
    struct adjective_meaning *am_negated_from;           if explicitly constructed as such
    int adjective_form;                                  one of the *_KADJ constants: see below
    general_pointer detailed_meaning;                    to the relevant structure
    int task_via_support_routine[NO_ADJECTIVE_TASKS + 1];
    struct i6_schema i6s_to_transfer_to_SR[NO_ADJECTIVE_TASKS + 1];   where TRUE
    struct i6_schema i6s_for_runtime_task[NO_ADJECTIVE_TASKS + 1];    where TRUE
    int am_ready_flag;                                   optional flag to mark whether schemas prepared yet
    int defined_already;                                 temporary workspace used when compiling support routines
    MEMORY_MANAGEMENT
} adjective_meaning;
```

The structure adjective_meaning is private to this section.

¶3. What are adjectives for? Since an adjective is a unary predicate, it can be thought of as an assignment from its domain set to the set of two possibilities: true, false. Thus one sense of "open" maps doors to true if they are currently open, false if they are closed.

There are altogether five things we might want to do with an adjective:

(1) Test whether it is true at any given point during play.
(2) Assert that it is true at the start of play.
(3) Assert that it is false at the start of play.
(4) Assert that it is now to be true from this point on during play.
(5) Assert that it is now to be false from this point on during play.

We do not need to test whether it is false, since we need only test whether it is true and negate the result.

Adjectives for which all five of these operations can be carried out are the exception rather than the rule. "Open" is an example:

[1] if the marble door is open, ...

[2] The marble door is open.

[3] The marble door is not open.

[4] now the marble door is open;

[5] now the marble door is not open;

Every adjective in practice supports (1), testing for truth, but this is not required by the code below. Many adjectives – properly speaking, many senses of an adjective – only support testing: "empty" in the sense of texts, for instance.

Of the five possibilities, (1), (4) and (5) happen at run-time. These are called "tasks" and are identified by the following constants. While in theory an adjective's handling code can compile anything it likes to carry out these tasks, in practice most are defined by providing an I6 schema, which is why the `adjective_meaning` structure contains these – see below.

```
define NO_ADJECTIVE_TASKS 3
define TEST_ADJECTIVE_TASK 1                    test if currently true
define NOW_ADJECTIVE_TRUE_TASK 2                assert now true
define NOW_ADJECTIVE_FALSE_TASK 3               assert now false
```

¶4. For indexing (only) we need to run through the definitions of a given adjectival phrase in sorted order, so:

```
define LOOP_OVER_SORTED_MEANINGS(aph, am)
    for (am = aph_get_sorted_definition_list(aph); am; am=am->next_sorted)
```

¶5. Two adjectival phrases are special, and are needed by the Creator to ensure that newly made objects have the right naming.

```
adjectival_phrase *plural_named_aph = NULL;
adjectival_phrase *proper_named_aph = NULL;
```

---

§**1. Adjectival phrases.** These are registered as excerpt meanings with the `ADJECTIVE_MC` meaning code, so parsing a word range to match an adjective is easy. By construction there is only one `adjectival_phrase` for any given excerpt of text, so the following is unambiguous:

```
adjectival_phrase *aph_parse(int w1, int w2) {
    meaning_list *ml = SP_excerpt(ADJECTIVE_MC, w1, w2);
    if (ml == NULL) return NULL;
    return RETRIEVE_POINTER_adjectival_phrase(em_data(ml_meaning(ml)));
}
```

The function aph_parse is called from 12/cinv.

§**2.** Given a word range, we return its corresponding APH, creating it if necessary:

```
adjectival_phrase *aph_from_word_range(int w1, int w2) {
    adjectival_phrase *aph;
    aph = aph_parse(w1, w2);
    if (aph) return aph;
    aph = CREATE(adjectival_phrase);
    aph->word_ref1 = w1; aph->word_ref2 = w2;
    if [[w1, w2 == plural_named]] plural_named_aph = aph;
    if [[w1, w2 == proper_named]] proper_named_aph = aph;
    aph->possible_meanings = NULL; aph->sorted_meanings = NULL;
    if ((w1 == w2) && (vocab_test_flags(w1, ARTICLE_MC))) {
        sentence_problem(_P_(C5ArticleAsAdjective),
            "a defined adjective cannot consist only of an article such as "
            "'a' or 'the'",
            "since this will lead to parsing ambiguities.");
    } else
    register_excerpt_meaning(ADJECTIVE_MC, 0, w1, w2, STORE_POINTER_adjectival_phrase(aph));
    LOGIF(QUANTITY_CREATIONS, "Created adjectival phrase: $a\n", aph);
    return aph;
}
```

§**3. The list of definitions.** The following assigns a new meaning to a given word range: we find the appropriate APH (creating if necessary) and then add the new meaning to the end of its unsorted meaning list.

```
adjectival_phrase *am_declare(adjective_meaning *am, int w1, int w2) {
    adjectival_phrase *aph = aph_from_word_range(w1, w2);
    adjective_meaning *aml = aph->possible_meanings;
    if (aml == NULL) aph->possible_meanings = am;
    else {
        while (aml->next_meaning) aml = aml->next_meaning;
        aml->next_meaning = am;
    }
    am->next_meaning = NULL;
    am->owning_adjective = aph;
    return aph;
}
```

The function am_declare is called from 9/qty, 9/prop, 9/madj and 12/def.

§**4.** Once declared, an AM stays with the same APH for the whole of Inform's run, and it can only be declared once. So every AM belongs to one and only one APH, which we can read off as follows:

```
adjectival_phrase *am_get_aph(adjective_meaning *am) {
    return am->owning_adjective;
}
```

The function am_get_aph is called from 9/prop.

§**5.** After meanings have been declared, a typical APH will have a disordered "possible meaning" list and an empty "sorted meaning" list. The following sorts the possibles list into the sorted list.

```
void aph_sort_meanings(adjectival_phrase *aph) {
    if (aph == NULL) internal_error("tried to sort meanings for null APH");
    aph->sorted_meanings = am_list_sort(aph->possible_meanings);
}
adjective_meaning *am_list_sort(adjective_meaning *unsorted_head) {
    adjective_meaning *sorted_head = NULL;
    adjective_meaning *am, *am2;
    for (am = unsorted_head; am; am = am->next_meaning)
        if (am->domain_kov == NULL)
            am_set_definition_domain(am, FALSE);
    for (am = unsorted_head; am; am = am->next_meaning) {
        if (sorted_head == NULL) {
            sorted_head = am;
            am->next_sorted = NULL;
        } else {
            adjective_meaning *lastdef = NULL;
            for (am2 = sorted_head; am2; am2 = am2->next_sorted) {
                if (compare_ams(am, am2) == 1) {
                    if (lastdef == NULL) {
                        sorted_head = am;
                        am->next_sorted = am2;
                    } else {
                        lastdef->next_sorted = am;
```

```
                    am->next_sorted = am2;
                }
                break;
            }
            if (am2->next_sorted == NULL) {
                am2->next_sorted = am;
                am->next_sorted = NULL;
                break;
            }
            lastdef = am2;
        }
    }
}
return sorted_head;
}
```

§**6.** And voilà, the result can be read here:

```
adjective_meaning *aph_get_sorted_definition_list(adjectival_phrase *aph) {
    return aph->sorted_meanings;
}
```

§**7. Logging.** To identify an adjective in the debugging log:

```
void log_adjectival_phrase(adjectival_phrase *aph) {
    if (aph == NULL) { LOG("<null adjectival phrase>"); return; }
    if (logging_to_I6_text) LOG("'$W'", aph->word_ref1, aph->word_ref2);
    else LOG("A%d'$W'", aph->allocation_id, aph->word_ref1, aph->word_ref2);
}
```

The function log_adjectival_phrase is called from 2/dl and 6/aprop.

§**8.** And here we log the unsorted meaning list.

```
void aph_log_meanings(adjectival_phrase *aph) {
    adjective_meaning *am;
    int n;
    if (aph == NULL) { LOG("<null-APH>\n"); return; }
    for (n=1, am = aph->possible_meanings; am; n++, am = am->next_meaning)
        LOG("%d: $W ($u; $O)\n", n, am->index_w1, am->index_w2,
            am->domain_kov, am->domain_wo);
}
```

§**9. Individual meanings.** So you want to define a new meaning for an adjective? Here's the procedure:

(1) Call `am_new` to create it. The `form` should be one of the `*_KADJ` constants, and the `details` should contain a pointer to the data structure it uses. The word range is used for indexing only.
(2) Call `am_declare` to associate it with a given adjective name, and thus have it added to the possible meanings list of the appropriate APH.
(3) Give it a domain of definition (see below).
(4) Optionally, give it explicit I6 schemas for testing and asserting (see below) – this makes coding what the adjective compiles to much easier.

```
adjective_meaning *am_new(int form, general_pointer details, int ix1, int ix2) {
    int i;
    adjective_meaning *am = CREATE(adjective_meaning);
    am->defined_at = current_sentence;
    am->index_w1 = ix1; am->index_w2 = ix2;
    am->owning_adjective = NULL;
    am->next_meaning = NULL;
    am->next_sorted = NULL;
    am->definition_domain_w1 = -1; am->definition_domain_w2 = -1;
    am->domain_kov = NULL; am->domain_wo = NULL;
    am->adjective_form = form;
    am->detailed_meaning = details;
    am->defined_already = FALSE;
    am->problems_thrown = 0;
    am->meaning_parity = TRUE;
    am->am_ready_flag = FALSE;
    for (i=1; i<=NO_ADJECTIVE_TASKS; i++) {
        am->task_via_support_routine[i] = NOT_APPLICABLE;
        sch_write_to_existing(&(am->i6s_for_runtime_task[i]), "");
        sch_write_to_existing(&(am->i6s_to_transfer_to_SR[i]), "");
    }
    am->am_negated_from = NULL;
    return am;
}
```

The function am_new is called from 9/qty, 9/prop, 9/madj and 12/def.

§**10.** Negating an AM. If you want to define an adjective as the logical negation of an existing one, take any AM which has been through stages (1) to (4) and then apply `am_negate` to create a new AM. Then use `am_declare` to associate this with a (presumably different) name, but there's no need to specify its I6 schemas or its domain – those are inherited.

```
adjective_meaning *am_negate(adjective_meaning *am) {
    int i;
    adjective_meaning *neg = CREATE(adjective_meaning);
    neg->defined_at = current_sentence;
    neg->index_w1 = am->index_w1; neg->index_w2 = am->index_w2;
    neg->owning_adjective = NULL;
    neg->next_meaning = NULL;
    neg->next_sorted = NULL;
    neg->definition_domain_w1 = am->definition_domain_w1;
    neg->definition_domain_w2 = am->definition_domain_w2;
    neg->domain_kov = am->domain_kov; neg->domain_wo = am->domain_wo;
    neg->adjective_form = am->adjective_form;
```

```
    neg->detailed_meaning = am->detailed_meaning;
    neg->defined_already = FALSE;
    neg->problems_thrown = 0;
    neg->am_ready_flag = FALSE;
    neg->meaning_parity = (am->meaning_parity)?FALSE:TRUE;
    for (i=1; i<=NO_ADJECTIVE_TASKS; i++) {
        int j = i;
        if (i == NOW_ADJECTIVE_TRUE_TASK) j = NOW_ADJECTIVE_FALSE_TASK;
        if (i == NOW_ADJECTIVE_FALSE_TASK) j = NOW_ADJECTIVE_TRUE_TASK;
        neg->task_via_support_routine[j] = am->task_via_support_routine[i];
        neg->i6s_for_runtime_task[j] = am->i6s_for_runtime_task[i];
        sch_write_to_existing(&(neg->i6s_to_transfer_to_SR[j]), "");
    }
    neg->am_negated_from = am;
    return neg;
}

int am_get_form(adjective_meaning *am) {
    if (am == NULL) return -1;
    return am->adjective_form;
}
```

The function am_negate is called from 12/def.
The function am_get_form is called from 12/def.

§**11. The domain of validity.** Every AM has a clearly defined range of values or objects to which it applies. This can be either a single object, a kind of object, or a kind of value. (It cannot be a single value.)

There are two fields specifying the domain, `domain_kov` and `domain_wo`. Two are needed because a single object is allowed as a domain of an adjective even though it cannot on its own be a KOV. So

(a) either the domain is expressed exactly by `domain_kov` and `domain_wo` is null, or
(b) the domain is a single object (not a kind) in `domain_wo` and `domain_kov` holds the smallest KOV which contains this, that is, the KOV corresponding to its kind.

For example, "odd" for numbers has `domain_kov` equal to `kova(NUMBER_TY)` and `domain_wo` null, while the sense of "odd" created by

> Mrs Elspeth Spong can be odd, eccentric or mildly dotty.

would have `domain_wo` equal to the world object for Mrs Spong and `domain_kov` equal to `kovko(kind_women)`, representing the set of all women.

§**12.** In comparing and testing domains, we use two different levels of matching: weak and strong.

Strong checking makes an exact match, but weak checking blurs the definitions so that two domains are counted as equal if they are close enough that run-time type checking can be used to tell them apart.

In general, any two base KOVs are different even in weak checking – "scene" and "number", for instance. On the other hand, "list of scenes" weakly matches "list of numbers", and "container" weakly matches "animal". As this last example shows, two domains can be completely disjoint and still make a weak match.

```
int domain_weak_match(kind_of_value *kov1, kind_of_value *kov2) {
    if (kov_I6_ID(kov1) == kov_I6_ID(kov2)) return TRUE;
    return FALSE;
}
```

§**13.** Whereas the following makes a strict check of whether a given object is within the domain of an adjective meaning.

```
int domain_wo_compare(world_object *wo, adjective_meaning *am) {
    if (wo == NULL) return TRUE;
    if (am->domain_wo) { if (wo == am->domain_wo) return TRUE; return FALSE; }
    if (kovko_get_kind(am->domain_kov) == NULL) return TRUE;
    if (wo->kind == NULL) return TRUE;
    if ((wo->kind_flag) && (wo == kovko_get_kind(am->domain_kov))) return TRUE;
    if (wo_of_kind(wo, kovko_get_kind(am->domain_kov))) return TRUE;
    return FALSE;
}
```

§**14. Specifying the domain of a new AM.** In principle the domain should be set as soon as the AM is created, but in practice some AMs – those coming from properties – might need to be created very early in Inform's run, at a time when objects and kinds of object do not exist. For those cases, an alternative is to give a word range – "a number", say, or "a container" – and if necessary this is left until later on in the run to parse. (For "a number", it wouldn't be necessary; for "a container", it would.)

To set the domain, call exactly one of the following three routines:

```
void am_set_domain_from_word_range(adjective_meaning *am, int w1, int w2) {
    am->domain_kov = NULL; am->domain_wo = NULL;
    am->definition_domain_w1 = w1; am->definition_domain_w2 = w2;
    am_set_definition_domain(am, TRUE);
}
void am_set_domain_from_wo(adjective_meaning *am, world_object *wo) {
    am->domain_kov = NULL; am->domain_wo = NULL;
    am->definition_domain_w1 = -1; am->definition_domain_w2 = -1;
    if (wo == NULL) am->domain_kov = kova(OBJECT_TY);
    else if (wo->kind_flag) am->domain_kov = kovko(wo);
    else if (wo->kind) { am->domain_kov = kovko(wo->kind); am->domain_wo = wo; }
    else { am->domain_kov = kova(OBJECT_TY); am->domain_wo = wo; }
}
void am_set_domain_from_kov(adjective_meaning *am, kind_of_value *kov) {
    am->domain_kov = kov; am->domain_wo = NULL;
    am->definition_domain_w1 = -1; am->definition_domain_w2 = -1;
}
```

The function am_set_domain_from_word_range is called from 9/madj and 12/def.

The function am_set_domain_from_wo is called from 9/qty.

The function am_set_domain_from_kov is called from 9/qty and 9/prop.

§**15.** And we can read the main domain thus:

```
kind_of_value *am_get_domain(adjective_meaning *am) {
    return am->domain_kov;
}
```

The function am_get_domain is called from 9/prop.

§**16.** In the case where the domain is declared as a word range, the following routine eventually converts it to the correct form. In effect, this is a lazy evaluation trick – the routine is called just before the domain is actually needed.

```
void am_set_definition_domain(adjective_meaning *am, int early) {
    if (am->domain_kov) return;
    if (am->definition_domain_w1 < 0) internal_error("undeclared domain KOV for AM");
    specification *supplied = parse_expression(
        am->definition_domain_w1, am->definition_domain_w2, DESCRIPTIVE_TYPE_EXPCON);
    ⟨Reject domain of adjective if meaning of supplied text is unknown 17⟩;
    ⟨Reject domain of adjective unless a kind of value or description of objects 18⟩;
    kind_of_value *kov = NULL;
    if (family_is(supplied, CONDITION_FMY)) {
        if (spec_get_described_kind(supplied)) kov = kovko(spec_get_described_kind(supplied));
        else if (spec_get_described_kov(supplied)) kov = spec_get_described_kov(supplied);
        else kov = kova(OBJECT_TY);
        ⟨Reject domain of adjective if it is a set of objects which may vary in play 19⟩;
    } else if (family_is(supplied, VALUE_FMY)) kov = kov_when_VALUE_is_evaluated(supplied);
    if (kov == NULL) internal_error("KOVless definition");
    am->domain_kov = kov;
    am->domain_wo = wo_of_CONSTANT_OBJECT_if_any(supplied);
    if (am->domain_wo) am->domain_kov = kovko(am->domain_wo->kind);
}
```

§**17.** Note that we throw only one problem message per AM, as otherwise duplication can't be avoided.

⟨Reject domain of adjective if meaning of supplied text is unknown 17⟩ ≡

```
    if (spec_is_UNKNOWN(supplied)) {
        if ((early) || (am->problems_thrown++ > 0)) return;
        LOG("Domain text: $W\n", am->definition_domain_w1, am->definition_domain_w2);
        current_sentence = am->defined_at;
        adjective_problem(_P_(C5AdjDomainUnknown),
            am->index_w1, am->index_w2, am->definition_domain_w1, am->definition_domain_w2,
            "this isn't a thing, a kind of thing or a kind of value",
            "and indeed doesn't have any meaning I can make sense of.");
        return;
    }
```

This code is used in §16.

§**18.** Similarly:

⟨Reject domain of adjective unless a kind of value or description of objects 18⟩ ≡

```
if ((spec_is_actual_CONSTANT(supplied)) &&
    (spec_describes_an_object_vaguely_or_exactly(supplied) == FALSE)) {
    if ((early) || (am->problems_thrown++ > 0)) return;
    LOG("Domain text: $S\n", supplied);
    current_sentence = am->defined_at;
    adjective_problem(_P_(C5AdjDomainSurreal),
        am->index_w1, am->index_w2, am->definition_domain_w1, am->definition_domain_w2,
        "this isn't allowed as the domain of a definition",
        "since adjectives like this can be applied only to specific things, "
        "kinds of things or kinds of values: so 'Definition: a door is ajar "
        "if...' is fine, because a door is a kind of thing, and 'Definition: "
        "a number is prime if ...' is fine too, but 'Definition: 5 is prime "
        "if ...' is not allowed.");
    return;
}
```

This code is used in §16.

§**19.** And a final possible objection:

⟨Reject domain of adjective if it is a set of objects which may vary in play 19⟩ ≡

```
if (spec_is_qualified_DESCRIPTION(supplied)) {
    if (am->problems_thrown++ > 0) return;
    current_sentence = am->defined_at;
    adjective_problem(_P_(C5AdjDomainSlippery),
        am->index_w1, am->index_w2, am->definition_domain_w1, am->definition_domain_w2,
        "this is slippery",
        "because it can change during play. Definitions can only be "
        "made in cases where it's clear for any given value or object "
        "what definition will apply. For instance, 'Definition: a "
        "door is shiny if ...' is fine, but 'Definition: an open "
        "door is shiny if ...' is not allowed - Inform wouldn't know "
        "whether or not to apply it to the Big Blue Door (say), since "
        "it would only apply some of the time.");
    return;
}
```

This code is used in §16.

§20. Comparing domains of validity. In order to sort AMs into logical precedence order, we rely on the following routine, which like `strcmp` returns a positive number to favour the first term, a negative to favour the second, and zero if they are equally good. Note that zero is only in fact returned when the two AMs compared are one and the same – we want to ensure that there is one and only one possible sorted state for any given list of AMs.

Suppose the adjectives A_1 and A_2 have domain sets D_1 and D_2. Then:

(i) If $D_1 \subseteq D_2$ and $D_1 \neq D_2$, then A_1 precedes A_2.
(ii) If $D_2 \subseteq D_1$ and $D_2 \neq D_1$, then A_2 precedes A_1.
(iii) If $D_1 = D_2$ or if $D_1 \cap D_2 = \emptyset$ then whichever was created earlier in Inform's run will take precedence.

Those are the only possibilities; the range of possible domains is set up so that there can never be an interesting Venn diagram of overlaps between them.

Unlike our weak domain tests above, this is a strict test.

```
int compare_ams(adjective_meaning *am1, adjective_meaning *am2) {
    kind_of_value *kov1, *kov2;
    int c1, c2;
    if (am1 == am2) return 0;
    if ((am1->domain_wo) && (am2->domain_wo == NULL)) return 1;
    if ((am1->domain_wo == NULL) && (am2->domain_wo)) return -1;
    kov1 = am1->domain_kov; kov2 = am2->domain_kov;
    c1 = can_we_cast_kovs(kov1, kov2); c2 = can_we_cast_kovs(kov2, kov1);
    if ((c1 == ALWAYS_MATCH) && (c2 != ALWAYS_MATCH)) return 1;
    if ((c1 != ALWAYS_MATCH) && (c2 == ALWAYS_MATCH)) return -1;
    return am2->allocation_id - am1->allocation_id;
}
```

§21. Checking an adjective's applicability. If the source tries to apply the word "open", say, to a given value or object X, when does that make sense?

We can only find out by checking every possible meaning of "open" to see if it can accommodate the kind of value of X. But this time we use weak checking, and make it weaker still since a null KOV is taken to mean "any object", either in the AM's definition – which can happen if we are very early in Inform's run – or because the caller doesn't actually know the kind of value of X. (In other words, adjectives tend to assume they apply to objects rather than other values.) This means we will accept some logically impossible outcomes – we would say that it's acceptable to apply "open" to an animal, say – but that is actually a good thing. It means that "list of open things" or "something open" are allowed. Source text such as:

```
The labrador puppy is an open animal.
```

will successfully parse, but then result in higher-level problem messages in Chapter 9. The following does compile:

```
now the labrador puppy is open;
```

but results in a run-time problem message when it executes.

It makes no difference what order we check the AMs in, so we can use the unsorted list, which is helpful since we may need to call this routine early in the run when sorting cannot yet be done.

```
int aph_applicable_to(adjectival_phrase *aph, kind_of_value *kov) {
    adjective_meaning *am;
    for (am = aph->possible_meanings; am; am = am->next_meaning) {
        if (am->domain_kov == NULL) am_set_definition_domain(am, FALSE);
        if (is_kova(am->domain_kov, OBJECT_TY)) {
            if (kov == FALSE) return TRUE;
```

```
            if (is_kova(kov, OBJECT_TY)) return TRUE;
        } else {
            if ((kov) && (is_kova(kov, OBJECT_TY) == FALSE) &&
                (can_we_cast_kovs(kov, am->domain_kov) == ALWAYS_MATCH))
                return TRUE;
        }
    }
    return FALSE;
}
```

The function aph_applicable_to is called from 5/candd and 6/tcpr.

§**22. Broad applicability tests.** Does a given APH have any interpretation as an enumerated property value, or an either/or property? If so we return the earliest known.

```
quantity *aph_has_ENUMERATIVE_meaning(adjectival_phrase *aph) {
    adjective_meaning *am;
    for (am = aph->possible_meanings; am; am = am->next_meaning)
        if (am->adjective_form == ENUMERATIVE_KADJ)
            return RETRIEVE_POINTER_quantity(am->detailed_meaning);
    return NULL;
}
property_name *aph_has_EORP_meaning(adjectival_phrase *aph) {
    adjective_meaning *am;
    for (am = aph->possible_meanings; am; am = am->next_meaning)
        if (am->adjective_form == EORP_KADJ)
            return RETRIEVE_POINTER_property_name(am->detailed_meaning);
    return NULL;
}
```

The function aph_has_ENUMERATIVE_meaning is called from 5/mlc, 6/term, 7/tc, 8/refpt, 10/tab and 13/tfg.
The function aph_has_EORP_meaning is called from 5/mlc, 6/term, 6/prop, 7/tc, 8/refpt, 8/imp and 13/tfg.

§23. Asserting the initial state. All that domain-checking machinery means we can begin to use an adjective.

Suppose an assertion sentence in the source text claims that, in the initial state of things, what the adjective tests is true. For example:

> The ormolu clock is fixed in place.

The S-parser, finding that this sentence is syntactically reasonable, identifies "fixed in place" as an adjective, and stores a pointer to its APH structure, but goes no further. Later on, the A-parser, working through sentences like this, works out that the adjective is to be applied to the world object "ormolu clock", whose KOV is "thing"; and that the sentence asserts a truth, not a falsity. It then calls the following routine, with `parity` equal to `TRUE`.

What happens is that the list of definitions for "fixed in place" is strictly checked in logical precedence order, and that `am_assert` is eventually called on the logically narrowest definition which the "ormolu clock" matches. (That will probably be the definition for the "fixed in place" either/or property for things, unless someone has given the adjective some special meaning unique to the clock.)

The following routine therefore acts as a junction-box, deciding which sense of the adjective is to be applied. We return `TRUE` if we were able to find a definition which could be asserted and which the clock matched, and `FALSE` if there was no definition which applied, or if none of those which did could be asserted for it.

```
int aph_assert(adjectival_phrase *aph, kind_of_value *kov_domain,
    world_object *wo_to_assert_on, specification *val_to_assert_on, int parity) {
    adjective_meaning *am;
    aph_sort_meanings(aph);
    for (am = aph->sorted_meanings; am; am = am->next_sorted) {
        if (domain_weak_match(kov_domain, am->domain_kov) == FALSE) continue;
        if (domain_wo_compare(wo_to_assert_on, am) == FALSE) continue;
        if (am_assert(am, wo_to_assert_on, val_to_assert_on, parity)) return TRUE;
    }
    return FALSE;
}
```

The function aph_assert is called from 6/asp.

§24. Testing and asserting in play. That takes care of two of the uses for an adjective, and now the other three: testing, making true and making false in play. We won't be there when the story file is played, of course, so what we have to do is to compile code to perform the test or force the state.

In fact what we do is to supply an I6 schema, which for this purpose is simply the text of I6 code in which the escape `*1` represents the value to which the adjective is applied. In the example of "open" for containers, we might choose:

```
if the sack is open, ...  -->   (Adj_53_t1_v61(*1))
now the sack is open; ...  -->   Adj_53_t2_v61(*1)
now the sack is not open; ...  -->   Adj_53_t3_v61(*1)
```

These schemas call an I6 routine called a "support routine". The names here are schematic: "open" on this run was APH number 53, the run-time tasks to perform were task 1, task 2 and task 3, and the sense of the adjective was the one applying to (weak) domain 61 – which in this run was the value of `OBJECT_TY`. In other words, these are routines to "test open in the sense of objects", "now open in the sense of objects", and "now not open in the sense of objects".

If we make a choice like that, then we say that the task is provided "via a support routine". We need not do so: for instance,

```
if the Entire Game is happening, ...  -->  (scene_status->(*1 - 1)==1)
```

is an example where the sense of "happening" for scenes can be tested directly using a schema, without calling a support routine. And clearly support routines only put off the problem, because we will also have

to compile the routine itself. So why use them? The answer is that in complicated situations where run-time type checking is needed, they avoid duplication of code, and can make repeated use of the `*1` value without repeating any side-effects produced by the calculation of this value. They also make the code simpler for human eyes to read.

§**25.** When an AM has been declared, the provider can choose to set an I6 schema for it, for any of the tasks, immediately; or can wait and do it later; or can choose not to do it, and instead provide code which generates a suitable schema on the fly. If at whatever stage the provider does set an I6 schema for a task, it should call the following.

Note that any AM working on objects always has to go via a support routine – this is because, thanks to weak domain-checking, there may be run-time type-checking code to apply. In other cases, the provider can choose to go via a support routine or not.

```
i6_schema *am_set_i6_schema(adjective_meaning *am, int T, int via_support) {
    kind_of_value *kov = am->domain_kov;
    if (kov == NULL) kov = kova(OBJECT_TY);
    if (is_kova(kov, OBJECT_TY)) via_support = TRUE;
    am->task_via_support_routine[T] = via_support;
    return &(am->i6s_for_runtime_task[T]);
}
```

The function am_set_i6_schema is called from 9/qty, 9/prop, 9/madj and 12/def.

§**26.** When Inform's code-generator needs to compile one of the tasks, then, it calls the following to obtain the correct I6 schema.

Note that the `task_via_support_routine` values are not flags: they can be `TRUE` (allowed, done via support routine), `FALSE` (allowed, done directly) or `NOT_APPLICABLE` (the task certainly can't be done). If none of the applicable meanings for the adjective are able to perform the task at run-time, we return `NULL` as our schema, and the code-generator will use that to issue a suitable problem message.

```
i6_schema *aph_get_i6_schema(adjectival_phrase *aph, kind_of_value *kov_domain,
    int T) {
    adjective_meaning *am;
    if (kov_domain == NULL) kov_domain = kova(OBJECT_TY);
    aph->sorted_meanings = am_list_sort(aph->possible_meanings);
    for (am = aph->sorted_meanings; am; am = am->next_sorted) {
        if (am->domain_kov == NULL) am_set_definition_domain(am, FALSE);
        if (domain_weak_match(kov_domain, am->domain_kov) == FALSE) continue;
        am_compiling_soon(am, T);
        switch (am->task_via_support_routine[T]) {
            case FALSE: return &(am->i6s_for_runtime_task[T]);
            case TRUE:
                if (sch_empty(&(am->i6s_to_transfer_to_SR[T])))
                    sch_write_to_existing_3d(&(am->i6s_to_transfer_to_SR[T]),
                        "Adj_%d_t%d_v%d(*1)",
                        aph->allocation_id, T, kov_I6_ID(am->domain_kov));
                return &(am->i6s_to_transfer_to_SR[T]);
        }
    }
    return NULL;
}
```

The function aph_get_i6_schema is called from 6/atoms.

§**27.** The following instructs an AM to use a support routine to handle a given task.

```
void am_pass_task_to_support_routine(adjective_meaning *am, int T) {
    am_set_i6_schema(am, T, TRUE);
}
```

The function am_pass_task_to_support_routine is called from 9/madj and 12/def.

§**28.** Some kinds of adjective find it useful to do some preparation work just before first compilation, but only once. For those, the ready flag is available:

```
int am_get_ready_flag(adjective_meaning *am) {
    return am->am_ready_flag;
}
void am_set_ready_flag(adjective_meaning *am) {
    am->am_ready_flag = TRUE;
}
```

The function am_get_ready_flag is called from 9/prop.
The function am_set_ready_flag is called from 9/prop.

§**29. Support routines.** Using these is only passing the buck: and the buck stops here.

The following utility is used to loop through the sorted meaning list, skipping over any which have been dealt with already.

```
adjective_meaning *am_list_next_domain_kov(adjective_meaning *am, kind_of_value **kov, int T) {
    while ((am) && ((am->defined_already) || (am_compile(am, T, NULL, NULL) == FALSE)))
        am = am->next_sorted;
    if (am == NULL) return NULL;
    *kov = am->domain_kov;
    return am->next_sorted;
}
```

§**30.** And this is where we do the iteration. The idea is that one adjective definition routine is defined (for each task number) which covers all of the weakly-domain-equal definitions for the same adjective. Thus one routine might handle "detailed" for rulebooks, and another might handle "detailed" for all of its meanings associated with objects – possibly many AMs.

```
void aph_compile_support_code(OUTPUT_STREAM) {
    ⟨Ensure, just in case, that domains exist and are sorted on 31⟩;
    int T;
    for (T=1; T<=NO_ADJECTIVE_TASKS; T++) {
        adjectival_phrase *aph;
        LOOP_OVER(aph, adjectival_phrase) {
            adjective_meaning *am;
            for (am = aph->possible_meanings; am; am = am->next_meaning)
                am->defined_already = FALSE;
            for (am = aph->sorted_meanings; am; ) {
                kind_of_value *kov = NULL;
                am = am_list_next_domain_kov(am, &kov, T);
                if (kov)
                    ⟨Compile adjective definition for this atomic kind of value 32⟩;
            }
        }
    }
}
```

The function aph_compile_support_code is called from 12/cs.

§**31.** It's unlikely that we have got this far without the domains for the AMs having been established, but certainly possible. We need the domains to be known in order to sort.

⟨Ensure, just in case, that domains exist and are sorted on 31⟩ ≡

```
adjectival_phrase *aph;
LOOP_OVER(aph, adjectival_phrase) {
    adjective_meaning *am;
    for (am = aph->possible_meanings; am; am = am->next_meaning) {
        am_set_definition_domain(am, FALSE);
        am->defined_already = FALSE;
    }
    aph->sorted_meanings = am_list_sort(aph->possible_meanings);
}
```

This code is used in §30.

§**32.** The following is a standard way to compile a one-off routine; we create a new stack frame, compile the code of the routine, then the header for it, and then fold the stack frame up again.

⟨Compile adjective definition for this atomic kind of value 32⟩ ≡

```
LOGIF(QUANTITY_CREATIONS, "Compiling support code for $W applying to $u, task %d\n",
    aph->word_ref1, aph->word_ref2, kov, T);
ph_stack_frame *phsf;
phsf = phsf_create_nonphrase_stack_frame();
OUT = begin_compiling_phrase(OUT);
begin_code_blocks();
⟨Add an it-variable to represent the value or object in the domain 33⟩;
INDENT;
if (problem_count == 0) am_list_compile(aph->sorted_meanings, OUT, phsf, kov, T);
WRITE("rfalse;\n");
OUTDENT; WRITE("];\n\n");
enable_its = -1;
OUT = write_routine_header();
WRITE("[ Adj_%d_t%d_v%d ! meaning of \"", aph->allocation_id, T, kov_I6_ID(kov));
print_raw_text_within_i6_literal(OUT, aph->word_ref1, aph->word_ref2);
WRITE("\"\n");
copy_compiled_phrase();
end_code_blocks();
phsf_remove_nonphrase_stack_frame();
```

This code is used in §30.

§**33.** The stack frame has just one call parameter: the value x which might, or might not, be such that *adjective*(x) is true. We allow this to be called "it", though it can also have a calling name in some cases (see below).

Clearly it ought to have the KOV which defines the domain – so it's a rulebook if the domain is all rulebooks, and so on – but it doesn't always do so. The exception is that it is bogusly given the KOV "number" if the adjective is being defined only by I6 routines. This is done to avoid compiling very inefficient code from the Standard Rules. For instance, the SR reads, in slightly simplified form:

Definition: an indexed text is empty if I6 routine "INDEXED_TEXT_TY_Empty" says so.

rather than the more obvious:

Definition: an indexed text is empty if it is not "".

Both of these definitions work. But if the routine defining "empty" for indexed text is allowed to act on an indexed text variable, Inform needs to compile code which acts on block values held on the memory heap at run-time. That means it needs to compile a memory heap; and that costs 8K or so of storage, making large Z-machine games which don't need indexed text or lists impossible to fit into the 64K array space limit. (There's also a benefit even if we do need a heap; the adjective can act on a direct pointer to the structure, and no time is wasted allocating memory and copying the block value first.)

⟨Add an it-variable to represent the value or object in the domain 33⟩ ≡

```
int conceal_kov = TRUE;
adjective_meaning *am;
for (am = aph->sorted_meanings; am; am = am->next_sorted)
    if ((am->adjective_form != I6_ROUTINE_KADJ) && (domain_weak_match(kov, am->domain_kov)))
        conceal_kov = FALSE;
if (conceal_kov)
    phsf_add_it_variable(phsf, -1, -1, kova(NUMBER_TY));
else
    phsf_add_it_variable(phsf, -1, -1, kov);
enable_its = 0;                                    the local variable number referred to by "its"
```

This code is used in §32.

§**34.** We run through possible meanings of the APH which share the current weak domain, and compile code which performs the stronger part of the domain test at run-time. In practice, at present the only weak domain which might have multiple definitions is "object", but that may change.

```
void am_list_compile(adjective_meaning *list_head, OUTPUT_STREAM,
    ph_stack_frame *phsf, kind_of_value *kov, int T) {
    adjective_meaning *am;
    for (am = list_head; am; am = am->next_sorted)
        if ((am_compile(am, T, NULL, NULL)) && (domain_weak_match(kov, am->domain_kov))) {
            current_sentence = am->defined_at;
            char cond[1024];
            if (is_kova(am->domain_kov, OBJECT_TY) == FALSE)
                cond[0] = 0;
            else if (am->domain_wo)
                sprintf(cond, "t_0 == %s",
                    wo_get_I6_representation(am->domain_wo));
            else if (kovko_get_kind(am->domain_kov))
                sprintf(cond, "t_0 ofclass %s",
                    wo_get_I6_representation(kovko_get_kind(am->domain_kov)));
            else
                sprintf(cond, "t_0");
```

```
            if (cond[0] != 0) WRITE("  if (%s) ", cond);
            WRITE("return ");
            if ((am->meaning_parity == FALSE) && (T == TEST_ADJECTIVE_TASK)) WRITE("(~~(");
            am_compile(am, T, OUT, phsf);
            if ((am->meaning_parity == FALSE) && (T == TEST_ADJECTIVE_TASK)) WRITE("))");
            WRITE(";\n");
            am->defined_already = TRUE;
        }
}
```

§**35. Kinds of adjectives.** This is where `inweb`'s use of C rather than `C++` or Python as a base language becomes a little embarrassing: we really want to have seven or eight subclasses of an "adjective" class, and provide a group of methods. Instead we simulate this with the following clumsy code. (More elegant code using pointers to functions would trip up `inweb`'s structure-element usage checking.)

To define a new kind of adjective, first allocate it a new `*_KADJ` constant (see above). Then declare functions to handle the following methods.

§**36.** 1. `*_KADJ_parse`. This enables the kind of adjective to claim a definition which the user has explicitly written, like so:

> Definition: A ... (called ...) is ... if ...

In place of the ellipses are the adjective name, domain name, condition text and (optionally) also the calling name. The routine should return a pointer to the AM it creates, if it does want to claim the definition; and `NULL` if it doesn't want it. `sense` is either 1, meaning that "if" was used (the condition has positive sense); or -1, meaning that it was "unless" (a negative sense); or 0, meaning that instead of a condition, a rule was supplied. (Most kinds of adjective will only claim if the sense is 1; some never claim at all.)

```
adjective_meaning *am_parse(parse_node *q,
    int sense,
    int adj_name_w1, int adj_name_w2,
    int dom_name_w1, int dom_name_w2,
    int cond_w1, int cond_w2,
    int called_w1, int called_w2) {
    adjective_meaning *am = NULL;
    if (am == NULL) am = EORP_KADJ_parse(q, sense, adj_name_w1, adj_name_w2,
        dom_name_w1, dom_name_w2, cond_w1, cond_w2, called_w1, called_w2);
    if (am == NULL) am = ENUMERATIVE_KADJ_parse(q, sense, adj_name_w1, adj_name_w2,
        dom_name_w1, dom_name_w2, cond_w1, cond_w2, called_w1, called_w2);
    if (am == NULL) am = MEASUREMENT_KADJ_parse(q, sense, adj_name_w1, adj_name_w2,
        dom_name_w1, dom_name_w2, cond_w1, cond_w2, called_w1, called_w2);
    if (am == NULL) am = I6_CONDITION_KADJ_parse(q, sense, adj_name_w1, adj_name_w2,
        dom_name_w1, dom_name_w2, cond_w1, cond_w2, called_w1, called_w2);
    if (am == NULL) am = I6_ROUTINE_KADJ_parse(q, sense, adj_name_w1, adj_name_w2,
        dom_name_w1, dom_name_w2, cond_w1, cond_w2, called_w1, called_w2);
    if (am == NULL) am = PHRASE_KADJ_parse(q, sense, adj_name_w1, adj_name_w2,
        dom_name_w1, dom_name_w2, cond_w1, cond_w2, called_w1, called_w2);
    if (am == NULL) am = CONDITION_KADJ_parse(q, sense, adj_name_w1, adj_name_w2,
        dom_name_w1, dom_name_w2, cond_w1, cond_w2, called_w1, called_w2);
    return am;
}
```

The function am_parse is called from 12/def.

§**37.** 2. `*_KADJ_compiling_soon`. This warns the adjective that it will shortly be needed in compilation, that is, that code will soon be compiled which uses it. This advance warning is an opportunity to compile a schema for the adjective at the last minute, but there is no obligation. There is also no return value.

```
void am_compiling_soon(adjective_meaning *am, int T) {
    switch (am->adjective_form) {
        case CONDITION_KADJ: CONDITION_KADJ_compiling_soon(am,
            RETRIEVE_POINTER_definition(am->detailed_meaning), T); break;
        case I6_CONDITION_KADJ: I6_CONDITION_KADJ_compiling_soon(am,
            RETRIEVE_POINTER_definition(am->detailed_meaning), T); break;
        case I6_ROUTINE_KADJ: I6_ROUTINE_KADJ_compiling_soon(am,
            RETRIEVE_POINTER_definition(am->detailed_meaning), T); break;
        case PHRASE_KADJ: PHRASE_KADJ_compiling_soon(am,
            RETRIEVE_POINTER_definition(am->detailed_meaning), T); break;
        case MEASUREMENT_KADJ: MEASUREMENT_KADJ_compiling_soon(am,
            RETRIEVE_POINTER_measurement_definition(am->detailed_meaning), T); break;
        case ENUMERATIVE_KADJ: ENUMERATIVE_KADJ_compiling_soon(am,
            RETRIEVE_POINTER_quantity(am->detailed_meaning), T); break;
        case EORP_KADJ: EORP_KADJ_compiling_soon(am,
            RETRIEVE_POINTER_property_name(am->detailed_meaning), T); break;
    }
}
```

§**38.** 3. `*_KADJ_compile`. We should now *either* compile code which, in the given stack frame and writing code to the given file handle, carries out the given task for the adjective, and return `TRUE`; *or* return `FALSE` to tell Inform that the task is impossible.

Note that if an adjective has defined a schema to handle the task, then its `*_KADJ_compile` is not needed and not consulted.

```
int am_compile(adjective_meaning *am, int T, OUTPUT_STREAM, ph_stack_frame *phsf) {
    am_compiling_soon(am, T);
    ⟨Use the I6 schema instead to compile the task, if one exists 39⟩;
    switch (am->adjective_form) {
        case CONDITION_KADJ: return CONDITION_KADJ_compile(
            RETRIEVE_POINTER_definition(am->detailed_meaning), T, OUT, phsf);
        case I6_ROUTINE_KADJ: return I6_ROUTINE_KADJ_compile(
            RETRIEVE_POINTER_definition(am->detailed_meaning), T, OUT, phsf);
        case I6_CONDITION_KADJ: return I6_CONDITION_KADJ_compile(
            RETRIEVE_POINTER_definition(am->detailed_meaning), T, OUT, phsf);
        case PHRASE_KADJ: return PHRASE_KADJ_compile(
            RETRIEVE_POINTER_definition(am->detailed_meaning), T, OUT, phsf);
        case MEASUREMENT_KADJ: return MEASUREMENT_KADJ_compile(
            RETRIEVE_POINTER_measurement_definition(am->detailed_meaning), T, OUT, phsf);
        case ENUMERATIVE_KADJ: return ENUMERATIVE_KADJ_compile(
            RETRIEVE_POINTER_quantity(am->detailed_meaning), T, OUT, phsf);
        case EORP_KADJ: return EORP_KADJ_compile(
            RETRIEVE_POINTER_property_name(am->detailed_meaning), T, OUT, phsf);
    }
    internal_error("unknown KADJ code");
    return FALSE;
}
```

§**39.** We expand the I6 schema, placing the "it" variable – a nameless call parameter which is always local variable number 0 for this stack frame – into `*1`.

⟨Use the I6 schema instead to compile the task, if one exists 39⟩ ≡

```
if (sch_empty(&(am->i6s_for_runtime_task[T])) == FALSE) {
    specification *it_var = new_LOCAL_VARIABLE_spec(-1, -1, 0);
    pcalc_term it_term = term_new_constant(it_var);
    WRITE("(");
    sch_expand(&(am->i6s_for_runtime_task[T]), OUT, &it_term, NULL);
    WRITE(")");
    return TRUE;
}
```

This code is used in §38.

§**40.** 4. `*_KADJ_assert`. We should now *either* take action to ensure that the adjective will hold (or not hold, according to `parity`) for the given object or value; *or* return `FALSE` to tell Inform that this cannot be asserted, which will trigger a problem message.

```
int am_assert(adjective_meaning *am, world_object *wo_to_assert_on,
    specification *val_to_assert_on, int parity) {
    switch (am->adjective_form) {
        case CONDITION_KADJ: return CONDITION_KADJ_assert(
            RETRIEVE_POINTER_definition(am->detailed_meaning),
            wo_to_assert_on, val_to_assert_on, parity);
        case I6_CONDITION_KADJ: return I6_CONDITION_KADJ_assert(
            RETRIEVE_POINTER_definition(am->detailed_meaning),
            wo_to_assert_on, val_to_assert_on, parity);
        case I6_ROUTINE_KADJ: return I6_ROUTINE_KADJ_assert(
            RETRIEVE_POINTER_definition(am->detailed_meaning),
            wo_to_assert_on, val_to_assert_on, parity);
        case PHRASE_KADJ: return PHRASE_KADJ_assert(
            RETRIEVE_POINTER_definition(am->detailed_meaning),
            wo_to_assert_on, val_to_assert_on, parity);
        case MEASUREMENT_KADJ: return MEASUREMENT_KADJ_assert(
            RETRIEVE_POINTER_measurement_definition(am->detailed_meaning),
            wo_to_assert_on, val_to_assert_on, parity);
        case ENUMERATIVE_KADJ: return ENUMERATIVE_KADJ_assert(
            RETRIEVE_POINTER_quantity(am->detailed_meaning),
            wo_to_assert_on, val_to_assert_on, parity);
        case EORP_KADJ: return EORP_KADJ_assert(
            RETRIEVE_POINTER_property_name(am->detailed_meaning),
            wo_to_assert_on, val_to_assert_on, parity);
    }
    internal_error("unknown KADJ code");
    return FALSE;
}
```

§**41.** 5. `*_KADJ_index`. This should print a description of the adjective to the index, for use in the Phrasebook lexicon. Note that it is only needed where the AM has been constructed positively, that is, it is not needed if the AM was made as a negation of something else.

Note also that if the AM was defined with any indexing text then that will be printed if the routine does nothing better.

```
void am_print_to_index(adjective_meaning *am) {
    int rv;
    ⟨Index the domain of validity of the AM 42⟩;
    if (am->am_negated_from) {
        INDEX(" opposite of </i>");
        print_raw_text_to_file(am->am_negated_from->owning_adjective->word_ref1,
            am->am_negated_from->owning_adjective->word_ref2, ifl);
        INDEX("<i>");
    } else {
        switch (am->adjective_form) {
            case CONDITION_KADJ: rv = CONDITION_KADJ_index(
                RETRIEVE_POINTER_definition(am->detailed_meaning)); break;
            case I6_CONDITION_KADJ: rv = I6_CONDITION_KADJ_index(
                RETRIEVE_POINTER_definition(am->detailed_meaning)); break;
            case I6_ROUTINE_KADJ: rv = I6_ROUTINE_KADJ_index(
                RETRIEVE_POINTER_definition(am->detailed_meaning)); break;
            case PHRASE_KADJ: rv = PHRASE_KADJ_index(
                RETRIEVE_POINTER_definition(am->detailed_meaning)); break;
            case MEASUREMENT_KADJ: rv = MEASUREMENT_KADJ_index(
                RETRIEVE_POINTER_measurement_definition(am->detailed_meaning)); break;
            case ENUMERATIVE_KADJ: rv = ENUMERATIVE_KADJ_index(
                RETRIEVE_POINTER_quantity(am->detailed_meaning)); break;
            case EORP_KADJ: rv = EORP_KADJ_index(
                RETRIEVE_POINTER_property_name(am->detailed_meaning)); break;
            default: rv = FALSE; break;
        }
        if ((rv == FALSE) && (am->index_w1 >= 0))
            print_raw_text_to_file(am->index_w1, am->index_w2, ifl);
    }
    index_link(lw_array[am->index_w1].lw_source);
}
```

The function am_print_to_index is called from 2/lexi.

§**42.** This is supposed to imitate dictionaries, distinguishing meanings by concisely showing their usage. Thus "empty" would have indexed entries prefaced "(of a rulebook)", "(of an activity)", and so on.

⟨Index the domain of validity of the AM 42⟩ ≡

```
if ((am->domain_wo) ||
    ((am->domain_kov) && (kov_compare(am->domain_kov, kova(OBJECT_TY)) == FALSE))) {
    INDEX("(of </i>");
    if (am->domain_wo)
        print_raw_text_to_file(am->domain_wo->word_ref1,
            am->domain_wo->word_ref2,
            ifl);
    else if (kovko_get_kind(am->domain_kov))
        print_raw_text_to_file(kovko_get_kind(am->domain_kov)->word_ref1,
            kovko_get_kind(am->domain_kov)->word_ref2,
            ifl);
    else {
        char kovname[1024]; kovname[0] = 0;
        copy_kov_to_string(am->domain_kov, kovname, FALSE);
        print_literal_string_to_file(ifl, kovname);
    }
    INDEX("<i>) ");
}
```

This code is used in §41.

Literal Patterns 5/litp

Purpose

To manage the possible notations with which literal values can be written.

5/litp.§1-3 Creating patterns, tokens and elements; §4-12 Listing LPs; §13 Optional break points; §14-23 Matching an LP in the source text; §24-30 Matching an LP at run-time; §31-36 Indexing literal patterns for a given data type; §37-44 Printing values in an LP's notation to the index at compile-time; §45-53 Printing the I6 variable `value` out in an LP's notation at run-time; §54-72 Creating new literal patterns; §73-75 I7 phrases to print values in specified ways; §76-78 I7 phrases to pack and unpack the value

---

Template interpreter commands

```
74  {-callv:define_named_printing_phrases}
```

Definitions

¶1. Literals are excerpts of text which explicitly specify values, rather than by indirectly naming them. "15" is a literal but "the score" is not, even if it happens to have the value 15. Inform contains specific code to parse literals such as

```
-314, "Morocco leather", 10:41 PM
```

(see "Lexer.w" and "Parsing Literals.w"), but it also has a system allowing the user to create new notations for quasi-numerical kinds of value. For example,

```
16:9 specifies an aspect ratio.
```

establishes a new notation for writing literal aspect ratios. This notation is stored internally as a "literal pattern", and the code to handle it is found in this section. (No other sorts of literal are parsed here.) Each kind of value has a linked list of literal notations which can specify it, if any. We sometimes need to iterate through the this list, and can do so with the following macro:

```
define LITERAL_FORMS_LOOP(lp, data_type)
    for (lp = data_type_list_of_literal_forms(data_type); lp;
        lp=lp->next_for_this_kov)
```

¶2. LPs with just a single numerical part to them (like "20 yards" rather than "16:9") are of special interest for holding scientific measurements, and we provide elaborate extra features for this form of LP.

In particular the single number is represented in decimal notation but is scaled and/or offset. Each such LP has an "overall offset" O and an "overall multiplier" M such that a value written k is stored as the I6 value $Mk + O$.

A given KOV can have many different LPs to represent it, and this is especially convenient for physics – it means we can give ways to describe mass (a kind of value) in grams, kilograms or tonnes (all literal patterns with different O and M values). Among these, one LP is special and is called the "benchmark" for the KOV – it is the default notation, the one considered most natural, and other LPs for the same KOV are scaled relative to this. For instance, the benchmark for mass might be the notation "1 kg"; the notations "1 g" and "1 tonne" would then be scaled down by 1000, or scaled up by 1000, as compared with the benchmark.

¶3. Syntactically, a literal pattern is a series of "tokens", of which more below. Some tokens are simply fixed lettering or wording, but others represent positions where "elements" – the numerical parts – appear. In the "16:9" notation, there are three tokens – an element token, a fixed colon, and another element token. At least one of the tokens has to be a element token.

```
define MAX_ELEMENTS_PER_LITERAL 16
define MAX_TOKENS_PER_LITERAL 100

typedef struct literal_pattern {
    struct kind_of_value *kov_specified;                    the data type of the result: i.e., what it specifies
    struct literal_pattern *next_for_this_kov;                          continuing list for this data type
    int prototype_w1, prototype_w2;                                    where the prototype specification is
    int no_lp_tokens;                                                   number of tokens in specification
    struct literal_pattern_token lp_tokens[MAX_TOKENS_PER_LITERAL];
    int no_lp_elements;                                                              how many tokens are numbers
    struct literal_pattern_element lp_elements[MAX_ELEMENTS_PER_LITERAL];
    int number_signed;                                          for instance -10 cm would be allowed if this is set
    used when we have a sequence of alternative notations for the same unit
    int primary_alternative;                                                         first of a set of alternatives?
    struct literal_pattern *next_alternative_lp;                        continuing list of alternatives
    int singular_form_only;                                          print using this notation only for 1 unit
    int plural_form_only;                                  print using this notation for 2 units, 0.5 units, etc.
    int overall_offset;                                                                the O value described above
    int overall_multiplier;                                                            the M value described above
    used in the process of defining patterns and calculating their O and M values
    int scaled_at;                                                        defined with this scaling factor, e.g., 100
    int scaled_up;                                      or, scaled up from the benchmark by this factor, e.g., 1000
    int scaled_down;                                                        or, scaled down from it similarly
    int equivalent_unit;                                                  is this just an equivalent to another LP?
    int benchmark;                                                         is this the benchmark LP for its KOV?
    int last_resort;                          is this the last possible LP to use when printing a value of the KOV?
    int marked_for_printing;                                                  used in compiling printing routines
    MEMORY_MANAGEMENT
} literal_pattern;
```

The structure literal_pattern is private to this section.

¶4. There are three sorts of token: character, word and element. Each token can be a whole word, or only part of a word. For instance, in

28kg net specifies a weight.

we have a sequence of four tokens: an element token, marked as beginning a word; a character token `k`; a character token `g`; and a word token `net`, which necessarily begins a word. Word boundaries in the source text must match those in the specification, so this notation does not match the text "41 kg net", for instance.

```
define WORD_LPT 1
define CHARACTER_LPT 2
define ELEMENT_LPT 3

typedef struct literal_pattern_token {
    int new_word_at;                                                        does token start a new word?
    int lpt_type;                                                      one of the three constants defined above
    char token_char;                                                CHARACTER_LPT only; the character to match
    int token_wn;                                          WORD_LPT only; word number in source text of the prototype
} literal_pattern_token;
```

The structure literal_pattern_token is private to this section.

¶5. A value notated this way is like an old-school Pascal packed integer, where a small data structure was joined into a single word of data. For instance, in the "16:9" example, $e_0 : e_1$ would be stored as $e_0 r_1 + e_1$ where $r_1 = 10$ is one more than the maximum value of e_1. So "4:3" would be stored as $4 \cdot (9 + 1) + 3 = 43$. More formally, we call the numbers in such a literal its "elements". In the case of "16:9", there are two elements, $e_0 = 16$ and $e_1 = 9$. The general formula is:

$$N = \sum_{i=0}^{n-1} e_i \cdot \prod_{j>i} r_j$$

where $(e_0, e_1, ..., e_{n-1})$ are the values and r_j, the "range", is the constraint such that $0 \leq e_j < r_j$. Note that r_0 is never required, since e_0 is constrained in size only by the need for N to fit into a single virtual machine integer. The value

$$m_i = \prod_{j>i} r_j$$

is called the "multiplier", and note that $m_{n-1} = 1$. Conversely,

$$e_i = \begin{cases} N/m_0 & \text{if } i = 0, \\ N/m_i \bmod r_i & \text{otherwise.} \end{cases}$$

The rightmost element e_{n-1} is the least significant numerically.

```
typedef struct literal_pattern_element {
    int element_index;                    /* the value i placing this within its LP, where 0 ≤ i < n */
    int element_range;                    /* the value r_i for this LP */
    int element_multiplier;               /* the value m_i for this LP */
    int word_ref1, word_ref2;             /* if we define a name for the element */
    int without_leading_zeros;            /* normally without? */
    int element_optional;                 /* can we truncate the LP here? */
    int preamble_optional;                /* if so, can we lose the preamble as well? */
} literal_pattern_element;
```

The structure literal_pattern_element is private to this section.

¶6. For the sake of printing, we can specify which notation is to be used in printing a value back. For instance,

1 tonne (in tonnes, singular) specifies a mass scaled up by 1000.

assigns the name "in tonnes" to this notation for writing a mass. There can be several notation associated with "in tonnes":

2 tonnes (in tonnes, plural) specifies a mass scaled up by 1000.

and hence the linked list of LPs associated with a single "literal pattern name". Moreover, a given kind of value can support multiple named notations; mass might also support "in kilograms" and "in grams", for instance.

```
typedef struct literal_pattern_name {
    int word_ref1, word_ref2;             /* name for this notation, if any; e.g. "in centimetres" */
    struct literal_pattern *can_use_this_lp;  /* list of LPs used under this name */
    struct literal_pattern_name *next;    /* other names for the same KOV */
    int lpn_compiled_already;
    MEMORY_MANAGEMENT
} literal_pattern_name;
```

The structure literal_pattern_name is private to this section.

§1. Creating patterns, tokens and elements.

```
literal_pattern *lp_new(kind_of_value *kov, int spw1, int spw2) {
    literal_pattern *lp = CREATE(literal_pattern);
    lp->plural_form_only = FALSE;
    lp->singular_form_only = FALSE;
    lp->kov_specified = kov;
    lp->prototype_w1 = spw1; lp->prototype_w2 = spw2;
    lp->next_for_this_kov = NULL;
    lp->primary_alternative = FALSE;
    lp->next_alternative_lp = NULL;
    lp->no_lp_elements = 0;
    lp->no_lp_tokens = 0;
    lp->number_signed = FALSE;
    lp->overall_offset = 1;
    lp->overall_multiplier = 1;
    lp->scaled_at = 1;
    lp->scaled_up = 1;
    lp->scaled_down = 1;
    lp->equivalent_unit = FALSE;
    lp->benchmark = FALSE;
    return lp;
}
```

§2.

```
literal_pattern_token lpt_new(int t, int nw) {
    literal_pattern_token lpt;
    lpt.new_word_at = nw;
    lpt.lpt_type = t;
    lpt.token_char = 0;
    lpt.token_wn = -1;
    return lpt;
}
```

§3.

```
literal_pattern_element lpe_new(int i, int r, int sgn) {
    literal_pattern_element lpe;
    if (i == 0) lpe.element_range = -1; else lpe.element_range = r;
    lpe.element_multiplier = 1;
    lpe.element_index = i;
    lpe.word_ref1 = -1; lpe.word_ref2 = -1;
    lpe.preamble_optional = FALSE;
    lpe.element_optional = FALSE;
    lpe.without_leading_zeros = FALSE;
    return lpe;
}
```

§**4. Listing LPs.** A routine to append a LP to the linked list of LPs for a given KOV. But it's a little more involved because this is where we calculate the scale factors which relate LPs in the list, and also because we need to keep the list in a particular order.

```
literal_pattern *lp_list_add(literal_pattern *list_head, literal_pattern *new_lp) {
    if (list_head == NULL) ⟨Begin a new list with just the new LP in it 5⟩
    else ⟨Add the new LP to the existing list 6⟩;
    ⟨Correct the "last resort" flags in the list of LPs 8⟩;
    ⟨Automatically enable signed literals if there are scaled LPs in the list 9⟩;
    return list_head;
}
```

The function lp_list_add is called from 7/data.

§**5.** When the new LP is the first one, it can only be scaled in absolute terms: "scaled at", which specifies its M value.

```
⟨Begin a new list with just the new LP in it 5⟩ ≡
    if ((new_lp->scaled_up != 1) || (new_lp->scaled_down != 1) || (new_lp->equivalent_unit))
        sentence_problem(_P_(C5LPCantScaleYet),
            "this tries to scale up or down a value which so far has no point of "
            "reference to scale from",
            "which is impossible.");
    new_lp->overall_multiplier = new_lp->scaled_at;
    list_head = new_lp;
```

This code is used in §4.

§**6.** But if other LPs already exist, then absolute scalings are forbidden. The new LP must be scaled up or down relative to existing notations, or pegged equivalent to an exact value.

```
⟨Add the new LP to the existing list 6⟩ ≡
    if (new_lp->scaled_at != 1) {
        if (new_lp->primary_alternative)
            sentence_problem(_P_(C5LPCantScaleTwice),
                "this tries to specify the scaling for a kind of value whose "
                "scaling is already established",
                "which is impossible.");
        new_lp->scaled_at = 1;
    }
    literal_pattern *lp, *benchmark_lp = NULL;
    for (lp = list_head; lp; lp = lp->next_for_this_kov)
        if (lp->benchmark) benchmark_lp = lp;
    if (new_lp->equivalent_unit) new_lp->overall_multiplier = new_lp->scaled_up;
    else if (benchmark_lp) ⟨Calculate the multiplier for the LP relative to the benchmark 7⟩
    else new_lp->overall_multiplier = 1;
    list_head = lp_list_add_inner(list_head, new_lp);
```

This code is used in §4.

§**7.** An equivalent unit exactly specifies its M-value relative to the benchmark's M-value, which we call B. If it is scaled up by k, then $M = kB$ and there's no problem (ignoring overflows, anyway).

If scaled down then we want $M = B/k$, but that may be impossible since we're performing integer division and k might not divide B. We make it possible by increasing every M-value in the list by a factor of $k/\gcd(B, k)$, thus making B divisible by k. To keep the proportions right we must increase M for the new LP by the same factor, so we now want

$$M = (B/k) \cdot (k/\gcd(B, k)) = B/\gcd(B, k)$$

and this, of course, is an integer division which is always possible, since the gcd is by construction a factor of B.

⟨Calculate the multiplier for the LP relative to the benchmark 7⟩ ≡

```
int B = benchmark_lp->overall_multiplier;
if (new_lp->scaled_up != 1)
    new_lp->overall_multiplier = B * new_lp->scaled_up;
if (new_lp->scaled_down != 1) {
    int k = new_lp->scaled_down;
    int g = gcd(B, k);
    literal_pattern *lp;
    for (lp = list_head; lp; lp = lp->next_for_this_kov)
        if (lp->equivalent_unit == FALSE)
            lp->overall_multiplier = (k/g)*(lp->overall_multiplier);
    new_lp->overall_multiplier = B/g;
}
```

This code is used in §6.

§**8.** Within the list, exactly one LP is marked with the `last_resort` flag: the last one not marked as an equivalent unit. (You can only be equivalent to something already there, so it's not possible for all the LPs in the list to be equivalent.)

⟨Correct the "last resort" flags in the list of LPs 8⟩ ≡

```
literal_pattern *lp, *last_resorter = NULL;
for (lp = list_head; lp; lp = lp->next_for_this_kov) {
    lp->last_resort = FALSE;
    if (lp->equivalent_unit == FALSE) last_resorter = lp;
}
if (last_resorter) last_resorter->last_resort = TRUE;
```

This code is used in §4.

§**9.** Inform is ordinarily a bit picky about not allowing negative values within these notations, unless they have explicitly been defined to allow it. That makes sense for basically combinatorial notations (room 1 to room 64, say) but would be a nonsense for scientific measurements where we intend to perform arithmetic. So:

⟨Automatically enable signed literals if there are scaled LPs in the list 9⟩ ≡

```
    int scalings_exist = FALSE;
    literal_pattern *lp;
    for (lp = list_head; lp; lp = lp->next_for_this_kov)
        if (lp->overall_multiplier != 1)
            scalings_exist = TRUE;
    if (scalings_exist)
        for (lp = list_head; lp; lp = lp->next_for_this_kov)
            lp->number_signed = TRUE;
```

This code is used in §4.

§**10.** The actual insertion of the new LP into the list is carried out here, and is complicated by the fact that we need to keep these in a special order.

```
literal_pattern *lp_list_add_inner(literal_pattern *list_head, literal_pattern *new_lp) {
    literal_pattern *lp, *lp_prev;
    new_lp->next_for_this_kov = NULL;
    if (list_head == NULL) return new_lp;
    lp = list_head; lp_prev = NULL;
    while (lp) {
        if (lp_precedes(new_lp, lp)) {
            new_lp->next_for_this_kov = lp;
            if (lp_prev) lp_prev->next_for_this_kov = new_lp;
            else list_head = new_lp;
            return list_head;
        }
        lp_prev = lp;
        lp = lp->next_for_this_kov;
    }
    lp_prev->next_for_this_kov = new_lp;
    return list_head;
}
```

§**11.** Large M-values come before small ones; plural forms for the same M-value come before singular ones; and otherwise an earlier-defined LP comes before a later one.

```
int lp_precedes(literal_pattern *A, literal_pattern *B) {
    if (A->overall_multiplier > B->overall_multiplier) return TRUE;
    if (A->overall_multiplier < B->overall_multiplier) return FALSE;
    if ((A->plural_form_only) && (B->plural_form_only == FALSE)) return TRUE;
    if ((A->plural_form_only == FALSE) && (B->plural_form_only == TRUE)) return FALSE;
    if (A->allocation_id < B->allocation_id) return TRUE;
    return FALSE;
}
```

§**12.** This returns the multiplier of the benchmark, which is important for performing multiplications (see "Dimensions" in Chapter 7).

```
int data_type_scale_factor(int data_type) {
    literal_pattern *lp;
    LITERAL_FORMS_LOOP(lp, data_type)
        if (lp->benchmark)
            return lp->overall_multiplier;
    return 1;
}
```

The function data_type_scale_factor is called from 7/kov.

§**13. Optional break points.** Sometimes the pattern allows later numerical elements to be skipped, in which case they are understood to be 0.

```
int at_optional_break_point(literal_pattern *lp, int ec, int tc) {
    if ((ec<lp->no_lp_elements) &&                    i.e., if there are still numerical elements to supply
        (lp->lp_elements[ec].element_optional) &&                                  but which are optional
        ((lp->lp_elements[ec].preamble_optional) ||     and either the preamble tokens are also optional
            (lp->lp_tokens[tc].lpt_type == ELEMENT_LPT)))                  or we're at the number token
        return TRUE;
    return FALSE;
}
```

§**14. Matching an LP in the source text.** Given an excerpt `(w1, w2)`, we try to parse it as a constant value written in the LP notation: if it passes, we return the kind of value, and if not we return `NULL`.

```
int waive_lp_overflows = FALSE;
int last_LP_problem_at = -1;
kind_of_value *match_literal_pattern(literal_pattern *lp, int w1, int w2, int *found) {
    int matched_number = 0, overflow_16_bit_flag = FALSE, overflow_32_bit_flag = FALSE;
    literal_pattern_element *sign_used_at = NULL, *element_overflow_at = NULL;
    if the excerpt is longer than the maximum length of such a notation, give up quickly:
    if (w2-w1 > lp->prototype_w2-lp->prototype_w1) return NULL;
    ⟨Try to match the excerpt against the whole prototype or up to an optional break 15⟩;
    if (sign_used_at) {
        ⟨Check that a negative number can be used in this notation 20⟩;
        matched_number = -matched_number;
    }
    if (waive_lp_overflows == FALSE) {
        if (element_overflow_at) ⟨Report a problem because one element in the notation overflows 22⟩;
        ⟨Check that the value found lies within the range which the VM can hold 21⟩;
    }
    *found = matched_number;
    return lp->kov_specified;
}
```

The function match_literal_pattern is called from 5/lit.

§**15.** Scanning the tokens one at a time. The scan position is represented as a word number `wn` together with a character position within the word, `wpos`. The `wpos` value −1 means that word `wn` has not yet been started.

⟨Try to match the excerpt against the whole prototype or up to an optional break 15⟩ ≡

```
int tc, wn = w1, wpos = -1, ec = 0, matched_scaledown = 1;
char *wd = lw_array[w1].lw_text;
for (tc=0; tc<lp->no_lp_tokens; tc++) {
    if (wn > w2) {
        if ((wpos == -1)                                    i.e., if we are cleanly at a word boundary
            && (at_optional_break_point(lp, ec, tc))) break;
        return NULL;
    }
    switch (lp->lp_tokens[tc].lpt_type) {
        case WORD_LPT: ⟨Match a fixed word token within a literal pattern 16⟩; break;
        case CHARACTER_LPT: ⟨Match a character token within a literal pattern 17⟩; break;
        case ELEMENT_LPT: ⟨Match an element token within a literal pattern 18⟩; break;
        default: internal_error("unknown literal pattern token type");
    }
}
if (wpos >= 0) return NULL;                                 we need to end cleanly, not in mid-word
if (wn <= w2) return NULL;                                  and we need to have used up all of the excerpt
if (lp->overall_multiplier % matched_scaledown != 0)
    ⟨Report a problem because not enough accuracy is available 23⟩;
long long int max_16_bit = 32767LL, max_32_bit = 2147483647LL;
matched_number = matched_number*(lp->overall_multiplier/matched_scaledown) + lp->overall_offset;
if (matched_number > max_16_bit) overflow_16_bit_flag = TRUE;
if (matched_number > max_32_bit) overflow_32_bit_flag = TRUE;
```

This code is used in §14.

§**16.** A word token matches an exact word (but allowing for variation in casing).

⟨Match a fixed word token within a literal pattern 16⟩ ≡

```
if (wpos >= 0) return NULL;                    if we're still in the middle of the last word, we must fail
if (compare_words(wn, lp->lp_tokens[tc].token_wn) == FALSE) return NULL;
wn++;
```

This code is used in §15.

§**17.** A character token matches only a single character – note the case insensitivity here, because of the use of `tolower`.

⟨Match a character token within a literal pattern 17⟩ ≡

```
if (wpos == -1) { wpos = 0; wd = lw_array[wn].lw_text; }        start parsing the interior of a word
if (tolower(wd[wpos++]) != tolower(lp->lp_tokens[tc].token_char)) return NULL;
if (wd[wpos] == 0) { wn++; wpos = -1; }                         and stop parsing the interior of a word
```

This code is used in §15.

§**18.** There are three different sorts of overflow:

(1) The calculation of the packed value exceeding the range which an integer can store on a 16-bit virtual machine;
(2) Ditto, but on a 32-bit virtual machine; and
(3) One of the numerical elements inside the notation being given out of range.

We report none of these as a problem immediately – only if the pattern would otherwise match.

The following assumes that `long long int` is at least 64-bit, so that it can hold any 32-bit integer multiplied by 10, and also any product of two 32-bit numbers. This is true for all modern `gcc` implementations and is required by C99, but was not required by C90, so it is just possible that this could cause trouble on unusual platforms.

⟨Match an element token within a literal pattern 18⟩ ≡

```
literal_pattern_element *lpe = &(lp->lp_elements[ec++]);                fetch details of next number
if (wpos == -1) { wpos = 0; wd = lw_array[wn].lw_text; }                start parsing the interior of a word
long long int tot = 0, max_32_bit, max_16_bit;
int digits_found = 0, point_at = -1;
if (wd[wpos] == '-') { sign_used_at = lpe; wpos++; }
max_16_bit = 32767LL; if (sign_used_at) max_16_bit = 32768LL;
max_32_bit = 2147483647LL; if (sign_used_at) max_32_bit = 2147483648LL;
while ((isdigit(wd[wpos])) ||
    ((wd[wpos] == '.') && (lp->overall_multiplier > 1) && (point_at == -1))) {
    if (wd[wpos] == '.') { point_at = digits_found; wpos++; continue; }
    tot = 10*tot + (wd[wpos++] - '0');
    if (tot > max_16_bit) overflow_16_bit_flag = TRUE;
    if (tot > max_32_bit) overflow_32_bit_flag = TRUE;
    digits_found++;
}
if ((point_at == 0) || (point_at == digits_found)) return NULL;

if (wd[wpos] == 0) { wn++; wpos = -1; }                    and stop parsing the interior of a word
```

This code is used in §15.

§**19.** Problem messages here have a tendency to be repeated, in some situations, which is annoying. So we have a mechanism to suppress duplicates:

```
define ISSUING_LP_PROBLEM
    if (last_LP_problem_at == w1) return NULL;
    last_LP_problem_at = w1;
```

§**20.**

⟨Check that a negative number can be used in this notation 20⟩ ≡

```
if (sign_used_at->element_index != 0) {
    ISSUING_LP_PROBLEM;
    sentence_problem(_P_(C5NegationInternal),
        "a negative number can't be used in the middle of a constant",
        "and the minus sign makes it look as if that's what you are "
        "trying here.");
    return NULL;
}
if (lp->number_signed == FALSE) {
    ISSUING_LP_PROBLEM;
    sentence_problem(_P_(C5NegationForbidden),
        "the minus sign is not allowed here",
        "since this is a kind of value which only allows positive "
        "values to be written.");
    return NULL;
}
```

This code is used in §14.

§**21.** The out of range problem messages:

⟨Check that the value found lies within the range which the VM can hold 21⟩ ≡

```
if (overflow_32_bit_flag) {
    ISSUING_LP_PROBLEM;
    sentence_problem(_P_(C5EvenOverflow-G),
        "you use a literal specification to make a value which is too large",
        "even for a story file compiled with the Glulx setting. (You can "
        "see the size limits for each way of writing a value on the Kinds "
        "page of the Index.)");
    return NULL;
}
if ((overflow_16_bit_flag) && (target_VM_is_16_bit())) {
    ISSUING_LP_PROBLEM;
    sentence_problem(_P_(C5ZMachineOverflow),
        "you use a literal specification to make a value which is too large",
        "at least with the Settings for this project as they currently are. "
        "(Change to Glulx to be allowed to use much larger numbers; "
        "meanwhile, you can see the size limits for each way of writing a "
        "value on the Kinds page of the Index.)");
    return NULL;
}
```

This code is used in §14.

§**22.** The more specific problem of an internal overflow:

⟨Report a problem because one element in the notation overflows 22⟩ ≡

```
int max = element_overflow_at->element_range - 1;
quote_source(1, current_sentence);
quote_words(2, w1, w2);
quote_words(3, lp->prototype_w1, lp->prototype_w2);
quote_number(4, &max);
switch (element_overflow_at->element_index) {
    case 0: quote_text(5, "first"); break;
    case 1: quote_text(5, "second"); break;
    case 2: quote_text(5, "third"); break;
    case 3: quote_text(5, "fourth"); break;
    case 4: quote_text(5, "fifth"); break;
    case 5: quote_text(5, "sixth"); break;
    case 6: quote_text(5, "seventh"); break;
    case 7: quote_text(5, "eighth"); break;
    case 8: quote_text(5, "ninth"); break;
    case 9: quote_text(5, "tenth"); break;
    default: quote_text(5, "eventual"); break;
}
handmade_problem(_P_(C5ElementOverflow));
issue_problem_segment(
    "In the sentence %1, you use the notation '%2' to write a constant value. "
    "But the notation was specified as '%3', which means that the %5 numerical "
    "part should range between 0 and %4.");
issue_problem_end();
return NULL;
```

This code is used in §14.

§**23.**

⟨Report a problem because not enough accuracy is available 23⟩ ≡

```
quote_source(1, current_sentence);
quote_words(2, w1, w2);
quote_words(3, lp->prototype_w1, lp->prototype_w2);
handmade_problem(_P_(C5LPTooLittleAccuracy));
issue_problem_segment(
    "In the sentence %1, you use the notation '%2' to write a constant value. "
    "But to store that, I would need greater accuracy than this kind of "
    "value has - see the Kinds page of the Index for the range it has.");
issue_problem_end();
return NULL;
```

This code is used in §15.

§24. Matching an LP at run-time. The following routine compiles an I6 general parsing routine (GPR) to match typed input in the correct notation. It amounts to printing out a version of the above routine, but ported to I6, and with the token loop "rolled out" so that no `tc` and `ec` variables are needed at run-time, and simplified by having the numerical overflow detection removed. (It's a little slow to perform that check within the VM.)

Properly speaking this is not an entire GPR, but only a segment of one, and we should compile code which allows execution to reach the end if and only if we fail to make a match.

```
void gpr_for_lp(OUTPUT_STREAM, literal_pattern *lp) {
    int label = lp->allocation_id;
    int tc, ec;
    comment_use_of_lp(OUT, lp);
    WRITE("wpos = 0; mid_word = false; matched_number = 0;\n");
    for (tc=0, ec=0; tc<lp->no_lp_tokens; tc++) {
        int lookahead = -1;
        if ((tc+1<lp->no_lp_tokens) && (lp->lp_tokens[tc+1].lpt_type == CHARACTER_LPT))
            lookahead = lp->lp_tokens[tc+1].token_char;
        WRITE("if (mid_word == false) {\n"); INDENT;
        WRITE("cur_word = NextWordStopped(); wn--;\n");
        WRITE("if (cur_word == -1) ");
        if (at_optional_break_point(lp, ec, tc))
            WRITE("jump Succeeded_LP_%d;\n", label);
        else
            WRITE("jump Failed_LP_%d;\n", label);
        OUTDENT; WRITE("}\n");
        switch (lp->lp_tokens[tc].lpt_type) {
            case WORD_LPT: ⟨Compile I6 code to match a fixed word token within a literal pattern 25⟩; break;
            case CHARACTER_LPT: ⟨Compile I6 code to match a character token within a literal pattern 26⟩; break;
            case ELEMENT_LPT: ⟨Compile I6 code to match an element token within a literal pattern 27⟩; break;
            default: internal_error("unknown literal pattern token type");
        }
    }
    WRITE(".Succeeded_LP_%d;\n", label);
    WRITE("if (mid_word) jump Failed_LP_%d;\n", label);
    WRITE("if (sgn<0) matched_number = -1*matched_number;\n");
    WRITE("parsed_number = matched_number;\n");
    char offset_text[16]; sprintf(offset_text, "%d+x", lp->overall_offset);
    carefully_scale_and_add(OUT, "parsed_number", lp->overall_multiplier, offset_text, label);
    WRITE("if (parser_trace >= 3) { print \"  [parsed value \", parsed_number, \" by: ");

            var, (int) (max/scale_factor), var, (int) (max/scale_factor),
            to_add, (int) (max%scale_factor)); INDENT;
        WRITE("jump Failed_LP_%d;\n", label);
        OUTDENT; OUTDENT; WRITE("} else {\n"); INDENT;
        max++;
        WRITE("if ((%s > %d) || ((%s == %d) && (%s > %d)))\n",
            var, (int) (max/scale_factor), var, (int) (max/scale_factor),
            to_add, (int) (max%scale_factor)); INDENT;
        WRITE("jump Failed_LP_%d;\n", label);
        OUTDENT; OUTDENT; WRITE("}\n");
    }
    WRITE("%s = %d*%s + %s;\n", var, scale_factor, var, to_add);
}
```

§31. Indexing literal patterns for a given data type. (A data type is an ID number used to identify base kinds of value, or KOV constructors – though the latter can never occur here.)

```
void index_literal_patterns(int data_type) {
    literal_pattern *lp, *benchmark_lp = NULL;
    int B = 1, scalings_exist = FALSE;
    LITERAL_FORMS_LOOP(lp, data_type) {
        if (lp->benchmark) {
            benchmark_lp = lp;
            B = lp->overall_multiplier;
        }
        if (lp->overall_multiplier != 1) scalings_exist = TRUE;
    }
    ⟨Index the list of possible LPs for the KOV, not counting equivalents 32⟩;
    ⟨Index the list of possible LPs for the KOV, only counting equivalents 33⟩;
    ⟨Index the possible names for these notations, as ways of printing them back 34⟩;
}
```

The function index_literal_patterns is called from 7/kix.

§32. Each entry in this list is, in principle, a list all by itself – of alternatives such as "1 tonne" vs "2 tonnes", which aren't different enough to be listed separately. Of these exactly one is the "primary" alternative.

⟨Index the list of possible LPs for the KOV, not counting equivalents 32⟩ ≡

```
    int f = FALSE;
    LITERAL_FORMS_LOOP(lp, data_type)
        if ((lp->primary_alternative) && (lp->equivalent_unit == FALSE)) {
            if (f) INDEX("<br>");
            else INDEX("<i>Written as:</i><br>");
            if ((scalings_exist) && (benchmark_lp)) {
                index_lp_possibilities(lp, benchmark_lp);
            } else {
                print_raw_text_to_file(lp->prototype_w1, lp->prototype_w2, ifl);
            }
            f = TRUE;
        }
```

This code is used in §31.

§33.

⟨Index the list of possible LPs for the KOV, only counting equivalents 33⟩ ≡

```
    int f = FALSE;
    LITERAL_FORMS_LOOP(lp, data_type)
        if ((lp->primary_alternative) && (lp->equivalent_unit)) {
            if (f) INDEX("<br>");
            else INDEX("<br><i>With these equivalent units:</i><br>");
            index_lp_possibilities(lp, benchmark_lp);
            f = TRUE;
        }
```

This code is used in §31.

§**34.**

⟨Index the possible names for these notations, as ways of printing them back 34⟩ ≡

```
int f = FALSE;
literal_pattern_name *lpn;
LOOP_OVER(lpn, literal_pattern_name)
    if (lpn->word_ref1 >= 0) {
        LITERAL_FORMS_LOOP(lp, data_type) {
            literal_pattern_name *lpn2;
            for (lpn2 = lpn; lpn2; lpn2 = lpn2->next)
                if (lp == lpn2->can_use_this_lp) {
                    if (f) INDEX("; ");
                    else {
                        INDEX("<br><i>Can be printed back:</i><br>");
                        INDEX("    ");
                    }
                    f = TRUE;
                    print_raw_text_to_file(lpn->word_ref1, lpn->word_ref2, ifl);
                    goto NextLPN;
                }
        }
        NextLPN: ;
    }
```

This code is used in §31.

§**35.** And here we list of alternatives followed by the relationship this notation has to the benchmark, e.g., "where 1 tonne = 1000 kg".

```
void index_lp_possibilities(literal_pattern *lp, literal_pattern *benchmark_lp) {
    int B = benchmark_lp->overall_multiplier;
    INDEX("    ");
    index_lp_possibility(lp, benchmark_lp);
    if (lp->equivalent_unit) {
        INDEX(" <i>where</i> ");
        lp_index_value_specific(lp, lp->overall_multiplier);
        INDEX(" = ");
        lp_index_value_specific(benchmark_lp, lp->overall_multiplier);
    } else {
        if (lp->overall_multiplier < B) {
            INDEX(" <i>where</i> ");
            lp_index_value_specific(lp, B);
            INDEX(" = ");
            lp_index_value_specific(benchmark_lp, B);
        }
        if (lp->overall_multiplier > B) {
            INDEX(" <i>where</i> ");
            lp_index_value_specific(lp, lp->overall_multiplier);
            INDEX(" = ");
            lp_index_value_specific(benchmark_lp, lp->overall_multiplier);
        }
    }
}
```

§**36.** This is where the list of alternatives, "1 tonne" followed by "2 tonnes", say, is produced:

```
void index_lp_possibility(literal_pattern *lp, literal_pattern *benchmark_lp) {
    if (lp == benchmark_lp) INDEX("<b>");
    if (lp->plural_form_only)
        lp_index_value_specific(lp, 2*lp->overall_multiplier);
    else
        lp_index_value_specific(lp, lp->overall_multiplier);
    if (lp == benchmark_lp) INDEX("</b>");
    if (lp->next_alternative_lp) {
        INDEX(" <i>or</i> ");
        index_lp_possibility(lp->next_alternative_lp, benchmark_lp);
    }
}
```

§**37. Printing values in an LP's notation to the index at compile-time.** This front-end routine chooses the most appropriate notation to use when indexing a given value. For instance, a mass of 1000000 is best expressed as "1 tonne", not "1000000 grams".

```
void lp_index_value(literal_pattern *lp_list, int v) {
    literal_pattern *lp;
    literal_pattern *lp_possibility = NULL;
    int k = 0;
    for (lp = lp_list; lp; lp = lp->next_for_this_kov) {
        if (v == 0) {
            if (lp->benchmark) {
                lp_index_value_specific(lp, v); return;
            }
        } else {
            if ((lp->primary_alternative) && (lp->equivalent_unit == FALSE)) {
                if ((lp_possibility == NULL) || (lp->overall_multiplier != k)) {
                    lp_possibility = lp;
                    k = lp->overall_multiplier;
                }
                if ((v-lp->overall_offset) >= (lp->overall_multiplier)) {
                    lp_index_value_specific(lp, v); return;
                }
            }
        }
    }
    if (lp_possibility) lp_index_value_specific(lp_possibility, v);
    else lp_index_value_specific(lp_list, v);
}
```

The function lp_index_value is called from 7/dim and 7/kix.

§**38.** Here we index the benchmark value. Pursuing our example of mass, if the benchmark is 1 kilogram, then the following indexes the value 1000 in kilograms, resulting in "1 kg". (This will always effectively look like "1 something", whatever the something is.)

```
void data_type_index_benchmark_value(int data_type) {
    literal_pattern *lp;
    LITERAL_FORMS_LOOP(lp, data_type)
        if (lp->benchmark) {
            lp_index_value_specific(lp, lp->overall_multiplier);
            return;
        }
    INDEX("1");
}
```

The function data_type_index_benchmark_value is called from 7/dim.

§**39.** We are rather formal when printing values to the index, so we choose not to make use of optional truncation.

```
void lp_index_value_specific(literal_pattern *lp, int v) {
    int tc, ec, remainder;
    remainder = (v - lp->overall_offset)%(lp->overall_multiplier);
    v = (v - lp->overall_offset)/(lp->overall_multiplier);
    for (tc=0, ec=0; tc<lp->no_lp_tokens; tc++) {
        if ((tc>0) && (lp->lp_tokens[tc].new_word_at)) INDEX(" ");
        switch (lp->lp_tokens[tc].lpt_type) {
            case WORD_LPT: ⟨Index a fixed word token within a literal pattern 40⟩; break;
            case CHARACTER_LPT: ⟨Index a character token within a literal pattern 41⟩; break;
            case ELEMENT_LPT: ⟨Index an element token within a literal pattern 42⟩; break;
            default: internal_error("unknown literal pattern token type");
        }
    }
}
```

§**40.** We parse in a case-insensitive way, but print back case-sensitively – note that the following uses the raw text of the word.

⟨Index a fixed word token within a literal pattern 40⟩ ≡

```
    if (tc > 0) INDEX(" ");
    print_literal_string_to_file(ifl, lw_array[lp->lp_tokens[tc].token_wn].lw_rawtext);
```

This code is used in §39.

§**41.**

⟨Index a character token within a literal pattern 41⟩ ≡

```
    html_char_out(ifl, lp->lp_tokens[tc].token_char);
```

This code is used in §39.

§**42.**

⟨Index an element token within a literal pattern 42⟩ ≡

```
    literal_pattern_element *lpe = &(lp->lp_elements[ec]);
    if (ec == 0) INDEX("%d", v/(lpe->element_multiplier));
    else {
        char *prototype = "%d";
        if ((lp->lp_tokens[tc].new_word_at == FALSE) && (lpe->without_leading_zeros == FALSE))
            prototype = leading_zero_prototype(lpe->element_range);
        INDEX(prototype, (v/(lpe->element_multiplier)) % (lpe->element_range));
    }
    if (ec == 0) ⟨Index the fractional part of the value 43⟩;
    ec++;
```

This code is used in §39.

§**43.**

⟨Index the fractional part of the value 43⟩ ≡

```
int ranger = 1;
while (lp->overall_multiplier > ranger) ranger = ranger*10;
remainder = remainder*(ranger/lp->overall_multiplier);
while ((remainder > 0) && ((remainder % 10) == 0)) {
    ranger = ranger/10; remainder = remainder/10;
}
if (remainder > 0) {
    INDEX(".");
    INDEX(leading_zero_prototype(ranger), remainder);
}
```

This code is used in §42.

§**44.** Please don't mention the words "logarithm" or "shift". It works fine.

```
char *leading_zero_prototype(int range) {
    if (range > 1000000000) return "%010d";
    if (range > 100000000) return "%09d";
    if (range > 10000000) return "%08d";

    }
    WRITE("print (value/%d)%%%d;\n", lpe->element_multiplier, lpe->element_range);
}
if (ec == 0) ⟨Compile I6 code to print the fractional part of the value 51⟩;
ec++;
```

This code is used in §47.

§**51.** We need to print a decimal approximation to the fraction `rem/ran`.

⟨Compile I6 code to print the fractional part of the value 51⟩ ≡

```
    int remm = 1, ran = 1;
    while (lp->overall_multiplier > ran) ran = ran*10;
    remm = ran/lp->overall_multiplier;
    WRITE("if (rem > 0) {\n"); INDENT;
    WRITE("print \".\";\n");
    if (remm != 1) WRITE("rem = rem*%d;\n", remm);
    WRITE("ran = %d;\n", ran);
    WRITE("while ((rem %% 10 == 0) && (rem > 0)) { rem=rem/10; ran=ran/10; }\n");
    WRITE("while (rem < ran/10) { print \"0\"; ran=ran/10; }\n");
    WRITE("print rem;\n");
    OUTDENT; WRITE("}\n");
```

This code is used in §50.

§**52.**

⟨Truncate the printed form here if subsequent numerical parts are zero 52⟩ ≡

```
    if (oc == ec) {
        if (ec == 0)
            WRITE("if ((value/%d) == 0) rtrue;\n",
                lp->lp_elements[ec].element_multiplier);
        else
            WRITE("if ((value/%d)%%%d == 0) rtrue;\n",
                lp->lp_elements[ec].element_multiplier,
                lp->lp_elements[ec].element_range);
        oc = ec + 1;
    }
```

This code is used in §47,50,47,50,47,50.

§**53.**

```
void comment_use_of_lp(OUTPUT_STREAM, literal_pattern *lp) {
    WRITE("! ");
    print_text_to_file(lp->prototype_w1, lp->prototype_w2, OUT);
    WRITE(", with offset=%d, multiplier=%d\n", lp->overall_offset, lp->overall_multiplier);
    WRITE("\n");
}
```

§**54. Creating new literal patterns.** We create new LPs during traverse 1 of the parse tree. This imposes two timing constraints:

(a) The specification sentence must come after the sentence creating the kind of value being specified; but
(b) It must come before any sentences using constants written in this notation.

In practice both constraints seem to be accepted by users as reasonable, and this causes no trouble.

```
sentence_handler SPECIFIES_SH_handler =
    { SENTENCE_NT, SPECIFIES_VB, 1, new_literal_specification };

void new_literal_specification(parse_node *pn) {
    int ltw1, ltw2, spw1, spw2;
    [[spw1, spw2 <-- pn->down->next]];                    the text of the notation
    [[ltw1, ltw2 <-- pn->down->next->next]];              the name of the KOV specified
    new_literal_specification_list(spw1, spw2, ltw1, ltw2, NULL);
}
```

§**55.** One can define LPs with a list of alternatives, of which the first is the "primary alternative" and said to be the "owner" of the rest. For instance:

> 1 tonne (in metric units, in tonnes, singular) or 2 tonnes (in metric units,
> in tonnes, plural) specifies a mass scaled up by 1000.

Here we call `new_literal_specification_list` on "1 tonne" with no owner, and then on "2 tonnes" with the "1 tonne" LP as its owner.

```
literal_pattern *new_literal_specification_list(int spw1, int spw2, int ltw1, int ltw2,
    literal_pattern *lp_main) {
    if (is_list_divided(spw1, spw2, LOOK_FOR_OR)) {
        int lw1 = left_w1, lw2 = left_w2, rw1 = right_w1, rw2 = right_w2;
        lp_main = new_literal_specification_list(lw1, lw2, ltw1, ltw2, lp_main);
        return new_literal_specification_list(rw1, rw2, ltw1, ltw2, lp_main);
    }
    return new_literal_specification_inner(spw1, spw2, ltw1, ltw2, lp_main);
}
```

§**56.** So here we parse a single LP.

```
define LP_SCALED_UP 1
define LP_SCALED_DOWN -1
define LP_SCALED_AT 2

literal_pattern *new_literal_specification_inner(int spw1, int spw2, int ltw1, int ltw2,
    literal_pattern *owner) {
    int i, scaled = 1, scaled_dir = LP_SCALED_UP, offset = 0;
    int notation_name_w1 = -1, notation_name_w2 = -1, parts_w1 = -1, parts_w2 = -1;
    int equivalent_w1 = -1, equivalent_w2 = -1;
    int offset_w1 = -1, offset_w2 = -1;
    kind_of_value *kov;
    literal_pattern *lp;
    ⟨Parse and remove notation name at the end of the pattern 58⟩;
    ⟨Parse and remove optional clauses at the end of the specification 59⟩;
    ⟨Check that the new notation does not overlap with that of any existing LP 62⟩;
    ⟨Find the kind of value being specified by the new LP 63⟩;
    ⟨Deal with the case where a dimensionality rule is being specified 64⟩;
```

```
    ⟨Check that the KOV is acceptable as the owner of a LP 65⟩;
    ⟨Check that any other value mentioned as an equivalent or scaled equivalent has the right KOV 61⟩;
    lp = lp_new(kov, spw1, spw2);
    lp->overall_offset = offset;
    if (owner == NULL) lp->primary_alternative = TRUE;
    if (equivalent_w1 >= 0) lp->equivalent_unit = TRUE;
    switch (scaled_dir) {
        case LP_SCALED_UP: lp->scaled_up = scaled; break;
        case LP_SCALED_DOWN: lp->scaled_down = scaled; break;
        case LP_SCALED_AT: lp->scaled_at = scaled; break;
    }
    lp_set_notations(lp, notation_name_w1, notation_name_w2);
    ⟨Break down the specification text into tokens and elements 66⟩;
    ⟨Calculate the multipliers for packing the elements into a single integer 69⟩;
    if (kov_list_of_literal_forms(kov) == NULL) lp->benchmark = TRUE;
    kov_add_literal_pattern(kov, lp);
    if (parts_w1 >= 0) {
        ⟨Work through parts text to assign names to the individual elements 70⟩;
        ⟨Check that any notes to do with optional elements are mutually compatible 71⟩;
        define_packing_phrases(lp, ltw1, ltw2);
    }
    if (owner == NULL) owner = lp;
    else ⟨Add this new alternative to the list belonging to our owner 57⟩;
    return owner;
}
```

§57.

⟨Add this new alternative to the list belonging to our owner 57⟩ ≡

```
    literal_pattern *alt = owner;
    while ((alt) && (alt->next_alternative_lp)) alt = alt->next_alternative_lp;
    alt->next_alternative_lp = lp;
```

This code is used in §56.

§58.

⟨Parse and remove notation name at the end of the pattern 58⟩ ≡

```
    int i;
    [[spw1, spw2 == ... OPENBRACKET ... CLOSEBRACKET : i --> spw1, spw2 ... notation_name_w1, notation_name_w2]]
;
```

This code is used in §56.

§59.

⟨Parse and remove optional clauses at the end of the specification 59⟩ ≡

```
    int clause = TRUE;
    while (clause) {
        clause = FALSE;
        ⟨Look for an optional clause attached to the specification 60⟩;
    }
```

This code is used in §56.

§60.

⟨Look for an optional clause attached to the specification 60⟩ ≡

```
if ([[ltw1, ltw2 == ... with ... : i]] &&
    [[i, ltw2 == with parts ... --> parts_w1, parts_w2]]) {
    ltw2 = i-1; clause = TRUE;
}
if (vocab_test_flags(ltw2, NUMBER_MC)) {
    int v = vocab_get_literal_number_value(lw_array[ltw2].lw_identity);
    if [[ltw1, ltw2 == ... scaled up by ### --> ltw1, ltw2]] {
        scaled = v; scaled_dir = LP_SCALED_UP; clause = TRUE;
    } else
    if [[ltw1, ltw2 == ... scaled down by ### --> ltw1, ltw2]] {
        scaled = v; scaled_dir = LP_SCALED_DOWN; clause = TRUE;
    } else
    if [[ltw1, ltw2 == ... scaled at ### --> ltw1, ltw2]] {
        scaled = v; scaled_dir = LP_SCALED_AT; clause = TRUE;
    }
}
if ([[ltw1, ltw2 == ... offset ... : i]] &&
    [[i, ltw2 == offset by ... --> offset_w1, offset_w2]]) {
    ltw2 = i-1; clause = TRUE;
}
if ([[ltw1, ltw2 == ... equivalent ... : i]] &&
    [[i, ltw2 == equivalent to ... --> equivalent_w1, equivalent_w2]]) {
    ltw2 = i-1; clause = TRUE;
}
```

This code is used in §59.

§61.

⟨Check that any other value mentioned as an equivalent or scaled equivalent has the right KOV 61⟩ ≡

```
if (equivalent_w1 >= 0) {
    if (kov_compare(is_a_literal(equivalent_w1, equivalent_w2), kov)) {
        scaled_dir = LP_SCALED_UP; scaled = last_literal_evaluated;
    } else {
        sentence_problem_with_note(_P_(C5BadLPEquivalent),
            "the equivalent value needs to be a constant of the same kind "
            "of value as you are specifying",
            "and this seems not to be.",
            "Note that you can only use notations specified in sentences "
            "before the current one.");
    }
}
if (offset_w1 >= 0) {
    if (kov_compare(is_a_literal(offset_w1, offset_w2), kov)) {
        offset = last_literal_evaluated;
    } else {
        sentence_problem_with_note(_P_(C5BadLPOffset),
            "the offset value needs to be a constant of the same kind "
            "of value as you are specifying",
            "and this seems not to be.",
```

```
            "Note that you can only use notations specified in sentences "
            "before the current one.");
    }
}
```

This code is used in §56.

§**62.** We parse the specification text as if it were a constant value, hoping for the result `NULL` – so that it doesn't already mean something else. During this process, we waive checking of numerical overflows in matching an LP: this is done so that

3/13 specifies a bar. 2/19 specifies a foo.

reports "2/19" as a duplicate using the following problem message, but does not throw a problem message as being a bar which is out of range (because in the bar notation, the number after the slash can be at most 13, so that 19 is illegal).

⟨Check that the new notation does not overlap with that of any existing LP 62⟩ ≡

```
waive_lp_overflows = TRUE; kov = is_a_literal(spw1, spw2); waive_lp_overflows = FALSE;
if (kov) {
    quote_source(1, current_sentence);
    quote_kov(2, kov);
    quote_words(3, spw1, spw2);
    handmade_problem(_P_(C5DuplicateUnitSpec));
    issue_problem_segment(
        "In the sentence %1, it looks as if you intend to give a new meaning "
        "to expressions like '%3', but this is already something I "
        "recognise - specifying %2 - so a more distinctive specification "
        "must be chosen.");
    issue_problem_end();
    return owner;
}
```

This code is used in §56.

§**63.** For the present, at least, LPs can only be used to specify a limited range of possible values:

⟨Find the kind of value being specified by the new LP 63⟩ ≡

```
specification *spec = parse_expression(ltw1, ltw2, TYPE_EXPCON);
if (spec_is_actual_CONSTANT(spec)) {
    sentence_problem(_P_(C5LPNotKOV),
        "you can only specify ways to write kinds of value",
        "as created with sentences like 'A weight is a kind of value.'");
    return owner;
}
kov = spec_get_kind_of_value(spec);
```

This code is used in §56.

§**64.** We react to the word "times", in the specification, only when the matter either side of it can be recognised as something; this in principle makes it possible to define LPs containing the word, though in fact that is very unlikely to end happily, given that "times" will usually be interpreted as multiplication when parsing values in any case.

⟨Deal with the case where a dimensionality rule is being specified 64⟩ ≡

```
int left_w1, left_w2, right_w1, right_w2;
if [[spw1, spw2 == ... times ... : i --> left_w1, left_w2 ... right_w1, right_w2]] {
    specification *left_spec = parse_expression(left_w1, left_w2, TYPE_EXPCON);
    specification *right_spec = parse_expression(right_w1, right_w2, TYPE_EXPCON);
    if ((spec_is_UNKNOWN(left_spec) == FALSE) && (spec_is_UNKNOWN(right_spec) == FALSE)) {
        if ((spec_is_generic_CONSTANT(left_spec)) && (spec_is_generic_CONSTANT(right_spec)))
            dim_set_multiplication(
                spec_get_kind_of_value(left_spec), spec_get_kind_of_value(right_spec), kov);
        else
            sentence_problem(_P_(C5MultiplyingNonKOVs),
                "only kinds of value can be multiplied here",
                "and only in a sentence like 'A length times a length "
                "specifies an area.'");
        return owner;
    }
}
```

This code is used in §56.

§**65.** This checking did not apply to the dimensionality rules case, which looks after itself.

⟨Check that the KOV is acceptable as the owner of a LP 65⟩ ≡

```
if (kov_is_built_in(kov)) {
    sentence_problem(_P_(C5LPBuiltInKOV),
        "you can only specify ways to write new kinds of value",
        "as created with sentences like 'A weight is a kind of value.', "
        "and not the built-in ones like 'number' or 'time'.");
    return owner;
}
if (kov_convert_to_unit(kov) == FALSE) {
    sentence_problem(_P_(C5LPEnumeration),
        "this is a kind of value which already has named values",
        "so it can't have a basically numerical form as well.");
    return owner;
}
```

This code is used in §56.

§**66.** Each word is either a whole token in itself, or a stream of tokens representing alphabetic vs numeric pieces of a word:

⟨Break down the specification text into tokens and elements 66⟩ ≡

```
int i, j, tc, ec;
for (i=0, tc=0, ec=0; spw1+i<=spw2; i++) {
    literal_pattern_token new_token;
    int digit_found = FALSE;
    char *text_of_word = lw_array[spw1+i].lw_rawtext;
    for (j=0; text_of_word[j]; j++) if (isdigit(text_of_word[j])) digit_found = TRUE;
    if (digit_found)
        ⟨Break up the word into at least one element token, and perhaps also character tokens 67⟩
    else {
        new_token = lpt_new(WORD_LPT, TRUE);
        new_token.token_wn = spw1+i;
        ⟨Add new token to LP 68⟩;
    }
}
lp->no_lp_tokens = tc;
lp->no_lp_elements = ec;
if (lp->no_lp_elements == 0) {
    sentence_problem(_P_(C5LPWithoutElement),
        "a way to specify a kind of value must involve numbers",
        "so '10kg specifies a weight' is allowed, but not 'tonne "
        "specifies a weight'.");
    return owner;
}
```

This code is used in §56.

§**67.** Bounds checking is easier here since we know that a LP specification will not ever need to create the maximum conceivable value which a C integer can hold – so we need not fool around with long long ints.

⟨Break up the word into at least one element token, and perhaps also character tokens 67⟩ ≡

```
int j, sgn = 1, next_token_begins_word = TRUE;
for (j=0; text_of_word[j]; j++) {
    int tot = 0, digit_found = FALSE;
    if ((text_of_word[j] == '-') && (isdigit(text_of_word[j+1])) && (ec == 0)) {
        sgn = -1; continue;
    }
    while (isdigit(text_of_word[j++])) {
        digit_found = TRUE;
        if (tot > 999999999) {
            sentence_problem(_P_(C5LPElementTooLarge),
                "that specification contains numbers that are too large",
                "and would construct values which could not sensibly "
                "be stored at run-time.");
            return owner;
        }
        tot = 10*tot + (text_of_word[j-1]-'0');
    }
    j--;
    if (digit_found) {
        literal_pattern_element new_element = lpe_new(ec, tot+1, sgn);
```

```
            if (ec >= MAX_ELEMENTS_PER_LITERAL) {
                sentence_problem(_P_(C5LPTooManyElements),
                    "that specification contains too many numerical elements",
                    "and is too complicated for Inform to handle.");
                return owner;
            }
            lp->lp_elements[ec++] = new_element;
            if (sgn == -1) lp->number_signed = TRUE;
            new_token = lpt_new(ELEMENT_LPT, next_token_begins_word);
            ⟨Add new token to LP 68⟩;
            j--;
        } else {
            new_token = lpt_new(CHARACTER_LPT, next_token_begins_word);
            new_token.token_char = text_of_word[j];
            ⟨Add new token to LP 68⟩;
        }
        sgn = 1; next_token_begins_word = FALSE;
    }
```

This code is used in §66.

§**68.** In fact counting tokens is not necessarily a good way to measure the complexity of an LP, since any long run of characters in a word which also contains a number will splurge the number of tokens. So `MAX_TOKENS_PER_LITERAL` is set to a high enough value that this will not really distort matters.

⟨Add new token to LP 68⟩ ≡

```
    if (tc >= MAX_TOKENS_PER_LITERAL) {
        sentence_problem(_P_(C5LPTooComplicated),
            "that specification is too complicated",
            "and will have to be shortened.");
        return owner;
    }
    lp->lp_tokens[tc++] = new_token;
```

This code is used in §66,67,66,67,66,67.

§**69.** The elements are created in parsing order, that is, left to right. But the multipliers can only be calculated by working from right to left, so this is deferred until all elements exist, at which point we –

⟨Calculate the multipliers for packing the elements into a single integer 69⟩ ≡

```
    int i, m = 1;
    for (i=lp->no_lp_elements-1; i>=0; i--) {
        literal_pattern_element *lpe = &(lp->lp_elements[i]);
        lpe->element_multiplier = m;
        m = m*(lpe->element_range);
    }
```

This code is used in §56.

§**70.** Today, we have naming of parts:

⟨Work through parts text to assign names to the individual elements 70⟩ ≡

```
int i, named_parts = 0;
for (i=0, named_parts = 0; (i<lp->no_lp_elements) && (parts_w1 <= parts_w2); i++) {
    literal_pattern_element *lpe = &(lp->lp_elements[i]);
    int x1, x2, opt1, opt2, j;
    lpe->word_ref1 = parts_w1;
    if (is_list_divided(parts_w1, parts_w2, LOOK_FOR_AND)) {
        lpe->word_ref2 = left_w2; parts_w1 = right_w1;
    } else {
        lpe->word_ref2 = parts_w2; parts_w1 = parts_w2+1;
    }
    if [[lpe == ... OPENBRACKET ... CLOSEBRACKET : j --> x1, x2 ... opt1, opt2]] {
        lpe->word_ref1 = x1; lpe->word_ref2 = x2;
        literal_specification_option(lpe, opt1, opt2);
    }
    named_parts++;
}
if ((named_parts > 0) && (named_parts != lp->no_lp_elements)) {
    sentence_problem(_P_(C5LPNotAllNamed),
        "you must supply names for all the parts",
        "if for any");
    return owner;
}
```

This code is used in §56.

§**71.** In fact, the test is a simple one: there can be only one element declared optional, and it must not be the first.

⟨Check that any notes to do with optional elements are mutually compatible 71⟩ ≡

```
int i, opt_count = 0;
for (i=0; i<lp->no_lp_elements; i++) if (lp->lp_elements[i].element_optional) {
    opt_count++;
    if (i == 0) {
        sentence_problem(_P_(C5LPFirstOptional),
            "the first part is not allowed to be optional",
            "since it is needed to identify the value.");
        return owner;
    }
}
if (opt_count >= 2) {
    sentence_problem(_P_(C5LPMultipleOptional),
        "only one part can be called optional",
        "since if any part is omitted then so are all subsequent parts.");
    return owner;
}
```

This code is used in §56.

§**72.** Finally, a small recursive routine looks at the bracketed notes attached to names of elements, and translates them directly to flags in the LPE structure:

```
void literal_specification_option(literal_pattern_element *lpe, int x1, int x2) {
    if (is_list_divided(x1, x2, LOOK_FOR_AND)) {
        x1 = right_w1; x2 = right_w2;
        literal_specification_option(lpe, left_w1, left_w2);
        literal_specification_option(lpe, x1, x2);
        return;
    }
    if [[x1, x2 == optional]] { lpe->element_optional = TRUE; return; }
    if [[x1, x2 == preamble optional]] {
        lpe->element_optional = TRUE; lpe->preamble_optional = TRUE; return;
    }
    if [[x1, x2 == without leading zeros]] { lpe->without_leading_zeros = TRUE; return; }
    quote_source(1, current_sentence);
    quote_words(2, x1, x2);
    handmade_problem(_P_(C5BadLPPartOption));
    issue_problem_segment(
        "In the specification %1, I was expecting that '%2' would be an optional "
        "note about one of the parts: it should have been one of 'optional', "
        "'preamble optional' or 'without leading zeros'.");
    issue_problem_end();
}
```

§**73. I7 phrases to print values in specified ways.** When an LP has a name, it's a notation which the source text can request to be used in saying a value.

```
void lp_set_notations(literal_pattern *lp, int w1, int w2) {
    if ((w1<0) || (w2<w1)) return;
    int lw1, lw2, rw1, rw2, j;
    if [[w1, w2 == ... COMMA ... : j --> lw1, lw2 ... rw1, rw2]] {
        lp_set_notations(lp, lw1, lw2);
        lp_set_notations(lp, rw1, rw2);
        return;
    }
    if [[w1, w2 == singular]] { lp->singular_form_only = TRUE; return; }
    if [[w1, w2 == plural]] { lp->plural_form_only = TRUE; return; }
    if [[w1, w2 == in ...]] {
        literal_pattern_name *lpn;
        LOOP_OVER(lpn, literal_pattern_name) {
            if (compare_word_range(lpn->word_ref1, lpn->word_ref2, w1, w2)) {
                literal_pattern_name *new = CREATE(literal_pattern_name);
                new->word_ref1 = -1; new->word_ref2 = -1;
                new->can_use_this_lp = lp;
                new->next = NULL;
                while ((lpn) && (lpn->next)) lpn = lpn->next;
                lpn->next = new;
                return;
            }
        }
        literal_pattern_name *new = CREATE(literal_pattern_name);
        new->word_ref1 = w1; new->word_ref2 = w2;
        new->can_use_this_lp = lp;
        new->next = NULL;
    } else {
        quote_source(1, current_sentence);
        quote_words(2, w1, w2);
        handmade_problem(_P_(C5BadLPNameOption));
        issue_problem_segment(
            "In the specification %1, I was expecting that '%2' would be an optional "
            "note about one of the notations: it should have been one of 'singular', "
            "'plural' or 'in ...'.");
        issue_problem_end();
    }
}
```

§**74.** And this is where the corresponding text substitutions are declared.

```
void define_named_printing_phrases(void) {
    literal_pattern_name *lpn;
    LOOP_OVER(lpn, literal_pattern_name)
        lpn->lpn_compiled_already = FALSE;
    LOOP_OVER(lpn, literal_pattern_name) {
        if (lpn->word_ref1 >= 0) {
            literal_pattern_name *lpn2;
            for (lpn2 = lpn; lpn2; lpn2 = lpn2->next)
                if (lpn2->lpn_compiled_already == FALSE)
                    ⟨Compile the printing phrase for this and perhaps subsequent LPs 75⟩;
        }
    }
    register_recently_lexed_phrases();
}
```

The function define_named_printing_phrases is invoked by a command in a `.i6t` template file.

§**75.** These text substitutions correspond exactly neither to the LPs nor to the names. For instance, "in tonnes" produces a text substitution which takes in both the LP for "1 tonne" and for "2 tonnes", deciding at run-time which to use. And on the other hand, "in metric units" may produce text substitutions for many different KOVs, distinguished by type-checking:

To say (val - mass) in metric units: ...

To say (val - length) in metric units: ...

The following creates one text substitution for each different KOV among the LPs under each named possibility.

⟨Compile the printing phrase for this and perhaps subsequent LPs 75⟩ ≡

```
    kind_of_value *kov = lpn2->can_use_this_lp->kov_specified;
    int ltw1, ltw2;
    int name1 = lpn->word_ref1, name2 = lpn->word_ref2;
    kov_get_name(kov, &ltw1, &ltw2, FALSE);
    int x1 = lexer_wordcount, x2;
    feed_into_lexer("To say ( val - ", FALSE, FALSE);
    splice_words(ltw1, ltw2);
    feed_into_lexer(" ) ", FALSE, FALSE);
    splice_words(name1, name2);
    x2 = lexer_wordcount-1;
    make_sentence_node(x1, x2, ':');
    x1 = lexer_wordcount;
    char print_rule_buff[1024];
    sprintf(print_rule_buff, " (- %s({val}, %d); -) ",
        kov_get_name_of_printing_rule(kov), lpn->allocation_id + 1);
    feed_into_lexer(print_rule_buff, FALSE, FALSE);
    x2 = lexer_wordcount-1;
    make_sentence_node(x1, x2, '.');
    literal_pattern_name *lpn3;
    for (lpn3 = lpn2; lpn3; lpn3 = lpn3->next)
        if (kov_compare(kov, lpn3->can_use_this_lp->kov_specified))
            lpn3->lpn_compiled_already = TRUE;
```

This code is used in §74.

§76. I7 phrases to pack and unpack the value. Creating a LP implicitly defines further I7 source text, as follows.

```
void define_packing_phrases(literal_pattern *lp, int ltw1, int ltw2) {
    ⟨Define phrases to convert from a packed value to individual parts 77⟩;
    ⟨Define a phrase to convert from numerical parts to a packed value 78⟩;
    register_recently_lexed_phrases();
}
```

§**77.** First, we automatically create n phrases to unpack the elements given the value. For instance, defining:

> $10.99 specifies a price with parts dollars and cents.

automatically generates:

> To define which number is dollars part of (full - price) :
> `(- ({full}/100) -).`
>
> To define which number is cents part of (full - price) :
> `(- ({full}%100) -).`

⟨Define phrases to convert from a packed value to individual parts 77⟩ ≡

```
    int i;
    for (i=0; i<lp->no_lp_elements; i++) {
        literal_pattern_element *lpe = &(lp->lp_elements[i]);
        int x1, x2;
        char print_rule_buff[1024];
        x1 = lexer_wordcount;
        feed_into_lexer("To decide which number is ", FALSE, FALSE);
        splice_words(lpe->word_ref1, lpe->word_ref2);
        feed_into_lexer(" part of ( full - ", FALSE, FALSE);
        splice_words(ltw1, ltw2);
        feed_into_lexer(" ) ", FALSE, FALSE);
        x2 = lexer_wordcount-1;
        make_sentence_node(x1, x2, ':');
        x1 = lexer_wordcount;
        if (i==0)
            sprintf(print_rule_buff, " (- ({full}/%d) -) ", lpe->element_multiplier);
        else if (lpe->element_multiplier > 1)
            sprintf(print_rule_buff, " (- (({full}/%d)%%%d) -) ",
                lpe->element_multiplier, lpe->element_range);
        else
            sprintf(print_rule_buff, " (- ({full}%%%d) -) ", lpe->element_range);
        feed_into_lexer(print_rule_buff, FALSE, FALSE);
        x2 = lexer_wordcount-1;
        make_sentence_node(x1, x2, '.');
    }
```

This code is used in §76.

§**78.** And similarly, a packing phrase to calculate the value given its elements. For instance, the dollars-and-cents example compiles:

```
To decide which price is price with dollars part ( part0 - a number ) cents part ( part1 - a number) :
(- ({part0}*100+{part1}) -).
```

⟨Define a phrase to convert from numerical parts to a packed value 78⟩ ≡

```
if (lp->no_lp_elements > 0) {
    int i, x1, x2;
    char print_rule_buff[1024];
    x1 = lexer_wordcount;
    if [[ltw1, ltw2 == a/an ... --> ltw1, ltw2]];
    feed_into_lexer("To decide which ", FALSE, FALSE);
    splice_words(ltw1, ltw2);
    feed_into_lexer(" is ", FALSE, FALSE);
    splice_words(ltw1, ltw2);
    feed_into_lexer(" with ", FALSE, FALSE);
    for (i=0; i<lp->no_lp_elements; i++) {
        literal_pattern_element *lpe = &(lp->lp_elements[i]);
        sprintf(print_rule_buff, " part%d ", i);
        splice_words(lpe->word_ref1, lpe->word_ref2);
        feed_into_lexer(" part ( ", FALSE, FALSE);
        feed_into_lexer(print_rule_buff, FALSE, FALSE);
        feed_into_lexer(" - a number ) ", FALSE, FALSE);
    }
    x2 = lexer_wordcount-1;
    make_sentence_node(x1, x2, ':');
    x1 = lexer_wordcount;
    sprintf(print_rule_buff, " (- (");
    for (i=0; i<lp->no_lp_elements; i++) {
        literal_pattern_element *lpe = &(lp->lp_elements[i]);
        if (i>0) sprintf(print_rule_buff+strlen(print_rule_buff), "+");
        if (lpe->element_multiplier != 1)
            sprintf(print_rule_buff+strlen(print_rule_buff), "%d*",
                lpe->element_multiplier);
        sprintf(print_rule_buff+strlen(print_rule_buff), "{part%d}", i);
    }
    sprintf(print_rule_buff+strlen(print_rule_buff), ") -) ");
    feed_into_lexer(print_rule_buff, FALSE, FALSE);
    x2 = lexer_wordcount-1;
    make_sentence_node(x1, x2, '.');
}
```

This code is used in §76.

Excerpt Meanings 5/em

Purpose

To register and deregister meanings for excerpts of text as nouns, adjectives, imperative phrases and other usages.

Definitions

¶1. Excerpt meanings. Most compilers keep a "symbols table" of identifier names and what meanings they have: for instance, when compiling Inform, GCC's symbols table records that `problem_count` is the name of an integer variable and `excerpt_meaning` of a defined type. This is usually stored so that a new name can rapidly be checked to see if it matches one that is currently known.

Inform has a similar need to remember meanings of excerpts. (Recall that an "excerpt" is a run of one or more adjacent words in the source text.) So far in Chapter 5 we have already seen how determiners, verbs and prepositions are parsed – by direct comparison against fixed wordings stored in specialised structures. The excerpt meanings, by contrast, form a single vocabulary bank for nouns, adjectives, imperative phrases, and phrases to make decisions – which is to say, almost everything else. Examples include:

> american dialect, say close bracket, player's command, open, Hall of Mirrors

Most compilers use a symbols table whose efficiency depends on the fact that symbol names are relatively long strings (say, 8 or more units) drawn from a small alphabet (say, the 37 letters, digits and the underscore). But Inform has short symbols (typically one to three units) drawn from a huge alphabet (say, all 5,000 different words found in the source text). And we also need to parse in ways which a conventional compiler does not. If C has registered the identifier `pink_martini` then it never needs to notice `pnk_martin` as being related to it. But when Inform registers "pink martini" as the name of a world object, it then has to spot that either "pink" or "martini" alone might also refer to the same object. So we are not going to use the conventional algorithms.

¶2. We now define the `excerpt_meaning` data structure, which holds a single entry in this super-dictionary. The text to be matched is specified as a sequence of at least one, and at most 32, tokens: these can either be pointers to specific vocabulary, or can be null, which implies that arbitrary non-empty text can appear in the given position. (It is forbidden for the token list to contain two nulls in a row.) For instance, the token list:

```
drink # milk #
```

matches "drink more milk today and every day", but not "drink milk". (The sharp symbol `#` is printed in place of a null token, both in this documentation and in the debugging log.)

Each excerpt meaning also comes with a hash code, which is automatically generated from its token list, and a pointer to some structure. For a world object, this will be a pointer to the appropriate `world_object` structure; for a quantity, a pointer to the `quantity`; and so on. Because the pointer can only be used if we know what category of meaning we are looking at, the excerpt meaning is also supplied with a pair of integers called the meaning code (MC) and secondary meaning code (SMC).

```
define MAX_TOKENS_PER_EXCERPT_MEANING 32

typedef struct excerpt_meaning {
    int meaning_code;                          what kind of meaning: a single MC, not a bitmap
    int secondary_code;                        relevant only if the MC is MISCELLANEOUS_MC
    struct general_pointer data;               data structure being referred to
```

```
    int no_em_tokens;                                                    length of token list
    struct vocabulary_entry *em_tokens[MAX_TOKENS_PER_EXCERPT_MEANING];  token list
    int excerpt_hash;                                                    hash code generated from the token list
    MEMORY_MANAGEMENT
} excerpt_meaning;
```

The structure excerpt_meaning is shared with 5/parse.

¶3. One meaning we find it convenient to have direct access to: the meaning of the noun "player".

```
excerpt_meaning *meaning_of_player = NULL;
```

¶4. Meaning codes. These assign a context to a meaning, and so decide how the `data` pointer for an excerpt meaning is to interpreted. For instance, "Persian carpet" might have a meaning with code `WORLD_OBJECT_MC`, since it refers to a world object (a thing or kind): the pointer will then be to a `world_object`.

Meaning codes are used in other contexts in Inform besides this one. There are exactly 31 of them and each is a distinct power of two; there is no significance to their ordering. The point is that a signed integer (which we know can hold values at least up to $2^{31} - 1$) can hold a bitmap representing any subset of these meaning codes; for instance, `QUANTITY_MC + TABLE_MC` would mean "either a quantity or a table".

¶5. Meaning codes are divided into two. The first set represent meanings of excerpts; the `meaning_code` field of an `excerpt_meaning` is always exactly one of the following. (It is never a bitmap combination.)

```
define MISCELLANEOUS_MC 0x00000001                    see the secondary meaning code below
define VOID_PHRASE_MC 0x00000002                      e.g., award # points
define VALUE_PHRASE_MC 0x00000004                     e.g., number of rows in #
define COND_PHRASE_MC 0x00000008                      e.g., # has not ended
define WORLD_OBJECT_MC 0x00000010                     e.g., upright chair

define EQUATION_MC 0x00004000                         e.g., Newton's Second Law
an MC now dropped used to occupy this bit, which is now free
define NAMED_AP_MC 0x00010000                         e.g., bad behaviour
define END_PHRASE_MC 0x00020000                       e.g., end while
define SAY_PHRASE_MC 0x00040000                       e.g., say # in words
```

¶6. The second set of MCs signal the contexts in which particular words are found. They are used to mark `vocabulary_entry` structures of individual words, whose `flags` field is a bitmap combination of some or all of the following. For instance, the VE for "taking" is flagged with the `ING_MC` bit; "in" is flagged with both `INORON_MC` and `PREPOSITION_MC`.

```
define CVERB_MC 0x00080000                  a word which might introduce a verb usage
define ING_MC 0x00100000                    a word ending in -ing
define PREPOSITION_MC 0x00200000            a word which might introduce a relative clause
define NOT_MC 0x00400000                    not
define ORDINAL_MC 0x00800000                first, second, third, ..., twelfth
define ARTICLE_MC 0x01000000                a, an, the, some
define INORON_MC 0x02000000                 in, on
define BUILTINTYPE_MC 0x04000000            number, text, relation, rule, ...
define I6_MC 0x08000000                     piece of verbatim I6 code
define TEXTWITHSUBS_MC 0x10000000           double-quoted text literal with substitutions

define NUMBER_MC 0x40000000                 one, two, ..., twelve, 1, 2, ...
```

¶7. In fact, 31 meaning codes is not really enough, which is why we have the `MISCELLANEOUS_MC` value. This is a special case: it labels names which can relate to a variety of things, but which need not be parsed quickly.

A secondary meaning code, or SMC, then comes into play to explain what kind meaning we have. The SMC is irrelevant for any excerpt whose code is not `MISCELLANEOUS_MC`, and it is not a bitmap, but a simple enumeration. (Bitmaps of MCs are unable to distinguish the individual secondary meanings.)

In the examples below, the bracketed words are not stored in the token list, but are instead used when parsing to recognise that a secondary meaning may be needed. All of these cases have a "signature word" which alerts the S-parser that they may be being used: option, relation, Unicode, figure, outcome, action, sound, file. This is why we can afford to parse them a little more slowly than other excerpts – we are fairly unlikely to chase false leads.

```
define USE_OPTION_SMC 0x00000001            e.g., memory economy (option)
define RELATION_SMC 0x00000002              e.g., containment (relation)
define UNICODENAME_SMC 0x00000003           e.g., (Unicode) Greek letter alpha
define FIGURE_SMC 0x00000004                e.g., figure of daffodils
define RULE_OUTCOME_SMC 0x00000005          e.g., it is very unlikely (outcome)
define ACTION_NAME_SMC 0x00000006           e.g., going action
define SOUND_EFFECT_SMC 0x00000007          e.g., sound of creaking
define EXTERNAL_FILE_SMC 0x00000008         e.g., file of high scores
```

---

§**1. Creating EMs.** The following makes a skeletal EM structure, with no token list or hash code as yet.

```
excerpt_meaning *em_new(int mc, int smc, general_pointer data) {
    excerpt_meaning *em = CREATE(excerpt_meaning);
    em->meaning_code = mc;
    em->secondary_code = smc;
    em->data = data;
    em->no_em_tokens = 0;
    em->excerpt_hash = 0;
    return em;
}
```

The function em_new is called from 5/varc.

§**2.** Access routines:

```
int em_get_secondary_code(excerpt_meaning *em) {
    if (em->meaning_code != MISCELLANEOUS_MC)
        internal_error("looked up SMC for non-miscellaneous EM");
    return em->secondary_code;
}
general_pointer em_data(excerpt_meaning *em) {
    return em->data;
}
```

The function em_get_secondary_code is called from 5/unitr, 5/lit, 5/candd, 5/candp, 5/mlc, 10/fig, 10/sfx, 10/exf, 10/isin and 12/rb. The function em_data is called from 5/aph, 5/unitr, 5/lit, 5/candd, 5/varc, 5/mlc, 8/refpt, 9/qty, 9/wo, 9/prop, 10/tab, 10/isin, 11/ap, 11/nap, 11/av, 12/br and 12/rb.

§**3. Debugging log.** First to log a general bitmap made up from meaning codes:

```
void log_meaning_code(int mc) {
    int i, j, f = FALSE;
    for (i=0, j=1; i<31; i++, j*=2)
        if (mc & j) {
            if (f) LOG(" + "); f = TRUE;
            switch (j) {
                case ACTIVITY_MC: LOG("ACTIVITY_MC"); break;
                case ADJECTIVE_MC: LOG("ADJECTIVE_MC"); break;
                case ARTICLE_MC: LOG("ARTICLE_MC"); break;
                case BUILTINTYPE_MC: LOG("BUILTINTYPE_MC"); break;
                case COND_PHRASE_MC: LOG("COND_PHRASE_MC"); break;
                case CVERB_MC: LOG("CVERB_MC"); break;
                case DESIGNED_TYPE_MC: LOG("DESIGNED_TYPE_MC"); break;
                case END_PHRASE_MC: LOG("END_PHRASE_MC"); break;
                case EQUATION_MC: LOG("EQUATION_MC"); break;
                case I6_MC: LOG("I6_MC"); break;
                case ING_MC: LOG("ING_MC"); break;
                case INORON_MC: LOG("INORON_MC"); break;
                case MISCELLANEOUS_MC: LOG("MISCELLANEOUS_MC"); break;
                case NAMED_AP_MC: LOG("NAMED_AP_MC"); break;
                case NOT_MC: LOG("NOT_MC"); break;
                case NUMBER_MC: LOG("NUMBER_MC"); break;
                case ORDINAL_MC: LOG("ORDINAL_MC"); break;
                case PREPOSITION_MC: LOG("PREPOSITION_MC"); break;
                case PROPERTY_MC: LOG("PROPERTY_MC"); break;
                case QUANTITY_MC: LOG("QUANTITY_MC"); break;
                case RULE_MC: LOG("RULE_MC"); break;
                case RULEBOOK_MC: LOG("RULEBOOK_MC"); break;
                case SAY_PHRASE_MC: LOG("SAY_PHRASE_MC"); break;
                case TABLE_COLUMN_MC: LOG("TABLE_COLUMN_MC"); break;
                case TABLE_MC: LOG("TABLE_MC"); break;
                case TEXT_MC: LOG("TEXT_MC"); break;
                case TEXTWITHSUBS_MC: LOG("TEXTWITHSUBS_MC"); break;
                case VALUE_PHRASE_MC: LOG("VALUE_PHRASE_MC"); break;
                case VOID_PHRASE_MC: LOG("VOID_PHRASE_MC"); break;
                case WORLD_OBJECT_MC: LOG("WORLD_OBJECT_MC"); break;
                default: LOG("<unknown-mc>"); break;
```

```
            }
        }
}
```

The function log_meaning_code is called from 5/ml.

§4. And now for excerpt meanings:

```
void log_excerpt_meaning(excerpt_meaning *em) {
    int i;
    if (em == NULL) { LOG("<null-em>"); return; }
    LOG("{");
    for (i=0; i<em->no_em_tokens; i++) {
        if (i>0) LOG(" ");
        if (em->em_tokens[i] == NULL) { LOG("#"); continue; }
        if (vocab_get_exemplar(em->em_tokens[i], FALSE) == NULL)
            internal_error("Null token in EM");
        LOG("%s", vocab_get_exemplar(em->em_tokens[i], FALSE));
    }
    LOG(" = $p", em->meaning_code);
    if (em->secondary_code) LOG(" (secondary=%d)", em->secondary_code);
    LOG("}");
}
void log_all_meanings(void) {
    int i = 0;
    excerpt_meaning *em;
    LOOP_OVER(em, excerpt_meaning)
        LOG("%02d: %08x $M\n", i++, (pointer_sized_int) em, em);
}
```

The function log_excerpt_meaning is called from 2/dl.
The function log_all_meanings is called from 5/parse.

§5. **Hashing excerpts.** For excerpts `(w1, w2)`, we need a form of hash function which makes it easy to test whether the words in one excerpt can all be found in another, or to be more exact whether

$$\{I_j \mid w_1 \leq j \leq w_2\} \subseteq \{I_j \mid w_3 \leq j \leq w_4\}$$

where I_n is the identity of word n. As with all hash algorithms, we do not need to guarantee a positive match, only a negative, so we can throw away a lot of information. And we also want a hash function which makes it easy to test whether an excerpt contains any of the literals.

§**6.** There are two sources of text which we might want to hash in this way: first, actual excerpts found in the source text. These are not very expensive to calculate, but every ounce of speed helps here, so we cache the most recent.

The hash generated this way is an arbitrary bitmap of bits 1 to 30, with bits 31 and 32 left clear.

```
int cached_hash_w1 = -2, cached_hash_w2 = -2, cached_value;

int hash_code_from_excerpt(int w1, int w2) {
    int i, h = 0; vocabulary_entry *v;
    if ((w1 == cached_hash_w1) && (w2 == cached_hash_w2)) return cached_value;
    for (i=w1; i<=w2; i++) {
        v = lw_array[i].lw_identity;
        if (v) ⟨Allow this vocabulary entry to contribute to the excerpt's hash code 8⟩;
    }
    return h;
}
```

The function hash_code_from_excerpt is called from 5/parse and 12/phsf.

§**7.** Second, when a new excerpt meaning is to be registered, we want to hash code its token list. But only some of the tokens are vocabulary entries, while others instead represent gaps where arbitrary text can appear (referred to with a null pointer). Note that we simply ignore that gaps when hashing, that is, we produce the same hash as we would if the gaps were not there at all.

The hash generated this way is an arbitrary bitmap of bits 1 to 31, with bit 32 left clear. Bit 31 is set, as a special case, for excerpts in the context of text substitutions which begin with a word known to exist, and with differing meanings, in two differently cased forms: this is how "[the noun]" is distinguished from "[The noun]". (The lower 30 bits have the same meaning as in the first case above.)

```
define CAPITALISED_VARIANT_FORM (1 << 30)

void hash_code_from_token_list(excerpt_meaning *em) {
    int i, h = 0;
    if (em->no_em_tokens == 0) internal_error("Empty text when registering");
    if ((em->no_em_tokens >= 1) && (em->em_tokens[0])) {
        vocabulary_entry *lcf = vocab_get_lower_case_form(em->em_tokens[0]);
        if (lcf) {
            h = h | CAPITALISED_VARIANT_FORM;
            em->em_tokens[0] = lcf;
        }
    }
    for (i=0; i<em->no_em_tokens; i++) {
        vocabulary_entry *v = em->em_tokens[i];
        if (v) ⟨Allow this vocabulary entry to contribute to the excerpt's hash code 8⟩;
    }
    em->excerpt_hash = h;
}
```

§**8.** Now each vocabulary entry `v`, i.e., each distinct word identity, itself has a hash code to identify it. These are stored in `v->hash` and, except for literals, are more or less evenly distributed in about the range 0 to 1000.

The contribution made by a single word's individual hash to the bitmap hash for the whole excerpt is as follows.

⟨Allow this vocabulary entry to contribute to the excerpt's hash code 8⟩ ≡

```
if ((v->flags) & NUMBER_MC)    h = h | 1;
else if ((v->flags) & TEXT_MC) h = h | 2;
else if ((v->flags) & I6_MC)   h = h | 4;
else                           h = h | (8 << ((v->hash) % 27));
```

This code is used in §6,7,6,7,6,7.

§**9.** To sum up: the excerpt hash is a bitmap indicating what categories of words are present in the excerpt. It ignores "gaps" in token lists, and it ignores the order of the words and repetitions. The three least significant bits indicate whether numbers, text or I6 verbatims are present, and the next 27 bits indicate the presence of other words: e.g., bit 4 indicates that a word with hash code 0, 27, 54, ..., is present, and so on. Bit 31, which is used only for token lists of excerpt meanings, marks that an excerpt is a variant form whose first word must be capitalised in order for it to match. Bit 32 is always left blank (for superstitious reasons to do with the sign bit and differences between platforms in handling signed bit shifts).

The result is not a tremendously good hashing number, since it generally produces a sparse bitmap, so that the variety is not as great as might be thought. But it is optimised for the trickiest parsing cases where the rewards of saving unnecessary tests are greatest.

§**10. EM Listing.** We are clearly not going to store the excerpt meanings in a hash table keyed by the hash values of excerpts – with hash values as large as $2^{31} - 1$, that would be practically impossible.

Instead we key using the actual words. Each vocabulary entry has four linked lists of EMs: its subset list, its start list, its middle list, and its end list.

(a) If an EM needs to allow parsing as a subset, it must be placed in the subset list of every word. For instance, "buttress against cathedral wall" registered under the code `WORLD_OBJECT_MC` would be listed in the subset lists of "buttress", "against", "cathedral" and "wall".

(b) Otherwise it is placed in only one list:

(b1) If the token list consists only of a single gap `#`, we must be registering a "say" phrase to say a value. (There is one of these for each kind of value.) This meaning is listed under a special `blank_says_ml` list, which is not attached to any vocabulary entry.

(b2) Otherwise, if the first token is not a `#` gap, it goes into the start list for the first token's word: for instance, `award # points` joins the start list for "award".

(b3) Otherwise, if the last token is not a `#` gap, it goes into the end list for the last token's word: for instance, `# in # from now` joins the end list for "now".

(b4) Otherwise, it goes into the middle list of the word for the leftmost token which is not a `#`: for instance, `# plus #` joins the middle list for "plus".

Since no token lists of two or more consecutive `#`s cannot exist, this exhausts the possibilities.

Outside of subset mode, we will then test a given excerpt `(w1, w2)` in the source text against all possible meanings by checking the start list for `w1`, the end list for `w2` and the middle list for every one of `(w1+1, w2-1)`. Because of this:

(i) Performance suffers if lists for individual words become unbalanced in size. This is why we register Unicode translations as "white chess knight" rather than "Unicode white chess knight", and so on; the alternative would be a stupendously long start list for "unicode".

(ii) Middle lists are tested far more often than start or end lists, so we should keep them as small as possible. This is why (b4) above is our last resort; happily phrases both starting and ending with `#` are uncommon.

```
meaning_list *blank_says_ml = NULL;
void register_em(int meaning_code, excerpt_meaning *em) {
    warn_expression_cache();              the existence of new meanings jeopardises any cached parsing results
    ⟨Compute the new excerpt's hash code from its token list 11⟩;
    ⟨Watermark each word in the token list with the meaning code being applied 12⟩;
    LOGIF(EXCERPT_MEANINGS,
        "Logging meaning: $M with hash %08x, mc=%d, %d tokens\n",
        em, em->excerpt_hash, meaning_code, em->no_em_tokens);
    if (meaning_code & SUBSET_PARSING_BITMAP) {
        ⟨Place the new meaning under the subset list for each non-article word 13⟩;
    } else if ((em->no_em_tokens == 1) && (em->em_tokens[0] == NULL) &&
        (meaning_code == SAY_PHRASE_MC)) {
        ⟨Place the new meaning under the say-blank list 14⟩;
    } else if (em->em_tokens[0]) {
        ⟨Place the new meaning under the start list of the first word 15⟩;
    } else if (em->em_tokens[em->no_em_tokens-1]) {
        ⟨Place the new meaning under the end list of the last word 16⟩;
    } else {
        int i;
        for (i=1; i<em->no_em_tokens-1; i++)
            if (em->em_tokens[i]) { ⟨Place the new meaning under the middle list of word i 17⟩; break; }
        if (i >= em->no_em_tokens-1) internal_error("registered meaning of two or more #s");
    }
}
```

§**11.** See above.

⟨Compute the new excerpt's hash code from its token list 11⟩ ≡

```
    hash_code_from_token_list(em);
```

This code is used in §10.

§**12.** Another important optimisation is to flag each word in the meaning with the given meaning code – this is why vocabulary flags and excerpt meaning codes share the same numbering space. If we register "Table of Surgical Instruments" as a table name, the word "surgical", for instance, picks up the `TABLE_MC` bit in its `flags` bitmap.

The advantage of this is that if we want to see whether `(w1, w2)` might be a table name, we can take a bitwise AND of the flags for each word in the range; if the result doesn't have the `TABLE_MC` bit set, then at least one of the words never occurs in a table name, so the answer must be "no". This produces rapid, definite negatives with only a few false positives.

⟨Watermark each word in the token list with the meaning code being applied 12⟩ ≡

```
    int i;
    for (i=0; i<em->no_em_tokens; i++)
        if (em->em_tokens[i])
            ((em->em_tokens[i])->flags) |= meaning_code;
```

This code is used in §10.

§**13.** Note that articles (a, an, the, some) are excluded: this means we don't waste time trying to see if the excerpt "the" might be a reference to the object "Gregory the Great".

⟨Place the new meaning under the subset list for each non-article word 13⟩ ≡

```
int i;
for (i=0; i<em->no_em_tokens; i++) {
    vocabulary_entry *v = em->em_tokens[i];
    if (v == NULL) {
        LOG("Logging meaning: $M with hash %08x\n", em, em->excerpt_hash);
        internal_error("# in registration of subset meaning");
    }
    if ((v->flags) & ARTICLE_MC) continue;
    meaning_list *ml = new_permanent_ml(em->meaning_code);
    ml->em = em;
    ml->next_alternative = v->subset_list;
    v->subset_list = ml;
    v->subset_list_length++;
}
```

This code is used in §10.

§**14.** To register `#`, which is what "To say (N - a number)" and similar constructions translate to.

⟨Place the new meaning under the say-blank list 14⟩ ≡

```
meaning_list *ml = new_permanent_ml(em->meaning_code); ml->em = em;
if (blank_says_ml) {
    meaning_list *ml2 = blank_says_ml;
    while (ml2->next_alternative) ml2 = ml2->next_alternative;
    ml2->next_alternative = ml;
}
else blank_says_ml = ml;
LOGIF(EXCERPT_MEANINGS,
    "The blank list with $M is now:\n$m", em, blank_says_ml);
```

This code is used in §10.

§**15.**

⟨Place the new meaning under the start list of the first word 15⟩ ≡

```
meaning_list *ml = new_permanent_ml(em->meaning_code); ml->em = em;
ml->next_alternative = em->em_tokens[0]->start_list;
em->em_tokens[0]->start_list = ml;
```

This code is used in §10.

§**16.** ...and similarly...

⟨Place the new meaning under the end list of the last word 16⟩ ≡

```
meaning_list *ml = new_permanent_ml(em->meaning_code); ml->em = em;
ml->next_alternative = em->em_tokens[em->no_em_tokens-1]->end_list;
em->em_tokens[em->no_em_tokens-1]->end_list = ml;
```

This code is used in §10.

§**17.** ...and similarly again:

⟨Place the new meaning under the middle list of word i 17⟩ ≡

```
meaning_list *ml = new_permanent_ml(em->meaning_code); ml->em = em;
ml->next_alternative = em->em_tokens[i]->middle_list;
em->em_tokens[i]->middle_list = ml;
```

This code is used in §10.

§**18. Deregistration.** This is possible only for subset-parsed EMs, that is, world objects. We do it by striking the reference to the given data out of the relevant subset lists; a ticklish business but not needed often. (In fact, never, as of October 2008.)

```
void deregister_excerpt_meaning(int meaning_code, int w1, int w2,
    general_pointer data) {
    int k;
    meaning_list *ml, *back;
    LOGIF(EXCERPT_MEANINGS, "Unlogging meaning: <$W> data %08x\n", w1, w2,
        GENERAL_POINTER_AS_INT(data));
    for (k=w1; k<=w2; k++) {
        for (ml = lw_array[k].lw_identity->subset_list, back = NULL;
            ml; back = ml, ml = ml->next_alternative) {
            if ((COMPARE_GENERAL_POINTERS(ml_meaning(ml)->data, data))
                && (ml_meaning(ml)->meaning_code == meaning_code)) {
                if (back) back->next_alternative = ml->next_alternative;
                else lw_array[k].lw_identity->subset_list = ml->next_alternative;
                if (--(lw_array[k].lw_identity->subset_list_length) == 0)
                    lw_array[k].lw_identity->flags =
                        lw_array[k].lw_identity->flags - meaning_code;
                break;
            }
        }
    }
}
```

§**19. Registration.** The following is the main routine used throughout Inform to register new meanings.

```
excerpt_meaning *register_excerpt_meaning(int meaning_code, int secondary,
    int w1, int w2, general_pointer data) {
    excerpt_meaning *em = em_new(meaning_code, secondary, data);
    ⟨Unless this is a new phrase or text substitution, skip any initial article 20⟩;
    if (meaning_code == SAY_PHRASE_MC)
        ⟨Detect use of upper case on the first word of this new text substitution 21⟩;
    ⟨Build the token list for the new EM 22⟩;
    register_em(meaning_code, em);
    if ([[w1, w2 == player]] && (meaning_code & QUANTITY_MC)) meaning_of_player = em;
    return em;
}
```

The function register_excerpt_meaning is called from 5/aph, 5/unitr, 7/tids, 9/qty, 9/scene, 9/wo, 9/prop, 10/tab, 10/eqns, 10/fig, 10/sfx, 10/exf, 10/isin, 11/nap, 11/av, 12/phtd, 12/br and 12/rb.

§20. Articles are preserved at the front of phrase definitions, mainly because text substitutions need to distinguish (for instance) "say [the X]" from "say [an X]".

⟨Unless this is a new phrase or text substitution, skip any initial article 20⟩ ≡

```
if ((meaning_code & PARAMETRISED_PARSING_BITMAP) == 0) {
    if ((lw_array[w1].lw_identity->flags) & ARTICLE_MC) w1++;
    if (w1 > w2) internal_error("registered a meaning which was only an article");
}
```

This code is used in §19.

§21. Because an open bracket fails `isupper`, the following looks at the first letter of the first word only if it's not a blank. If it finds upper case, as it would when reading the "T" in:

To say The Portrait: ...

then it makes a new upper-case version of the word "the", i.e., "The", with a distinct lexical identity; and places this distinguished identity as the new first token. This ensures that we end up with a different token list from the one in:

To say the Portrait: ...

(These are the only circumstances in which phrase parsing has any case sensitivity.)

⟨Detect use of upper case on the first word of this new text substitution 21⟩ ≡

```
char *tx = lw_array[w1].lw_rawtext;
if ((tx[0]) && (isupper(tx[0]))) {
    vocabulary_entry *ucf = vocab_make_case_sensitive(lw_array[w1].lw_identity);
    lw_array[w1].lw_identity = ucf;
    LOGIF(EXCERPT_MEANINGS,
        "Allowing initial capitalised word %s: meaning_code = %08x\n",
            tx, meaning_code);
}
```

This code is used in §19.

§22. We read the text in something like:

award (P - a number) points

and transcribe it into the token list, collapsing bracketed parts into `#` tokens denoting gaps, to result in something like:

```
award # points
```

with a token count of 3.

⟨Build the token list for the new EM 22⟩ ≡

```
int i, tc;
for (i=0, tc=0; w1+i<=w2; i++) {
    if (tc >= MAX_TOKENS_PER_EXCERPT_MEANING) {
        ⟨Complain of excessive length of the new excerpt 25⟩;
        break;
    }
    if (compare_word(w1+i, OPENBRACKET_V)) {
        em->em_tokens[tc++] = NULL;
        ⟨Skip over bracketed token description 23⟩;
    } else em->em_tokens[tc++] = lw_array[w1+i].lw_identity;
}
em->no_em_tokens = tc;
```

This code is used in §19.

§**23.** This is all a little defensive, but syntax bugs higher up tend to find their way down to this plughole:

⟨Skip over bracketed token description 23⟩ ≡

```
while (compare_word(w1+i, CLOSEBRACKET_V) == FALSE) {
    i++;
    if (w1+i>w2)  {
        LOG("Bad meaning: <$W>\n", w1, w2);
        internal_error("Bracket mismatch when registering");
    }
}
if ((w1+i <= w2) && (compare_word(w1+i, OPENBRACKET_V))) {
    LOG("Bad meaning: <$W>\n", w1, w2);
    internal_error("Two consecutive bracketed tokens when registering");
}
```

This code is used in §22.

§**24. Reworded meanings.** In a few cases it is convenient to register a slightly altered wording. For instance, every table column – "quota", say – is registered not only under its own text ("quota") but under the same text with "column" added ("quota column"). The following routine allows up to two arbitrary words to be placed before `(w1, w2)`, and up to one after them.

But in other respects this is a simpler routine, because it's never needed for token lists with gaps in.

```
excerpt_meaning *register_reworded_meaning(int meaning_code, int secondary,
    vocabulary_entry *vb1, vocabulary_entry *vb2,
    int w1, int w2, vocabulary_entry *va, general_pointer data) {
    int i, tc = 0;
    excerpt_meaning *em = em_new(meaning_code, secondary, data);
    if ((w1 >= 0) &&
        ((meaning_code & PARAMETRISED_PARSING_BITMAP) == 0) &&
        ((lw_array[w1].lw_identity->flags) & ARTICLE_MC) && (vb1 == NULL)) w1++;
    if (vb1) em->em_tokens[tc++] = vb1;
    if (vb2) em->em_tokens[tc++] = vb2;
    if (w1 >= 0) {
        if (4 + w2 - w1 > MAX_TOKENS_PER_EXCERPT_MEANING) {
            ⟨Complain of excessive length of the new excerpt 25⟩;
            w2 = w1 + MAX_TOKENS_PER_EXCERPT_MEANING - 4;
        }
        for (i=0; w1+i<=w2; i++)
            em->em_tokens[tc++] = lw_array[w1+i].lw_identity;
    }
    if (va) em->em_tokens[tc++] = va;
    em->no_em_tokens = tc;
    register_em(meaning_code, em);
    return em;
}
```

The function register_reworded_meaning is called from 5/bp, 6/equal, 9/prop, 10/tab, 10/eqns, 11/act, 11/av, 12/phtd and 12/rb.

§**25.** In practice, nobody ever hits this message except deliberately. It has a tendency to fire twice or more on the same source text because of registering multiple inflected forms of the same text; but it's not worth going to any trouble to prevent this.

⟨Complain of excessive length of the new excerpt 25⟩ ≡

```
LOG("Tried to register <$W>\n", w1, w2);
sentence_problem(_P_(C5TooLongName),
    "that seems to involve far too long a name",
    "since in general names are limited to a maximum of 32 words.");
```

This code is used in §22,24,22,24,22,24.

Unicode Translations 5/unitr

Purpose

To manage the names assigned to Unicode character values.

---

§**1.** There are no data structures here; Unicode names are simply a category of excerpt meanings, so we read a "translates into Unicode as" sentence as a new name and its meaning to be.

```
sentence_handler TRANSLATESU_SH_handler =
    { SENTENCE_NT, TRANSLATESU_VB, 2, unicode_translates };

void unicode_translates(parse_node *pn) {
    int nn1, nn2, as1, as2, cc, occ;

    [[as1, as2 <-- pn->down->next->next]];
    [[as1, as2 == as ... --> as1, as2]];
    ⟨Check that we have a valid literal character code 2⟩;

    [[nn1, nn2 <-- pn->down->next]];
    occ = is_a_unicode_value(nn1, nn2);
    if (occ == cc) return;

    if (occ >= 0) {
        sentence_problem(_P_(C5UnicodeAlready),
            "this Unicode character name has already been translated",
            "so there must be some duplication somewhere.");
        return;
    }

    register_excerpt_meaning(
        MISCELLANEOUS_MC, UNICODENAME_SMC, nn1, nn2,
        STORE_POINTER_parse_node(new_nounphrase_raw(as1, as2)));
}
```

§**2.**

⟨Check that we have a valid literal character code 2⟩ ≡

```
    if ((as1 != as2) || (vocab_test_flags(as1, NUMBER_MC) == 0)) {
        sentence_problem(_P_(C5UnicodeNonLiteral),
            "a Unicode character name must be translated into a literal "
            "decimal number written out in digits",
            "which this seems not to be.");
        return;
    }
    cc = vocab_get_literal_number_value(lw_array[as1].lw_identity);
    if (Unicode_char_in_range(cc) == FALSE) return;
```

This code is used in §1.

§**3.** The following is called only on excerpts from the source where it is a fairly safe bet that a Unicode character is referred to. It returns either the character code, or −1 if the excerpt doesn't refer to such a character after all.

```
int is_a_unicode_value(int w1, int w2) {
    ⟨Match a literal Unicode character number in decimal 4⟩;
    ⟨Match a named Unicode character 5⟩;
    return -1;
}
```

The function is_a_unicode_value is called from 5/lit.

§**4.** The effect of making the following range check is that we can guarantee that any value of the kind "Unicode-character" in I7 is a valid Unicode:

⟨Match a literal Unicode character number in decimal 4⟩ ≡

```
    if ((w1 == w2) && (vocab_test_flags(w1, NUMBER_MC))) {
        int cc = vocab_get_literal_number_value(lw_array[w1].lw_identity);
        if (Unicode_char_in_range(cc)) return cc;
    }
```

This code is used in §3.

§**5.** We need not make the same check here because Inform only registers names for characters whose codes are known to be within range.

⟨Match a named Unicode character 5⟩ ≡

```
    meaning_list *ml = SP_excerpt(MISCELLANEOUS_MC, w1, w2);
    if ((ml) && (em_get_secondary_code(ml_meaning(ml)) == UNICODENAME_SMC)) {
        parse_node *p = RETRIEVE_POINTER_parse_node(em_data(ml_meaning(ml)));
        return vocab_get_literal_number_value(lw_array[p->word_ref1].lw_identity);
    }
```

This code is used in §3.

§**6.** And here is the range check used by both of the above routines:

```
int Unicode_char_in_range(int cc) {
    if ((cc < 0) || (cc >= 0x10000)) {
        sentence_problem(_P_(C5UnicodeOutOfRange),
            "Inform can only handle Unicode characters in the 16-bit range",
            "from 0 to 65535.");
        return FALSE;
    }
    return TRUE;
}
```

Meaning Lists 5/ml

Purpose

To build meaning lists, which despite the name are really tree structures, showing possible interpretations of a sequence of words.

Definitions

¶1. Meaning lists are an intermediate construction within the S-parser, used to hold the possible meanings of complex excerpts of text. The S-parser completes its work by turning any meaning list for a successfully parsed piece of text into a much more compact `specification` structure, perhaps with a proposition in predicate calculus attached. This is both smaller and much less ambiguous in meaning. It would remove a layer of code in Inform, and also one delicate interface between layers, if the S-parser could parse directly to specifications; and this is what the earliest builds did, in 2003 and 2004, but the result was that `specification` became a very complex structure, trying to perform two different tasks at once – being a sort of checklist of possibilities and then being a definite answer. Separating these two roles and inventing meaning lists was a very disruptive decision, but eventually resulted in cleaner and simpler code.

¶2. We have already seen meaning lists used to store lists of possible excerpt meanings attached to given words, but that's not their main function, and despite the name they are not necessarily simple lists. They are a sort of two-dimensional tree structure where every node P represents one possible meaning of a given excerpt of the original text. Because in general the meaning will be complicated, and not as simple as a single noun, P will also have children which are nodes representing meanings of subexcerpts.

A two-dimensional tree is hard to visualise, but in practice they are easy enough to read: they are basically standard parse-trees except that at certain points they fork off into different possibilities. For instance, if we try to parse the example phrase at the beginning of this chapter:

> if Mr Fitzwilliam Darcy was carrying at least three things which are in the box, increase the score by 7;

then the S-parser initially generates the following meaning list:

```
CMD_PRODUCTION / "if mr fitzwilliam darcy was carrying at least ..."
    PHRASE_PRODUCTION
        [1/2] (score 1) {# at # = VOID_PHRASE_MC} / "if mr fitzwilliam ..."
            UNPARSED_PRODUCTION / "if mr fitzwilliam darcy was carrying"
            UNPARSED_PRODUCTION / "least three things which are in the box..."
        [2/2] (score 1) {if # , # = VOID_PHRASE_MC} / "if mr fitzwilliam darcy..."
            UNPARSED_PRODUCTION / "mr fitzwilliam darcy was carrying at..."
            UNPARSED_PRODUCTION / "increase the score by 7"
```

The notation `[1/2]` means "possibility 1 of 2". This structure shows that the S-parser is certain that we have a command phrase, but that on textual grounds alone it could be one of two possibilities. In fact, `[2/2]` is the valid one, as will become clear when it returns to parse the arguments currently left as `UNPARSED_PRODUCTION` nodes.

¶3. When the S-parser gets to the condition (argument 1 of possibility `[2/2]` above), a more elaborate meaning list results, but which is unambiguous:

```
COND_PRODUCTION / "mr fitzwilliam darcy was carrying at least ... in the box"
    SV_PRODUCTION / "mr fitzwilliam darcy was carrying at least ... in the box"
        NP_PRODUCTION / "mr fitzwilliam darcy"
            VAL_PRODUCTION / "mr fitzwilliam darcy"
                DC_PRODUCTION / "mr fitzwilliam darcy"
                    DC_NOUN_PRODUCTION / "mr fitzwilliam darcy"
                        {mr fitzwilliam darcy = WORLD_OBJECT_MC}
        VP_PRODUCTION
            VERB_PRODUCTION => VU: was WAS_TENSE -> is
                PREP_PRODUCTION => PU: carrying -> carries
            NP_PRODUCTION / "at least three things which are in the box"
                VAL_PRODUCTION / "at least three things which are in the box"
                    DC_PRODUCTION / "at least three things which are in the box"
                        SN_PRODUCTION / "at least three things which are in the box"
                            DC_PRODUCTION / "at least three things"
                                DC_NOUN_PRODUCTION / "things"
                                    {things = WORLD_OBJECT_MC}
                                DETERMINER_PRODUCTION => Card>=3 / "at least three"
                            VP_PRODUCTION
                                VERB_PRODUCTION => VU: are IS_TENSE -> is
                                    PREP_PRODUCTION => PU: in -> is-in
                                DC_PRODUCTION / "box"
                                    DC_NOUN_PRODUCTION / "box"
                                        {mr bingham's box = WORLD_OBJECT_MC}
                        DETERMINER_PRODUCTION => Card>=3 / "at least three"
```

Note the three concrete noun phrases – Mr Darcy, the box, and "things". It's perhaps surprising that the determiner for "at least three" turns up twice in the tree, but this is because the sub-excerpt

> at least three things

is also validly subject to the determiner, so its subtree contains the appropriate node.

As this shows, the result of parsing can be an extravagantly big meaning list. When the S-parser finishes, it is translated into much more compact data: a single specification representing a condition,

```
(A)'mr fitzwilliam ... box'/CONDITION_FMY/TEST_PROPOSITION_SPC<0 times: WAS_TENSE>
```

and with the proposition

```
[ Card>=3 x: K2'thing'(x) ^ is(O104'mr bingham's box',ContainerOf(x)) =>
    is(O105'mr fitzwilliam darcy',CarrierOf(x)) ]
```

which can be paraphrased "at least three x which are things and such that their container is the box are also such that Mr Darcy is their carrier".

¶4. So, then, each meaning list node has children and siblings to place it into a parse tree, but also forking links to alternative meanings. The actual data at a node can be a value (the `type_spec`), an excerpt meaning, or in some cases a pointer to some other structure. For instance, a `VERB_PRODUCTION` node has a pointer to the relevant `verb_usage` attached.

```
typedef struct meaning_list {
    int expiry_time;                                  an integer measured in creation "cycles": see below
    int production;                                                                    a production code
    int word_pair;                                    word pair (w1,w2) packed into a single integer
    struct excerpt_meaning *em;                                                        what this seems to mean...
    struct specification *type_spec;                                                   evaluation used in compaction
    struct general_pointer data_attached;                                              certain productions have data attached
    struct meaning_list *next_alternative;                                             fork to alternative meaning
    int score;                                        a scoring system is used to choose most likely alternative
    struct meaning_list *sibling;                                                      tree of meanings of subordinate clauses
    struct meaning_list *child;
    MEMORY_MANAGEMENT
} meaning_list;

int no_permanent_MLs = 0, no_ephemeral_MLs = 0, GAP_movements = 0;
```

The structure meaning_list is shared with 5/em, 5/arch and 5/parse.

¶5. It will be noted that the meaning codes for excerpt meanings use the bottom 31 bits of a (presumably) 32-bit word to hold sets of contexts, but never have bit 32 set. Meaning codes with bit 32 set are *not* considered as sets but simply as magic values in themselves. When we parse a complicated piece of text, the result is a tree in which the leaves are excerpts with simple meanings, where the `production` field is a meaning code; but the higher nodes have `production` values from the following set.

(There is no significance to these numbers except that they must all be different, and must all have bit 32 set.)

```
define ABSENT_SUBJECT_PRODUCTION 0x80000010

§1. Logging production values.

```
void log_production(int production) {
    if (production == 0) { LOG("<null-production>"); return; }
    if (production & 0x80000000) {
        switch (production) {
            case ABSENT_SUBJECT_PRODUCTION: LOG("ABSENT_SUBJECT_PRODUCTION"); break;
            case ACTION_PRODUCTION: LOG("ACTION_PRODUCTION"); break;
            case ADVERB_PRODUCTION: LOG("ADVERB_PRODUCTION"); break;
            case AL_PRODUCTION: LOG("AL_PRODUCTION"); break;
            case AP_PRODUCTION: LOG("AP_PRODUCTION"); break;

            default: LOG("<unknown-production-%08x>", production); break;
        }
    } else log_meaning_code(production);
}
```

The function log_production is called from 2/dl.

§**2.** Logging a meaning list is more than a matter of displaying an indented tree, because of the ambiguities present. The log uses the notation `[1/3]` for "possibility 1 of 3".

```
void log_meaning_list(meaning_list *ml) {
    if (ml == NULL) { LOG("<null-meaning-list>\n"); return; }
    log_ml_recursively(ml, 0, 0);
}
void log_ml_recursively(meaning_list *ml, int num, int of) {
    int w1, w2;
    ⟨Calculate num and of such that this is [num/of] if they aren't already supplied 3⟩;
    if (ml == NULL) { LOG("NULL\n"); return; }
    if (of > 1) {
        LOG("[%d/%d] ", num, of);
        if (ml->score != 0) LOG("(score %d) ", ml->score);
    }
    if (ml->em) LOG("$M", ml->em);
    else log_production(ml->production);
    if (ml->type_spec) {
        LOG(" => ");
        if (ml->production == TIME_PRODUCTION) LOG("$t", spec_get_condition_tense(ml->type_spec));
        else LOG("$S", ml->type_spec);
    }
    ⟨Describe attached data for a few special cases with pointers attached 4⟩;
    ml_get_text(ml, &w1, &w2);
    if (w1 >= 0) LOG(" / \"$W\"", w1, w2);
    LOG("\n");
    if (ml->child) {
        STREAM_INDENT(dl); log_ml_recursively(ml->child, 0, 0); STREAM_OUTDENT(dl);
    }
    if (ml->next_alternative) log_ml_recursively(ml->next_alternative, num+1, of);
    if (ml->sibling) log_ml_recursively(ml->sibling, 0, 0);
}
```

The function log_meaning_list is called from 2/dl.

§**3.** When the first alternative is called, `log_ml_recursively` has arguments 0 and 0 for the possibility. The following code finds out the correct value for `of`, setting this possibility to be `[1/of]`. When we later iterate through other alternatives, we pass on correct values of `num` and `of`, so that this code won't be used again on the same horizontal list of possibilities.

⟨Calculate num and of such that this is [num/of] if they aren't already supplied 3⟩ ≡

```
if (num == 0) {
    meaning_list *ml2;
    for (ml2 = ml, of = 0; ml2; ml2 = ml2->next_alternative, of++) ;
    num = 1;
}
```

This code is used in §2.

§**4.** Most higher-up nodes in the list are described fully by production number alone – every `VAL_PRODUCTION` is like every other. But a few have data attached, a pointer to some other structure, to clarify them. Not every `PREP_PRODUCTION` is like every other; it depends what the preposition usage is.

⟨Describe attached data for a few special cases with pointers attached 4⟩ ≡

```
switch (ml->production) {
    case DETERMINER_PRODUCTION:
        LOG(" => ");
        log_quantifier(RETRIEVE_POINTER_quantifier(ml->data_attached), ml->score); break;
    case VERB_PRODUCTION:
        LOG(" => ");
        log_verb_usage(RETRIEVE_POINTER_verb_usage(ml->data_attached)); break;
    case PREP_PRODUCTION:
        LOG(" => ");
        log_preposition_usage(RETRIEVE_POINTER_preposition_usage(ml->data_attached)); break;
}
```

This code is used in §2.

§**5. Creation.** When we ask the memory manager to create a new structure, we increase the amount of memory claimed from the operating system, little by little. This memory will not be given back until Inform exits: structures, once created, are permanent. Normally this is what we want – to hold a phrase definition, for instance, which needs to be available for the rest of the run.

Meaning lists are the exception. In tests made in February 2009, compiling "Bronze" generated around 189,000 `meaning_list` structures, but only 1 in 50 were needed in permanent storage – to hold the lists of excerpt meanings attached to vocabulary words, which together make up Inform's equivalent of a symbols table. The other 49 in 50 `meaning_list` structures were ephemeral – an intermediate result of parsing text which could be thrown away once acted on. So that is what the following new system will do.

Each `meaning_list` is marked with an expiry date when created – most often the "current time", just as supermarket bread is tagged with a sell-by date which is the same as the day of baking. The rarer permanent MLs are marked instead with impossibly distant expiry dates, like Army field rations. The "current time", for this purpose, has no connection with the time of day. It begins at 0 and advances by 1 whenever Inform completes some parsing-heavy task: working through an assertion sentence, compiling a phrase, and so on. A meaning list structure whose expiry date is before the current time is said to have "expired".

```
define THE_INFINITE_FUTURE 2147483647
```

§**6.** When we need a new meaning list, we first look for an expired one to reuse – only if that fails do we ask the memory manager to create a new structure. A complete search of existing structures would produce the best-possible memory economy, but would also be slow. For speed reasons we therefore use the following pragmatic strategy:

(a) A new ephemeral ML reuses the first expired structure after the last-created permanent one, but
(b) A new permanent ML reuses the expired structure in memory.

We do this by keeping three markers: the earliest ephemeral ML occurring one or more places before some permanent ML, the "GAP"; the latest permanent one, the "LP"; and the start of the expired tail, "TAIL", characterised by the fact that it and all subsequent MLs have expired.

For instance, suppose the time is now 1021 and the list of MLs in memory shows expiry dates thus:

```
PERMANENT -> 1020 -> PERMANENT -> PERMANENT -> 1021 -> 1020 -> 976
             ^GAP                ^LP                 ^TAIL
```

A new ephemeral ML reuses the TAIL position, the second 1020, and TAIL moves forwards:

```
PERMANENT -> 1020 -> PERMANENT -> PERMANENT -> 1021 -> 1021 -> 976
             ^GAP                ^LP                          ^TAIL
```

Whereas a new permanent ML reuses the GAP position, filling in the gap, and GAP becomes `NULL`:

```
PERMANENT -> PERMANENT -> PERMANENT -> PERMANENT -> 1021 -> 1021 -> 976
                                       ^LP                          ^TAIL
```

Note that LP moves only forwards. GAP is `NULL` from time to time, but its non-`NULL` values always move forwards, too. The sequence is always GAP strictly behind LP strictly behind TAIL, when these are not `NULL`, and no two ever coincide.

Perfect efficiency is achieved when GAP is `NULL`, as here. In practice this doesn't always happen. But MLs do tend to concentrate early in memory; on a long run they end up about 90% contiguous, that is, if there are N permanent MLs then they tend to live in the first $1.1N$ positions. That will be good enough for us, and the important point about the above algorithm is that it allocates M objects in $O(M)$ time, not $O(M^2)$, which with $M \simeq 190,000$ would hurt.

```
meaning_list *LP_marker = NULL, *GAP_marker = NULL, *TAIL_marker = NULL;
meaning_list *earliest_ephemeral_ML_today = NULL;
int current_creation_time = 0, max_ML_creations_per_day = 0, no_ML_creations_today;
```

§**7.** First, the allocation.

```
meaning_list *get_available_ml(int seeking_permanent_slot) {
    meaning_list *new;
    if ((seeking_permanent_slot) && (GAP_marker)) {
        new = GAP_marker;
        LOGIF(ML_ALLOC, "Time %d: Using GAP position ML%d with expiry time %d\n",
            current_creation_time, new->allocation_id, new->expiry_time);
        here TAIL does not change
        ⟨Move the GAP marker forward to the next gap, if any 8⟩;
    } else if (TAIL_marker) {
        new = TAIL_marker;
        LOGIF(ML_ALLOC, "Time %d: Using TAIL position ML%d with expiry time %d\n",
            current_creation_time, new->allocation_id, new->expiry_time);
        here any GAP is unaltered
        TAIL_marker = NEXT_OBJECT(TAIL_marker, meaning_list);
        if (seeking_permanent_slot) LP_marker = new;
    } else {
        new = CREATE(meaning_list);
        LOGIF(ML_ALLOC, "Time %d: Using new position ML%d\n",
            current_creation_time, new->allocation_id);
        here any TAIL vanishes, but a GAP is unaltered
        TAIL_marker = NULL;
        if (seeking_permanent_slot) LP_marker = new;
    }
    if (seeking_permanent_slot) new->expiry_time = THE_INFINITE_FUTURE;
    else {
        new->expiry_time = current_creation_time;
        if (earliest_ephemeral_ML_today == NULL) earliest_ephemeral_ML_today = new;
    }
    no_ML_creations_today++;
    LOGIF(ML_ALLOC, "Time %d: GAP = ML%d, LP = ML%d, TAIL = ML%d\n",
        current_creation_time,
        (GAP_marker)?(GAP_marker->allocation_id):0,
        (LP_marker)?(LP_marker->allocation_id):0,
        (TAIL_marker)?(TAIL_marker->allocation_id):0);
    return new;
}
```

§**8.** Everything before the GAP is permanent, and the new item put there will also be permanent. We must move forward over unexpired items. There are then three possibilities: we run out (there are now no expired items in the list, so the new GAP is `NULL`); or we are at the TAIL position (so everything is expired from here on, and GAP must again be `NULL`); or we are at an expired item before the TAIL, which is therefore a new valid GAP item.

⟨Move the GAP marker forward to the next gap, if any 8⟩ ≡

```
    do {
        GAP_marker = NEXT_OBJECT(GAP_marker, meaning_list);
        GAP_movements++;
    } while ((GAP_marker) && (GAP_marker->expiry_time >= current_creation_time));
    if (GAP_marker == TAIL_marker) GAP_marker = NULL;
```

This code is used in §7.

§**9.** Second, moving time on to the next day. There is little prospect of reaching `THE_INFINITE_FUTURE`, but just in case we do, we stop time there; infinity is the day that never sees midnight.

```
void finish_this_session_of_parsing(void) {
    if (current_creation_time < THE_INFINITE_FUTURE) {
        if (dl_this(ML_ALLOC_DA)) {
            LOG("Time %d: %d items were created today ",
                current_creation_time, no_ML_creations_today);
            if (no_ML_creations_today > max_ML_creations_per_day) {
                LOG("- a new record!");
                max_ML_creations_per_day = no_ML_creations_today;
            }
            LOG("\n");
        }
        ⟨Adjust the markers at midnight 10⟩;
        current_creation_time++;
        earliest_ephemeral_ML_today = NULL;
        no_ML_creations_today = 0;
    }
}
```

The function finish_this_session_of_parsing is called from 8/tass, 10/str, 10/tab, 12/cs, 12/phsf, 12/cph and 13/tfg.

§**10.** To continue our example, at one minute to midnight on day 1021 we had:

```
PERMANENT -> PERMANENT -> PERMANENT -> PERMANENT -> 1021 -> 1021 -> 976
                                       ^LP                          ^TAIL
```

And at one minute past midnight on day 1022 we have:

```
PERMANENT -> PERMANENT -> PERMANENT -> PERMANENT -> 1021 -> 1021 -> 976
                                       ^LP          ^TAIL
```

LP doesn't move, since there is no change to the permanent items. Since every non-permanent item expired at midnight, the new TAIL always starts just after LP.

The tricky one is GAP. If it is non-`NULL` at midnight, it doesn't change, since it is still an expired item with everything before it permanent. But if it is `NULL`, we only know that any gaps in the permanent items are filled with day-1021 creations, like this:

```
PERMANENT -> PERMANENT -> PERMANENT -> 1021 -> 1021 -> PERMANENT -> 1021 -> 976
```

Consider the first day-1021 creation in the list. If it doesn't exist (i.e., there are no day-1021 items) there is still no GAP. Otherwise it exists, and is either before, at or after the new TAIL position. If before TAIL (or if there is no TAIL), it is the new GAP. If at or after TAIL then there are no permanent items after it, and once again there is still no GAP.

⟨Adjust the markers at midnight 10⟩ ≡

```
    TAIL_marker = NEXT_OBJECT(LP_marker, meaning_list);
    if (GAP_marker == NULL) {
        GAP_marker = earliest_ephemeral_ML_today;
        if ((TAIL_marker) && (GAP_marker) &&
            (GAP_marker->allocation_id >= TAIL_marker->allocation_id))
            GAP_marker = NULL;
    }
```

This code is used in §9.

§**11.** We can finally prove the running time of this algorithm over the entire run. Suppose M meaning lists are allocated during the run. The midnight operation runs in $O(1)$ but occurs on each of the D days; however, each day's activity requires the creation of at least one meaning list, so $D \leq M$ and midnight operations are worst $O(M)$. The allocation operation contains just one loop, when GAP moves forwards. Now GAP always advances until it becomes `NULL`, and since the list has length at most M, this is $\leq M$ iterations in total across Inform's run – *except* that the midnight operation sometimes puts it back after it has become `NULL`, forcing it to traverse the last few items again.

For each t, let $C(t)$ be the number of allocations made on day t. We prove by induction that the number of extra GAP movements due to being put back at the end of day t, which we call $X(t)$, satisfies $X(t) \leq C(t) + C(t+1)$.

Suppose, at midnight on day t, GAP is put back into the new list. How many extra steps forward will that cost us before it falls off again? The answer is that it is put back at the earliest ephemeral day t creation. This is at most $C(t)$ steps from the TAIL, which it will never advance past. However, the TAIL itself moves forwards during day $t+1$, by at most $C(t+1)$ steps. So the worst case is that the extra steps incurred due to day $t+1$ is actually $C(t) + C(t+1)$.

Therefore the total number of extra steps forward is

$$X = \sum_{t=0}^{D-1} X(t) \leq \sum_{t=0}^{D-1} C(t) + C(t+1) \leq 2 \sum_{t=0}^{D-1} C(t) = 2M.$$

It takes at most M regular steps forward, so, finally, the number of iterations of the loop is bounded across the whole run by $3M$, and hence our allocation algorithm runs in $O(M)$ time.

§**12.** Testing with "Bronze" in February 2009 in fact produced just 2438 steps where $M = 189165$, so in real-world usage it is very likely well under $3M$. At the end of the run there were 5411 MLs in memory, of which 4166 were permanent. Only 1245 ephemeral MLs existed, instead of 184,999, saving about 10.5MB of memory – a saving of 30% off the total memory bill.

Though it had been intended as a trade-off of speed for memory savings, it in fact shaved about 15% off Inform's total running time, because `get_available_ml` acts as a fast cache for spare memory in rapid-fire parsing.

(An interesting reflection on the usefulness of literate programming is that the author wrote the whole of this "Creation" section, all but this paragraph, before trying anything out. This took the better part of three hours, but the result compiled after two typos were fixed, and worked perfectly first time, completing the entire Inform test suite with no errors.)

§**13. Construction.** We can now forget how memory for MLs is found, and worry about how to make them and what to use them for. We request them either temporarily or permanently:

```
meaning_list *new_ml(int code_number) {
    meaning_list *ml = get_available_ml(FALSE);
    ⟨Initialise the rest of the ML structure 14⟩;
    no_ephemeral_MLs++;
    return ml;
}
meaning_list *new_permanent_ml(int code_number) {
    meaning_list *ml = get_available_ml(TRUE);
    ⟨Initialise the rest of the ML structure 14⟩;
    no_permanent_MLs++;
    return ml;
}
```

The function new_ml is called from 5/parse, 5/lit, 5/candd, 5/tandv, 5/varc, 5/candp and 5/mlc.
The function new_permanent_ml is called from 5/em.

§**14.** But in each case the result looks the same.

⟨Initialise the rest of the ML structure 14⟩ ≡

```
    ml->em = NULL;
    ml->next_alternative = NULL;
    ml->sibling = NULL;
    ml->child = NULL;
    ml->type_spec = NULL;
    ml->score = 0;
    ml->production = code_number;
    ml->word_pair = -1;
    ml->data_attached = NULL_GENERAL_POINTER;
```

This code is used in §13.

§**15.** The following constructor routines fill out the fields in useful ways. Here's one if a word range is to be attached:

```
meaning_list *new_ml_with_words(int code_number, int w1, int w2) {
    meaning_list *ml = new_ml(code_number);
    if ((w1 >= 0) && (w1<=w2)) ml->word_pair = w1 + ((w2-w1) << 20);
    else ml->word_pair = -1;
    return ml;
}
```

The function new_ml_with_words is called from 5/arch, 5/parse and 5/candd.

§**16.** And here is one deriving from a world object:

```
meaning_list *ml_from_wo(world_object *wo) {
    meaning_list *ml = new_ml(WORLD_OBJECT_MC);
    ml->em = wo_get_principal_meaning(wo);
    ml->score = 1;
    return ml;
}
```

The function ml_from_wo is called from 5/candd.

§**17.** TYPE_PRODUCTION nodes hold specifications. As we will see in Chapter 7, these can represent both actual and generic values (for instance, "7" and "a number"), but the ones attached to TYPE_PRODUCTION nodes are always generic – so they really do represent types. First, a version to create such a node from the type ID number:

```
meaning_list *make_type_ml_from_ID(int ID_number) {
    meaning_list *ml = new_ml(TYPE_PRODUCTION);
    ml->type_spec = new_generic_type_from_ID(ID_number);
    return ml;
}
```

The function make_type_ml_from_ID is called from 5/candd.

§**18.** Second, from a given kind of value:

```
meaning_list *make_type_ml_from_kov(kind_of_value *kov) {
    meaning_list *ml = new_ml(TYPE_PRODUCTION);
    ml->type_spec = new_generic_CONSTANT_type(kov);
    return ml;
}
```

The function make_type_ml_from_kov is called from 5/candd.

§**19.** DETERMINER_PRODUCTION nodes record a quantifier (the underlying meaning of a determiner, that is) together with its numeric parameter, in case relevant.

```
meaning_list *make_determiner_ml(quantifier *quant, int parameter, int w1, int w2) {
    meaning_list *ml = new_ml_with_words(DETERMINER_PRODUCTION, w1, w2);
    ml->data_attached = STORE_POINTER_quantifier(quant);
    ml->score = parameter;
    return ml;
}
```

The function make_determiner_ml is called from 5/candd.

§**20.** TIME_PRODUCTION nodes record a time period, a structure which despite its name can also simply be a tense indication. Slightly bogusly, the time period is attached by being part of a condition SP, though no specific condition is meant – it's just that conditions always have time periods attached to them, so this is the natural way to store them.

```
meaning_list *make_time_ml(time_period tp) {
    meaning_list *ml = new_ml(TIME_PRODUCTION);
    ml->type_spec = new_CONDITION_spec(store_tp(tp));
    return ml;
}
```

The function make_time_ml is called from 5/candp.

§**21.** An `OPTION_PRODUCTION` node holds a phrase option name. If negated with "not", it's the child of a `COND_NOT_PRODUCTION` production.

```
meaning_list *make_option_ml(int opt_num, int sense) {
    meaning_list *ml = new_ml(OPTION_PRODUCTION);
    ml->type_spec = new_TEST_PHRASE_OPTION_spec(opt_num);
    if (sense == FALSE) {
        meaning_list *ml2 = new_ml(COND_NOT_PRODUCTION);
        meaning_list *ml3 = new_ml(COND_PRODUCTION);
        ml2->child = ml3; ml3->child = ml;
        return ml2;
    }
    return ml;
}
```

The function make_option_ml is called from 5/candp.

§**22.** `ACTION_PRODUCTION` nodes hold action patterns – descriptions of a set of actions, such as "taking or dropping a container", in the present or past tense.

```
meaning_list *make_action_ml(action_pattern ap) {
    meaning_list *ml = new_ml(ACTION_PRODUCTION);
    ml->type_spec = new_TEST_ACTION_spec(store_ap(ap));
    return ml;
}
meaning_list *make_pastaction_ml(action_pattern ap) {
    meaning_list *ml = new_ml(ACTION_PRODUCTION);
    ml->type_spec = new_TEST_PAST_ACTION_spec(store_ap(ap));
    return ml;
}
```

The function make_action_ml is called from 5/candp.
The function make_pastaction_ml is called from 5/candp.

§**23. Copying MLs.** Note that this copies the contents of the ML, but not the expiry date, or indeed the memory manager's private fields.

```
void ml_copy(meaning_list *ml_to, meaning_list *ml_from) {
    ml_to->em = ml_from->em;
    ml_to->next_alternative = ml_from->next_alternative;
    ml_to->sibling = ml_from->sibling;
    ml_to->child = ml_from->child;
    ml_to->type_spec = ml_from->type_spec;
    ml_to->score = ml_from->score;
    ml_to->production = ml_from->production;
    ml_to->word_pair = ml_from->word_pair;
    ml_to->data_attached = ml_from->data_attached;
}
```

The function ml_copy is called from 5/parse.

§24. Access routines.

```
int ml_production(meaning_list *ml) {
    return ml->production;
}
void ml_set_production(meaning_list *ml, int pr) {
    ml->production = pr;
}
```

The function ml_production is called from 5/candd, 5/tandv, 5/varc, 5/mlc, 6/sconv, 12/phtd and 13/test.
The function ml_set_production is called from 5/varc and 5/mlc.

§25. Navigating the tree structure through subclauses:

```
meaning_list *ml_right(meaning_list *ml) {
    return ml->sibling;
}
void ml_set_right(meaning_list *ml, meaning_list *ml2) {
    ml->sibling = ml2;
}
meaning_list *ml_down(meaning_list *ml) {
    return ml->child;
}
void ml_set_down(meaning_list *ml, meaning_list *ml2) {
    ml->child = ml2;
}
```

The function ml_right is called from 5/candd, 5/varc, 5/candp, 5/mlc, 6/sconv and 12/phtd.
The function ml_set_right is called from 5/candd, 5/varc, 5/candp and 5/mlc.
The function ml_down is called from 5/tandv, 5/varc, 5/mlc, 6/sconv, 12/phtd and 13/test.
The function ml_set_down is called from 5/candd, 5/tandv, 5/varc, 5/candp and 5/mlc.

§26. Alternatives, where the meaning list forks:

```
meaning_list *ml_sideways(meaning_list *ml) {
    return ml->next_alternative;
}
int ml_match_score(meaning_list *ml) {
    return ml->score;
}
```

The function ml_sideways is called from 5/mlc and 9/wo.
The function ml_match_score is called from 5/candd, 5/mlc and 9/wo.

§**27.** The attached text:

```
void ml_set_text(meaning_list *ml, int w1, int w2) {
    if (w1<0) ml->word_pair = -1;
    else ml->word_pair = w1 + ((w2-w1) << 20);
}
void ml_get_text(meaning_list *ml, int *w1, int *w2) {
    int w = ml->word_pair;
    if (w == -1) {
        *w1 = -1; *w2 = -1;
    }
    else {
        *w1 = w & ((1<<20)-1);
        *w2 = (w >> 20) + (*w1);
    }
}
```

The function ml_set_text is called from 5/parse and 5/varc.
The function ml_get_text is called from 5/parse, 5/mlc, 6/sconv and 12/phtd.

§**28.** An excerpt meaning:

```
excerpt_meaning *ml_meaning(meaning_list *ml) {
    return ml->em;
}
void ml_set_meaning(meaning_list *ml, excerpt_meaning *em) {
    ml->em = em;
}
```

The function ml_meaning is called from 5/aph, 5/em, 5/unitr, 5/lit, 5/candd, 5/varc, 5/candp, 5/mlc, 8/refpt, 9/qty, 9/wo, 9/prop, 10/tab, 10/fig, 10/sfx, 10/exf, 10/isin, 11/ap, 11/nap, 11/av, 12/br and 12/rb.
The function ml_set_meaning is called from 5/varc.

§**29.** Or maybe a specification:

```
specification *ml_get_attached_spec(meaning_list *ml) {
    return ml->type_spec;
}
void ml_attach_spec(meaning_list *ml, specification *spec) {
    ml->type_spec = spec;
}
```

The function ml_get_attached_spec is called from 5/mlc.
The function ml_attach_spec is called from 5/lit and 5/tandv.

§**30.** And perhaps also an attached pointer to some other structure of unspecified type.

```
general_pointer ml_get_attached_data(meaning_list *ml) {
    return ml->data_attached;
}
void ml_attach_data(meaning_list *ml, general_pointer data) {
    ml->data_attached = data;
}
```

The function ml_get_attached_data is called from 5/mlc and 6/sconv.
The function ml_attach_data is called from 5/varc and 5/mlc.

Architecture of the S-Parser 5/arch

Purpose

To describe how the S-parser is organised, and to define a kit of C macros for writing its routines.

5/arch.§1 Plain Text; §2-6 Convenient macros for writing SP-routines

---

Definitions

¶1. The theory and practice of writing parsers, which turn text into explicit or implicit tree structures, was one of the first major fields of research in computer science. In the 1960s, work on systematising parsers, and on proving theorems about them, was perhaps the first independent line of thought in this new field – a field up to then divided between pragmatic engineering work and the numerical analysis of rounding errors. It was influenced by Chomsky, whose pioneering book on generative linguistics came at just the right moment for early compiler theorists such as the young Donald Knuth. Today this area of research is largely passé, and the problem is considered solved. University courses stress the importance of using tools like `yacc` ("yet another compiler compiler"), which are mathematically demonstrable as correct. In the sense that the output of `yacc` correctly implements the semantics implied by the grammar fed into it, `yacc` is indeed superb.

But Inform doesn't use it. I am a little stubborn, and prefer to write my own parsers; I also feel that automatically generated parsers tend to react badly to ungrammatical input. For Inform purposes, it's unacceptable to give generic or unspecific problem messages when something won't parse – the enormous cataracts of errors thrown by `gcc` when a single brace is missing, for instance. My own view is that incorrect input should be regarded as the main use case, not as some kind of aberration which can be given second-rate service. The user more often miscompiles than compiles, and quality lies in how good our problem messages are in reply. Besides this, the S-parser sometimes uses context in sneaky ways difficult to express in `yacc`. Natural language is, despite Chomsky, not all that easily reducible to generative syntax; and it tends not to have hierarchies of associative operators on different levels, which is the classical case for using `yacc`.

So we won't use `yacc`, `antlr`, etc. All the same, it would be foolish not to systematise the routines in the S-parser, if only because most of them take a standardised format – they take the same form of input, use the same variables in the same sort of way, return the same form of output.

¶2. To define terms: we will call a routine "an SP-routine" if it –

(i) takes as input an excerpt `(w1, w2)` and perhaps some other parameters;
(ii) returns `NULL` if the excerpt is empty, or if it makes no match;
(iii) returns a meaning list if it does make a match, and such that the code of the head of this list is predictable by the caller.

Many SP-routines automatically skip any initial article ("an", "the", etc.) at the start of the excerpt, but some do not.

To give an example of (iii), a call to `SP_value` returns either `NULL` or a list headed by `VAL_PRODUCTION`.

(We will sometimes loosely call these routines "productions", since they generally correspond to productions in the grammar being parsed, if we want to think about it formally.)

¶3. We will start at the bottom of the S-parser and work upwards, that is, we start at simple noun phrases and work up to complex sentence structure.

(a) `SP_plain_text` accepts any excerpt without parsing it, usually so that it can be looked at later rather than now;
(b) `SP_excerpt` is a Swiss Army knife able to handle excerpt meanings filed under many meaning codes – it parses names with a fixed wording, such as "the containment relation";
(c) `SP_literal` parses values expressed notationally rather than by name, such as "12" or "five PM".

For (a), see below. (b) and (c) take up a whole section of this chapter each: "Parse Excerpts.w" and "Parse Literals.w", respectively.

The remaining SP-routines build more complex structure, breaking down excerpts into composite meanings. Those are divided into two sets:

(d) "Early" SP-routines, gathered together in "Early Productions.w". These are the ones needed early in Inform's run, when the A-parser needs to ask the S-parser to look at excerpts occurring in assertion sentences. For instance, "The recycling target is a number that varies. The recycling target is 75." is parsed using `SP_type_expression` to read "number that varies", and `SP_constant_value` to read "75" (though of course it does this by making use of `SP_literal`).
(e) "Late" SP-routines, gathered together in "Late Productions.w". These are the additional ones needed later on in Inform's run, when compiling definitions of rules and phrases. We can now use values like "the score plus 5", or conditions like "the red door has been open", which would make no sense in assertions.

---

§**1. Plain Text.** The simplest example of an SP-routine is `SP_plain_text`, which accepts any excerpt and makes a leaf-node out of them.

Profiling suggests that about 5% of the compiler's CPU time is spent in this routine, or rather, in the memory allocation needed to make it work. (It is needed so often because arguments to phrases are left as unparsed nodes during one stage of parsing.)

```
meaning_list *SP_plain_text(int w1, int w2) {
    return new_ml_with_words(UNPARSED_PRODUCTION, w1, w2);
}
```

The function SP_plain_text is called from 5/parse and 5/tandv.

§**2. Convenient macros for writing SP-routines.** Since they share a specification and are all variations on a theme, we will write the more interesting SP-routines using a kit of C macros.

The routine should begin with one of the two macros:

```
    begin_SP_routine(w1, w2);
    begin_SP_routine_skipping_article(w1, w2);
```

These automatically calculate the conjunction and disjunction of the flags held by words in the range, putting the result in the variables `disjunction` and `conjunction`. As discussed above, these can be used to screen out many inapplicable, but expensive to check, possibilities.

```
define begin_SP_routine(w1, w2)
    BEGIN_PRODUCTION_PRIMITIVE(w1, w2, FALSE)
define begin_SP_routine_skipping_article(w1, w2)
    BEGIN_PRODUCTION_PRIMITIVE(w1, w2, TRUE)
define BEGIN_PRODUCTION_PRIMITIVE(w1, w2, skip_arts)
    int i, j, k, conjunction, disjunction;
    meaning_list *ml, *ml2, *ml3, *ml4, *ml5, *final_ml;
    if ((w1<0) || (w2<w1)) return NULL;                    reject an empty excerpt
```

```
    if ((skip_arts) && ((w2>w1) && ((lw_array[w1].lw_identity->flags) & ARTICLE_MC))) w1++;      skip
article word
    ml = NULL; ml2 = NULL; ml3 = NULL; ml4 = NULL; ml5 = NULL; final_ml = NULL;
    j = 0; k = 0;
    calculate conjunction and disjunction of the flags for words in the excerpt:
    conjunction = lw_array[w1].lw_identity->flags;
    disjunction = conjunction;
    for (i=w1+1; i<=w2; i++) {
        int f = lw_array[i].lw_identity->flags;
        disjunction = disjunction | f;
        conjunction = conjunction & f;
    }
```

§**3.** The routine should correspondingly end with the macro:

```
    on_success_invoke(P)
```

where `P` is the production number for the routine – for instance, the routine parsing values ends with this macro for `VAL_PRODUCTION`. If ordinary execution reaches this point, we have failed and return `NULL`. The idea is that code in the middle of the routine will have tried possibilities and performed a `goto` to the `Accept` label if any worked, with `ml` pointing to the children which the production node should have. So the macro defines this label, and what to do with those children.

```
define on_success_invoke(P)
    return NULL;
    Accept:
    final_ml = new_ml_with_words(P, w1, w2); final_ml->child = ml; return final_ml;
```

§**4.** But we don't want any `goto` in our own code, of course; the testing of possible syntaxes is also (mostly) done with macros. The most basic of these calls some other production routine, and accepts its findings if it has any:

```
define try_production(some_function_call) { if ((ml = some_function_call) != NULL) goto Accept; }
```

§**5.** And on the other hand, suppose we definitely want to accept the excerpt but as a subtree rather than a single node. We then use one of the `invoke_*` macros:

```
define invoke_0(x) { ml = new_ml_with_words(x, w1, w2); goto Accept; }
define invoke_1(x, y) { ml = new_ml_with_words(x, w1, w2); ml->child = y; goto Accept; }
define invoke_2(x, y, z) { ml = new_ml_with_words(x, w1, w2);
    ml->child = y; y->sibling = z; goto Accept; }
define invoke_3(x, y, z, w) {
    ml = new_ml_with_words(x, w1, w2); ml->child = y; y->sibling = z; z->sibling = w;
    goto Accept; }
define invoke_4(x, y, z, w, t) {
    ml = new_ml_with_words(x, w1, w2); ml->child = y; y->sibling = z; z->sibling = w;
    w->sibling = t;
    goto Accept; }
```

§**6.** For instance, the following bogus example tries to match a value followed by the literal word "alongside" and then another value. (It does this quite badly, but it's only an example.)

```
meaning_list *SP_hypothetical(int w1, int w2) {
    begin_SP_routine(w1, w2);
    if [[w1, w2 == ... alongside ... : i]]
        if ((ml2 = SP_value(w1, i-1)) && (ml3 = SP_value(i+1, w2)))
            invoke_2(ALONGSIDE_PRODUCTION, ml2, ml3);
    on_success_invoke(HYPOTHETICAL_PRODUCTION);
}
```

If it succeeded, the (top of the) resulting meaning list would be:

```
HYPOTHETICAL_PRODUCTION / "17 alongside the box"
    ALONGSIDE_PRODUCTION / "17 alongside the box"
        VAL_PRODUCTION / "17"
        VAL_PRODUCTION / "box"
```

Parse Excerpts 5/parse

Purpose

Given an excerpt `(w1,w2)`, to construct a meaning list of all registered excerpt meanings which it matches.

5/parse.§6-7 Exact parsing mode; §8-9 Maximal parsing mode; §10-11 Parametrised parsing mode; §12-13 Subset parsing mode; §14 Monitoring the efficiency of the parser

---

Template interpreter commands

```
14  {-callv:debug_parser_statistics}
```

Definitions

¶1. This is the lowest level of the S-parser, which looks only for atomic meanings ("red box"): routines higher up will look for more complex, compound meanings (such as "something in the red box"). The meaning list we return could be described as a list of alternative leaves, since each of the possible readings is a simple meaning which can't be broken down further (so, has no child nodes).

Any list of alternatives with two or more entries must be disambiguated much higher up in Inform. It is not at all easy to decide what "door" means, for instance: the class of doors, or a particular door, and if so then which one? We cannot answer that question here, and do not even try.

¶2. There are four basic parsing modes for excerpts.

(1) Exact parsing is what it sounds like: the texts have to match exactly, except that an initial article is skipped. Thus "the going action" exactly matches "going action", but "going" does not.
(2) In subset parsing, a match is achieved if the text parsed consists of words all of which are found in the meaning tested. Thus "red door" and "red" are each subset matches for "ornate red door with brass handle".
(3) In parametrised parsing, arbitrary (non-empty) text is allowed to match against `#` gaps in the token list. Thus "award 5 points" is a parametrised match for "award `#` points".
(4) In maximal parsing, we find the longest possible initial match, allowing it even if it does reach to the end of the excerpt, and we return a unique finding, not a list of possibilities.

```
define EXACT_PM 1
define SUBSET_PM 2
define PARAMETRISED_PM 4
define MAXIMAL_PM 8
```

¶3. We decide which of these to use with the following bitmaps.

```
define EXACT_PARSING_BITMAP
    (MISCELLANEOUS_MC + PROPERTY_MC + ADJECTIVE_MC +
    QUANTITY_MC + DESIGNED_TYPE_MC + RULE_MC + RULEBOOK_MC +
    TABLE_MC + TABLE_COLUMN_MC + NAMED_AP_MC + ACTIVITY_MC + EQUATION_MC)
define SUBSET_PARSING_BITMAP
    (WORLD_OBJECT_MC)
define PARAMETRISED_PARSING_BITMAP
    (VOID_PHRASE_MC + VALUE_PHRASE_MC +
    COND_PHRASE_MC + END_PHRASE_MC + SAY_PHRASE_MC)
define AL_BITMAP (NOT_MC + ARTICLE_MC + ADJECTIVE_MC)
```

¶4. To monitor the efficiency of the excerpt parser, we keep track of:

```
int no_calls_to_parse_excerpt = 0,
    no_meanings_tried = 0,
    no_meanings_tried_in_detail = 0,
    no_successful_calls_to_parse_excerpt = 0, no_matched_ems = 0;
```

---

§**1.** `SP_excerpt` is our first SP-routine, and it's the basic one from which most of the others are built.

As input, we give it not just the excerpt but also a context; or, to put it another way, a filter on which excerpt meanings to look at. This must be a bitmap made up from meaning codes, such as `TABLE_MC + TABLE_COLUMN_MC`, which would check for tables and table columns simultaneously.

However, there is one restriction on this. Recall that there are four parsing modes, and that different modes are used for different meaning codes. The `mc_bitmap` context is required not to mix MCs with different parsing modes.

```
meaning_list *SP_excerpt(int mc_bitmap, int w1, int w2) {
    int parsing_mode, h;
    meaning_list *results = NULL;
    no_calls_to_parse_excerpt++;
    if ((w1<0) || (w2<w1)) return NULL;                    in fact this case should never be needed
    h = 0;
    ⟨Choose which parsing mode we should use, given the MC bitmap 2⟩;
    ⟨Take note of casing on first word, in the few circumstances when we care 3⟩;
    ⟨Skip an initial article most of the time 4⟩;
    h = h | hash_code_from_excerpt(w1, w2);
    LOGIF(EXCERPT_PARSING,
        "Parsing excerpt <$W> hash %08x mc $p mode %d\n", w1, w2, h, mc_bitmap, parsing_mode);
    switch(parsing_mode) {
        case EXACT_PM: ⟨Enter exact parsing mode 6⟩; break;
        case MAXIMAL_PM: ⟨Enter maximal parsing mode 8⟩; break;
        case PARAMETRISED_PM: ⟨Enter parametrised parsing mode 10⟩; break;
        case SUBSET_PM: ⟨Enter subset parsing mode 12⟩; break;
        case 0: LOG("mc_bitmap: $p\n", mc_bitmap); internal_error("Unknown parsing mode");
        default: LOG("mc_bitmap: $p\n", mc_bitmap); internal_error("Mixed parsing modes");
    }
    LOGIF(EXCERPT_PARSING, "Completed:\n$m", results);
    meaning_list *loopy; for (loopy = results; loopy; loopy = loopy->next_alternative)
        no_matched_ems++;
    if (results) no_successful_calls_to_parse_excerpt++;
    return results;
}
```

The function SP_excerpt is called from 5/aph, 5/unitr, 5/lit, 5/candd, 5/tandv, 5/candp, 8/refpt, 8/mass, 9/qty, 9/wo, 9/prop, 10/tab, 10/fig, 10/sfx, 10/exf, 10/isin, 11/ap, 11/nap, 11/av, 12/br and 12/rb.

§**2.** Maximal parsing is something of a special case: it is used only for adjective lists, and we can only enter that mode by calling with exactly the correct bitmap for this. Otherwise, the parsing mode depends on which MC(s) are included in the bitmap.

⟨Choose which parsing mode we should use, given the MC bitmap 2⟩ ≡

```
parsing_mode = 0;
if (mc_bitmap & EXACT_PARSING_BITMAP) parsing_mode |= EXACT_PM;
if (mc_bitmap & SUBSET_PARSING_BITMAP) parsing_mode |= SUBSET_PM;
if (mc_bitmap & PARAMETRISED_PARSING_BITMAP) parsing_mode |= PARAMETRISED_PM;
if (mc_bitmap == AL_BITMAP) parsing_mode = MAXIMAL_PM;
```

This code is used in §1.

§**3.** Recall that excerpt parsing is case insensitive except for the first word of a text substitution, and then only when two definitions have been given, one capitalising the word and the other not. If we find the upper case form of such a text substitution, we set a special bit in the hash code. (The upper and lower case forms are both registered as excerpt meanings, with the same hash code except that one has this extra bit set and the other hasn't.)

⟨Take note of casing on first word, in the few circumstances when we care 3⟩ ≡

```
if (mc_bitmap & SAY_PHRASE_MC) {
    char *tx = lw_array[w1].lw_rawtext;
    if ((tx[0]) && (isupper(tx[0])) && (vocab_used_case_sensitively(lw_array[w1].lw_identity)))
        h = h | CAPITALISED_VARIANT_FORM;
}
```

This code is used in §1.

§**4.** An initial article is always skipped unless we are looking at a phrase; but then we are only allowed to skip an initial "the", and even then only if we aren't looking for text substitutions.

⟨Skip an initial article most of the time 4⟩ ≡

```
if (parsing_mode & PARAMETRISED_PM) {
    if (((mc_bitmap & SAY_PHRASE_MC) == 0) && [[w1, w2 == the ...]]) w1++;
} else {
    if ((w1<w2) && ((lw_array[w1].lw_identity->flags) & ARTICLE_MC)) w1++;
}
```

This code is used in §1.

§**5.** When checking cases below, we are always going to consider only those which have a meaning code among those we are looking for:

```
define EXCERPT_MEANING_RELEVANT(ml)
    (no_meanings_tried++, ((mc_bitmap & (ml->em->meaning_code))!=0))
define EXAMINE_EXCERPT_MEANING_IN_DETAIL
    LOGIF(EXCERPT_PARSING, "Trying $M (parsing mode %d)\n", ml->em, parsing_mode);
    no_meanings_tried_in_detail++;
```

§**6. Exact parsing mode.** Exact matching is just what it sounds like: the match must be word for word. Because of that, the excerpt meaning is guaranteed to be listed under the start list of the first word, if it matches (because there cannot be # tokens in the token list – if there were, we would be in parametrised parsing mode).

⟨Enter exact parsing mode 6⟩ ≡
```
meaning_list *ml;
vocabulary_entry *v = lw_array[w1].lw_identity;
if (v == NULL) internal_error("Unidentified word when parsing");
if ((v->flags) & mc_bitmap)
    for (ml = v->start_list; ml; ml = ml->next_alternative)
        ⟨Try to match excerpt in exact parsing mode 7⟩;
```
This code is used in §1.

§**7.** In exact parsing, the hash codes must agree perfectly:

⟨Try to match excerpt in exact parsing mode 7⟩ ≡
```
if (EXCERPT_MEANING_RELEVANT(ml) && (h == ml->em->excerpt_hash)) {
    EXAMINE_EXCERPT_MEANING_IN_DETAIL;
    if (ml->em->no_em_tokens == (w2-w1+1)) {
        int j, k, err;
        for (j=0, k=w1, err = FALSE; j<ml->em->no_em_tokens; j++, k++)
            if (ml->em->em_tokens[j] != lw_array[k].lw_identity) { err=TRUE; break; }
        if (err == FALSE) {
            meaning_list *further_result = new_ml(ml->em->meaning_code);
            further_result->em = ml->em;
            further_result->next_alternative = results;
            further_result->score = 1;
            results = further_result;
        }
    }
}
```
This code is used in §6.

§**8. Maximal parsing mode.**

⟨Enter maximal parsing mode 8⟩ ≡
```
vocabulary_entry *v = lw_array[w1].lw_identity;
if (v == NULL) internal_error("Unidentified word when parsing");
if ((v->flags) & mc_bitmap) {
    meaning_list *ml, *best_ml = NULL; int best_score = 0;
    for (ml = v->start_list; ml; ml = ml->next_alternative)
        ⟨Try to match excerpt in maximal parsing mode 9⟩;
    if (best_ml) {
        results = new_ml(best_ml->em->meaning_code);
        results->em = best_ml->em;
        results->score = best_score;
    }
}
```
This code is used in §1.

§**9.** In maximal matching, we keep only the longest exact match found, and if two have equal length then keep the first one found. (It should ideally never be the case that clashes occur.)

⟨Try to match excerpt in maximal parsing mode 9⟩ ≡
```
if (EXCERPT_MEANING_RELEVANT(ml) &&
    ((h & ml->em->excerpt_hash) == ml->em->excerpt_hash)) {
    EXAMINE_EXCERPT_MEANING_IN_DETAIL;
    if (ml->em->no_em_tokens <= w2-w1+1) {
        int j, k, err;
        for (err=FALSE, j=0, k=w1; j<ml->em->no_em_tokens; j++, k++)
            if (ml->em->em_tokens[j] != lw_array[k].lw_identity) { err = TRUE; break; }
        if ((err == FALSE) && (j>best_score)) {
            best_ml = ml; best_score = j;
        }
    }
}
```
This code is used in §8.

§**10. Parametrised parsing mode.** This is the only parsing mode which allows for arbitrary text to appear: i.e., where any text X can appear in "award X points", for example.

⟨Enter parametrised parsing mode 10⟩ ≡
```
int i;
vocabulary_entry *v = lw_array[w1].lw_identity;
if (v == NULL) internal_error("Unidentified word when parsing");
meaning_list *ml;
if (mc_bitmap & SAY_PHRASE_MC) {
    for (ml = blank_says_ml; ml; ml = ml->next_alternative) {
        int mw1, mw2;
        meaning_list *this_result = new_ml_with_words(SAY_PHRASE_MC, w1, w2);
        ml_get_text(this_result, &mw1, &mw2);
        ml_copy(this_result, ml);
        ml_set_text(this_result, mw1, mw2);
        this_result->child = SP_plain_text(w1, w2);
        this_result->next_alternative = results;
        results = this_result;
        no_meanings_tried++, no_meanings_tried_in_detail++;
    }
}
for (ml = v->start_list; ml; ml = ml->next_alternative)
    ⟨Try to match excerpt in parametrised parsing mode 11⟩;
if (w2>w1) {
    v = lw_array[w2].lw_identity;
    if (v == NULL) internal_error("Unidentified word when parsing");
    for (ml = v->end_list; ml; ml = ml->next_alternative)
        ⟨Try to match excerpt in parametrised parsing mode 11⟩;
}
for (i=w1+1; i<w2; i++) {
    v = lw_array[i].lw_identity;
    if (v == NULL) internal_error("Unidentified word when parsing");
    for (ml = v->middle_list; ml; ml = ml->next_alternative)
        ⟨Try to match excerpt in parametrised parsing mode 11⟩;
}
```

This code is used in §1.

§**11.** It is required here that the data supplied must be a pointer to a phrase, though it can be any type of phrase.

⟨Try to match excerpt in parametrised parsing mode 11⟩ ≡

```
    if (EXCERPT_MEANING_RELEVANT(ml) &&
        ((h & ml->em->excerpt_hash) == ml->em->excerpt_hash)) {

            results = this_result;
        }
        w1 = saved_w1; w2 = saved_w2;
    }
```

This code is used in §10.

§12. Subset parsing mode. In subset mode, each possible match is kept, and is assigned a numerical score based purely on the number of words in the full description which were missed out. This makes "door" a better match against "door" (0 words missed out) than against "green door" (1 word missed out).

Note that a single word which also has a meaning as a number is never matched. This is so that "11" (say) cannot be misinterpreted as an abbreviated form of an object name like "Chamber 11".

⟨Enter subset parsing mode 12⟩ ≡

```
    int i, j, k;
    if ((w1 == w2) && ((vocab_test_flags(w1, NUMBER_MC)) != 0)) goto SubsetFailed;
    for (i=w1, j=-1, k=-1; i<=w2; i++) {
        vocabulary_entry *v = lw_array[i].lw_identity;
        if (v == NULL) internal_error("Unidentified word when parsing");
        if ((v->flags) & ARTICLE_MC) continue;
        if (v->subset_list_length == 0) goto SubsetFailed;
        if (v->subset_list_length > j) { j = v->subset_list_length; k = i; }
    }
    if (k >= 0) {
        vocabulary_entry *v = lw_array[k].lw_identity;
        meaning_list *ml;
        for (ml = v->subset_list; ml; ml = ml->next_alternative)
```

```
        ⟨Try to match excerpt in subset parsing mode 13⟩;
    }
    SubsetFailed: ;
```

This code is used in §1.

§13.

⟨Try to match excerpt in subset parsing mode 13⟩ ≡

```
    if (EXCERPT_MEANING_RELEVANT(ml) && ((h & ml->em->excerpt_hash) == h)) {
        EXAMINE_EXCERPT_MEANING_IN_DETAIL;
        if (w2-w1 < ml->em->no_em_tokens) {
            int err = FALSE;
            if (ml->em->meaning_code == WORLD_OBJECT_MC) {
                world_object *wo = RETRIEVE_POINTER_world_object(ml->em->data);
                if ((wo) && (wo->kind_flag)) {
                    LOGIF(EXCERPT_PARSING, "Kind, so trying $M (exact)\n", ml->em);
                    err = TRUE;
                    if (ml->em->no_em_tokens == (w2-w1+1)) {
                        for (j=0, k=w1, err = FALSE; j<ml->em->no_em_tokens; j++, k++)
                            if (ml->em->em_tokens[j] != lw_array[k].lw_identity) {
                                err=TRUE; break;
                            }
                    }
                    goto SubsetMatchDecided;
                }
            }
            for (k=w1; k<=w2; k++) {
                err = TRUE;
                for (j=0; j<ml->em->no_em_tokens; j++)
                    if (ml->em->em_tokens[j] == lw_array[k].lw_identity) err=FALSE;
                if (err) break;
            }
            SubsetMatchDecided:
            if (err == FALSE) {
                meaning_list *this_result = new_ml(ml->em->meaning_code);
                this_result->em = ml->em;
                this_result->next_alternative = results;
                this_result->score = 100-((ml->em->no_em_tokens) - (w2-w1));
                results = this_result;
            }
        }
    }
```

This code is used in §12.

§14. Monitoring the efficiency of the parser. To give a rough idea, the medium-large *Bronze* runs to about 40,000 words of text including the extensions it uses, and around 4000 excerpt meanings are registered. In May 2008, `SP_excerpt` was being called 40,046 times (it seems a rough rule of thumb that it's called about once per word), so:

(a) a naive all-against-all comparison would mean 160,184,000 comparisons;
(b) considering only those excerpt meanings attached to relevant words reduces us to `no_meanings_tried` comparisons, which was 246,834;
(c) considering only those with a viable correct hash code reduces us further to `no_meanings_tried_in_detail` comparisons, which was 68,541.

Considering that `SP_excerpt` was successful 13,752 times, and that on many of those occasions it will have returned multiple results, we can be pretty confident that the tests in (b) and (c) – both very fast to perform – are quite good. In fact, further investigation showed that of the 68,541 comparisons we had to make, 63,762 were successful – so (b) and (c) were correct 93% of the time.

Moreover, even the expensive checking in detail was not too bad: in all but 21,774 of the 68,541 cases the token list to check was empty, because it was a test for "say [value]". Thus the mean number of direct word comparisons was only 0.5 per call, and of course even those only involve comparing pointers, not calling character-level routines like `strcmp`.

Profiling shows that time spent in the S-parser is dominated by memory allocation for the meaning lists it generates. Actual parsing is very rapid, and no further optimisation is worthwhile.

```
void debug_parser_statistics(void) {
    LOG("no_calls_to_parse_excerpt = %d\n", no_calls_to_parse_excerpt);
    LOG("no_meanings_tried = %d\n", no_meanings_tried);
    LOG("no_meanings_tried_in_detail = %d\n", no_meanings_tried_in_detail);
    LOG("no_successful_calls_to_parse_excerpt = %d\n", no_successful_calls_to_parse_excerpt);
    LOG("no_matched_ems = %d\n", no_matched_ems);
    LOG("number of excerpt meanings registered = %d\n", NUMBER_CREATED(excerpt_meaning));
    if (dl_this(EXCERPT_MEANINGS_DA)) log_all_meanings();
}
```

The function debug_parser_statistics is invoked by a command in a `.i6t` template file.

Parse Literals 5/lit

Purpose

To decide if the text in `(w1,w2)` is a value referred to notationally rather than by name.

Definitions

¶1. Literal values are explicitly written-out constants such as "false", "182" or "4:33 PM". In the event that the last literal value parsed was a number, a time, a truth state, a resource ID, or a quasi-numerical value written in a literal-pattern notation (see "Literal Patterns.w"), the actual value is conveniently stored in the global variable `last_literal_evaluated`. For other kinds of value, such as text, the variable is not used.

```
int last_literal_evaluated = 0;
```

---

§**1. The SP-routine for literals.** This amounts only to a wrapper for the general literal-parsing routine given below, which is also called by other parts of Inform directly to obtain constant values quickly.

```
meaning_list *SP_literal(int w1, int w2) {
    meaning_list *ml;
    specification *spec;
    kind_of_value *kov = is_a_literal(w1, w2);
    if (kov == NULL) return NULL;
    ml = new_ml(LITERAL_PRODUCTION);
    spec = new_actual_CONSTANT_spec(kov);
    spec->word_ref1 = w1; spec->word_ref2 = w2;
    ml_attach_spec(ml, spec);
    return ml;
}
```

The function SP_literal is called from 5/candd.

§**2.** It turns out to be convenient to provide routines which determine quickly whether a given excerpt is a literal number. Note that ordinals (`third`, `31st` and so on) are not normally legal as constants, and that `is_a_literal` below would return `NULL` on them.

```
int is_an_ordinal_or_cardinal(int w1, int w2) {
    if (is_a_literal_number(w1, w2, TRUE)) return TRUE;
    return FALSE;
}
int is_a_cardinal(int w1, int w2) {
    if (is_a_literal_number(w1, w2, FALSE)) return TRUE;
    return FALSE;
}
kind_of_value *is_a_literal_number(int w1, int w2, int allow_ordinals) {
    if ((w1<0) || (w1 != w2)) return NULL;
    ⟨Try a cardinal number as the literal 13⟩;
    if (allow_ordinals) ⟨Try an ordinal number as the literal 14⟩;
    return NULL;
}
```

The function is_an_ordinal_or_cardinal is called from 11/chron.
The function is_a_cardinal is called from 5/det.

§**3.** The following routine returns a KOV if `(w1, w2)` is a valid literal, storing the actual value in the global variable `last_literal_evaluated`: or else returns `NULL`, a value distinct from all valid KOV pointers, if not.

In the event that no match is made, so that the routine returns `NULL`, we set `last_literal_evaluated` to the quaint curiosity number. None of the rest of the code in Inform makes use of this fact, and it is done solely defensively, to protect us from bugs – more accurately, to protect us from writing incorrect code which accidentally works because a value left over from some previous call is still in the variable even though the most recent call failed.

```
define QUAINT_CURIOSITY_NUMBER 123456789
kind_of_value *is_a_literal(int w1, int w2) {
    last_literal_evaluated = QUAINT_CURIOSITY_NUMBER;
    if ((w1 < 0) || (w2<w1)) return NULL;
    if (w1 == w2) {
        ⟨Try a cardinal number as the literal 13⟩;
        ⟨Try double-quoted text as the literal 5⟩;
        ⟨Try true or false as the literal 6⟩;
    }
    ⟨Try a braced constant list as the literal 7⟩;
    ⟨Try a Unicode character code as the literal 8⟩;
    ⟨Try a figure, sound effect, or external file name as the literal 9⟩;
    ⟨Allow the word minus to precede a number or time 4⟩;
    ⟨Try any of the notations declared by literal patterns as the literal 10⟩;
    ⟨Try a length of time as the literal 11⟩;
    ⟨Try a time of day as the literal 12⟩;
    return NULL;
}
```

The function is_a_literal is called from 4/iext, 5/litp, 6/treec, 7/vasp, 8/sob, 8/mass, 9/wo, 9/madj, 10/tab, 10/bib, 10/fig, 10/sfx, 10/isin, 11/act, 12/phud, 12/phtd, 13/tfg and 13/gtok.

§**4.** "Minus" is only allowed for numbers and times, and the reason for this is that those are the numerical constants which are sometimes written out in words: thus "minus six" or "minus fifteen minutes". With units written in literal-pattern notations, numerical elements are written as digits, and a minus sign is used rather than the word "minus". So "minus 6 kg" (say) would not be legal, but "−6 kg" would.

⟨Allow the word minus to precede a number or time 4⟩ ≡

```
if [[w1, w2 == minus ...]] {
    kind_of_value *partial = is_a_literal(w1+1, w2);
    if ((is_kova(partial, NUMBER_TY)) || (is_kova(partial, TIME_TY))) {
        last_literal_evaluated = -last_literal_evaluated;
        return partial;
    }
}
```

This code is used in §3.

§**5. Text.** As far as we are concerned here, double-quoted strings of text are literals whose KOV is either `TEXT_ROUTINE_TY` (if they contain square-bracketed text substitutions) or `TEXT_TY` (if not). Higher up in Inform, they are sometimes reinterpreted as `QUOT_TY` (special quotation text used for box quotations overlaid on the main text window at run-time) or `UNDERSTANDING_TY` (grammar to match in the player's command), but that's invisible to us.

⟨Try double-quoted text as the literal 5⟩ ≡

```
if (vocab_test_flags(w1, TEXT_MC)) return kova(TEXT_TY);
if (vocab_test_flags(w1, TEXTWITHSUBS_MC)) return kova(TEXT_ROUTINE_TY);
```

This code is used in §3.

§**6. Truth states.**

⟨Try true or false as the literal 6⟩ ≡

```
if [[w1, w2 == false]] {
    last_literal_evaluated = 0;
    return kova(TRUTH_STATE_TY);
}
if [[w1, w2 == true]] {
    last_literal_evaluated = 1;
    return kova(TRUTH_STATE_TY);
}
```

This code is used in §3.

§**7. Constant lists.** Note that the empty list `{}` is a valid literal in Inform.

⟨Try a braced constant list as the literal 7⟩ ≡

```
if ([[w1, w2 == OPENBRACE CLOSEBRACE]] ||
    [[w1, w2 == OPENBRACE ... CLOSEBRACE]]) {
    kind_of_value *kov = parse_list_of_values(NULL, w1+1, w2-1, FALSE);
    if (kov) return kov;
}
```

This code is used in §3.

§**8. Unicode characters.** This includes named characters as well as decimal character codes: see "Unicode Translations.w".

⟨Try a Unicode character code as the literal 8⟩ ≡

```
if [[w1, w2 == unicode ...]] {
    int unicode_val = is_a_unicode_value(w1+1, w2);
    if (unicode_val >= 0) {
        last_literal_evaluated = unicode_val;
        return kova(UNICODECHAR_TY);
    }
}
```

This code is used in §3.

§**9. External resource names.** These three categories of name must all start with particular words, which enables us to avoid calling `SP_excerpt` almost all of the time – indeed this is why the names are set up that way, as it's essential for the current routine to produce negative results quickly.

⟨Try a figure, sound effect, or external file name as the literal 9⟩ ≡

```
if [[w1, w2 == figure/file/sound ...]] {
    meaning_list *ml = SP_excerpt(MISCELLANEOUS_MC, w1, w2);
    if (ml)
        switch(em_get_secondary_code(ml_meaning(ml))) {
            case FIGURE_SMC: {
                blorb_figure *bf = RETRIEVE_POINTER_blorb_figure(em_data(ml_meaning(ml)));
                last_literal_evaluated = fig_get_resource_ID(bf);
                return kova(FIGURENAME_TY);
            }
            case EXTERNAL_FILE_SMC: {
                external_file *exf =
                    RETRIEVE_POINTER_external_file(em_data(ml_meaning(ml)));
                last_literal_evaluated = exf->allocation_id;
                return kova(EXTERNALFILE_TY);
            }
            case SOUND_EFFECT_SMC: {
                blorb_sound *bs = RETRIEVE_POINTER_blorb_sound(em_data(ml_meaning(ml)));
                last_literal_evaluated = sfx_get_resource_ID(bs);
                return kova(SOUNDNAME_TY);
            }
        }
}
```

This code is used in §3.

§10. Literal patterns. This delegates the problem of matching user-defined notations for constants to "Literal Patterns.w".

⟨Try any of the notations declared by literal patterns as the literal 10⟩ ≡

```
literal_pattern *lp;
LOOP_OVER(lp, literal_pattern) {
    int val;
    kind_of_value *kov = match_literal_pattern(lp, w1, w2, &val);
    if (kov) {
        last_literal_evaluated = val;
        return kov;
    }
}
```

This code is used in §3.

§11. Time. An interesting, perhaps questionable, decision which Inform makes here is to assign durations – relative times – the same kind of value as absolute times. This is sensible in some ways, because arithmetic on times is then meaningful – 12:04 AM plus 40 minutes is 12:44 AM; 4:52 PM minus 3:31 PM is 1 hour 21 minutes, and so on. If we regarded relative and absolute times as being distinct KOVs, the arithmetic rules for them would be complicated to type-check. On the other hand, times really do not behave like integers, no matter how we might pretend. What is 4:52 PM plus 3:31 PM, in any very meaningful sense? (Inform adds these by treating them as durations since the previous midnight in each case, but it's hard to see why that makes much human sense.)

Recall that I7 stored time as integers, counting in minutes.

⟨Try a length of time as the literal 11⟩ ≡

```
int min1, min2, hr1, hr2, j;
if [[w1, w2 == ... hour/hours --> hr1, hr2]] {
    if (is_a_cardinal(hr1, hr2)) {
        last_literal_evaluated = last_literal_evaluated*60;
        return kova(TIME_TY);
    }
}
if [[w1, w2 == ... minute/minutes --> min1, min2]] {
    if ([[min1, min2 == ... hours ... : j --> hr1, hr2 ... min1, min2]] ||
        [[min1, min2 == ... hour ... : j --> hr1, hr2 ... min1, min2]]) {
        int time_minutes = 0, time_hours = 0, failed = FALSE;
        if (is_a_cardinal(hr1, hr2)) time_hours = last_literal_evaluated;
        else failed = TRUE;
        if (is_a_cardinal(min1, min2)) time_minutes = last_literal_evaluated;
        else failed = TRUE;
        if (failed) last_literal_evaluated = QUAINT_CURIOSITY_NUMBER;
        else {
            last_literal_evaluated = time_minutes + time_hours*60;
            return kova(TIME_TY);
        }
    } else {
        if (is_a_cardinal(min1, min2)) return kova(TIME_TY);
    }
}
```

This code is used in §3.

§**12.** An absolute time is stored as the number of minutes since midnight last, with midnight itself stored as 0.

Note that we allow "12:01 AM" (one minute past midnight) and "12:01 PM" (ditto noon), and also "0:01 AM" and "00:01 AM", but not "0:01 PM".

⟨Try a time of day as the literal 12⟩ ≡

```
int min1, min2, hr1, hr2, time_base = -1;
if [[w1, w2 == ... am --> w1, w2]] time_base = 0;
else if [[w1, w2 == ... pm --> w1, w2]] time_base = 12*60;
if (time_base >= 0) {
    int time_minutes = 0, time_hours = 0, j, failed = FALSE;
    if [[w1, w2 == ... COLON ... : j --> hr1, hr2 ... min1, min2]] {
        if (is_a_cardinal(hr1, hr2)) time_hours = last_literal_evaluated;
        else failed = TRUE;
        if (is_a_cardinal(min1, min2)) time_minutes = last_literal_evaluated;
        else failed = TRUE;
    } else {
        if (w1 != w2) failed = TRUE;
        else if (is_a_cardinal(w1, w1)) time_hours = last_literal_evaluated;
        else if (is_a_digital_clock_time(w1, &time_minutes, &time_hours)) ;
        else failed = TRUE;
    }
    if ((time_hours < 0) || (time_hours > 12)) failed = TRUE;
    if ((time_hours == 0) && (time_base > 0)) failed = TRUE;          reject for example "0:01 PM"
    if (time_hours == 12) time_hours = 0;                            allow for example "12:01 AM"
    if ((time_minutes < 0) || (time_minutes >= 60)) failed = TRUE;
    if (failed) last_literal_evaluated = QUAINT_CURIOSITY_NUMBER;
    else {
        last_literal_evaluated = time_base + time_hours*60 + time_minutes;
        return kova(TIME_TY);
    }
}
```

This code is used in §3.

§**13. Ordinals and cardinals.** A cardinal, that is, a number such as `five` or `351`:

⟨Try a cardinal number as the literal 13⟩ ≡

```
if (vocab_test_flags(w1, NUMBER_MC))
    ⟨Accept the evaluation of this literal number if it's in range for the VM 15⟩;
```

This code is used in §2,3,2,3,2,3.

§**14.** And an ordinal, that is, a number such as `fifth` or `351st`:

⟨Try an ordinal number as the literal 14⟩ ≡

```
if (vocab_test_flags(w1, ORDINAL_MC))
    ⟨Accept the evaluation of this literal number if it's in range for the VM 15⟩;
```

This code is used in §2.

§**15.** We are particularly sensitive to Z-machine overflows because this is a rare case where the choice of virtual machine affects the legal syntax for I7 source text – text originally written for use on Glulx, which allows for larger integers, might be moved over to a Z-machine project, with the user not realising the consequences.

⟨Accept the evaluation of this literal number if it's in range for the VM 15⟩ ≡

```
last_literal_evaluated = vocab_get_literal_number_value(lw_array[w1].lw_identity);
if (((last_literal_evaluated > 32767) || (last_literal_evaluated < -32768)) &&
    (target_VM_is_16_bit())) {
    sentence_problem(_P_(C5LiteralOverflow),
        "you use a number which is too large",
        "at least with the Settings for this project as they "
        "currently are. (Change to Glulx to be allowed to use "
        "much larger numbers.)");
    vocab_set_literal_number_value(lw_array[w1].lw_identity, 1);
    return NULL;
}
return kova(NUMBER_TY);
```

This code is used in §13,14,13,14,13,14.

Constants and Descriptions 5/candd

Purpose

To parse noun phrases in constant contexts, which specify values either explicitly or by describing them more or less vaguely.

5/candd.§1-3 Constant values; §4-7 Adjective lists; §8-19 Descriptions; §20 KOV names

---

§**1. Constant values.** The word "nothing" needs special treatment here. Sometimes it means the dummy value "not an object", and is genuinely a constant value; but at other times it behaves more like a determiner, as in "if nothing is on the table". To make this easier to resolve higher up, it gets its own production code `VAL_NOTHING_PRODUCTION`.

Constants are otherwise straightforward: literals and names of rules, rulebooks, quantities (but only if enumerated constant names), activities, tables, actions, use options, rulebook outcomes and relations.

```
meaning_list *SP_constant_value(int w1, int w2) {
    begin_SP_routine(w1, w2);
    if ((ml = SP_literal(w1, w2))) return ml;
    if [[w1, w2 == nothing]] return new_ml_with_words(VAL_NOTHING_PRODUCTION, w1, w2);
    [[w1, w2 == the ... --> w1, w2]];
    ⟨Try for an enumerated constant or the name of a rule, rulebook, activity or table 2⟩;
    ⟨Try for the name of an action, relation, rulebook outcome or use option 3⟩;
    return NULL;
}
```

The function SP_constant_value is called from 5/tandv.

§**2.** These nouns are all excerpt meanings registered under their own `*_MC` meaning codes, so we can combine their parsing in one call to `SP_excerpt`.

Note that quantity meanings can be either variable names or enumerated constant values: for instance, following

> Colour is a kind of value. Red, blue and green are colours. Hue is a colour that varies.

we want to recognise the quantity "blue" as a constant but not the quantity "hue".

```
define CONSTANT_VAL_BITMAP (RULE_MC + RULEBOOK_MC + QUANTITY_MC + ACTIVITY_MC + TABLE_MC + EQUATION_MC)
```

⟨Try for an enumerated constant or the name of a rule, rulebook, activity or table 2⟩ ≡

```
    if (disjunction & CONSTANT_VAL_BITMAP) {
        if ((ml = SP_excerpt(CONSTANT_VAL_BITMAP, w1, w2))) {
            if (ml_production(ml) == QUANTITY_MC) {
                quantity *q = RETRIEVE_POINTER_quantity(em_data(ml_meaning(ml)));
                if (qty_is_a_variable(q) == FALSE) return ml;
            } else return ml;
        }
    }
```

This code is used in §1.

§**3.** These nouns, on the other hand, are excerpt meanings registered under the "miscellaneous" category.

Note that `SP_excerpt` is called only if a signature word is present, which speeds matters up. Action names and relations are registered as meanings with the signature word included, rulebook outcomes and use options without.

⟨Try for the name of an action, relation, rulebook outcome or use option 3⟩ ≡

```
int x1 = -1, x2 = -1;
if [[w1, w2 == ... action/relation --> x1, x2]] x2++;
if [[w1, w2 == ... option/outcome --> x1, x2]] ;
if ((x1 >= 0) && ((ml = SP_excerpt(MISCELLANEOUS_MC, x1, x2)))) {
    switch (em_get_secondary_code(ml_meaning(ml))) {
        case ACTION_NAME_SMC: return ml;
        case RELATION_SMC: return ml;
        case RULE_OUTCOME_SMC: return ml;
        case USE_OPTION_SMC: return ml;
    }
}
```

This code is used in §1.

§**4. Adjective lists.** "I first tried to write a story when I was about seven. It was about a dragon. I remember nothing about it except a philological fact. My mother said nothing about the dragon, but pointed out that one could not say "a green great dragon", but had to say "a great green dragon". I wondered why, and still do" (Tolkien to Auden, 1955). We are going to allow lists of adjectives such as "green great" or "great green" in any order: although some have suggested conceptual hierarchies for adjectives (e.g., that size always precedes material) these are too tendentious to enforce.

The following tests whether an excerpt is a list of adjectives, mixing any of the various kinds of adjective which can occur. For example, the text

> exciting transparent green fixed in place

constructs the tree:

```
AL_PRODUCTION / exciting transparent green fixed in place
    {exciting = ADJECTIVE_MC}
    {transparent = ADJECTIVE_MC}
    {green = ADJECTIVE_MC}
    {fixed in place = ADJECTIVE_MC}
```

§**5.** Perhaps surprisingly, the word "not" is allowed in such lists, and for two independent reasons. Firstly, we want to be able to construct the negations of individual adjectives, so that for instance

> exciting not transparent fixed in place

constructs

```
AL_PRODUCTION / exciting not transparent fixed in place
    {exciting = ADJECTIVE_MC}
    ADJ_NOT_PRODUCTION
        {transparent = ADJECTIVE_MC}
    {fixed in place = ADJECTIVE_MC}
```

Though in this instance it would be equivalent to write "opaque" in place of "not transparent", some adjectives do not have named negations.

The other reason for negation is for a sentence such as:

> A hairless chimp is not a hairy animal.

(This was submitted as a bug report.) It would be grammatically sound to parse this as

(A hairless chimp) is not (a hairy animal).

but in fact we construe it as

(A hairless chimp) is (not a hairy animal).

This means that we do not need to reject the assertion as being negative, and can instead act on it, since "hairy" – in this example – is an either/or property; thus we can parse it as if it read

A hairless chimp is a not hairy animal.

```
meaning_list *parse_adjective_list(int w1, int w2, kind_of_value *domain_kov, int unrestricted) {
    int i, fw = w1, negate_all = FALSE;
    meaning_list *ml, *final_ml = NULL, *latest_ml = NULL;
    if ((w1<0) || (w2<w1)) return NULL;
    if [[fw, w2 == not a/an/some ... --> fw, w2]] negate_all = TRUE;
    for (i=fw; i<=w2; i++) if ((vocab_test_flags(i, AL_BITMAP)) == 0) return NULL;
    while (fw<=w2) {
        int negate = negate_all;
        if [[fw, w2 == not ... --> fw, w2]] negate = (negate)?FALSE:TRUE;
        ⟨Parse the longest possible adjective name from the front into ml 6⟩;
        if (negate) {
            meaning_list *ml2 = new_ml(ADJ_NOT_PRODUCTION);
            ml_set_down(ml2, ml); ml = ml2;
        }
        if (final_ml) ml_set_right(latest_ml, ml);
        else { final_ml = new_ml_with_words(AL_PRODUCTION, w1, w2); ml_set_down(final_ml, ml); }
        latest_ml = ml;
    }
    if (final_ml) {
        LOGIF(S_GRAMMAR, "parse_adjective_list on <$W> yields:\n$m\n", w1, w2, final_ml);
    }
    return final_ml;
}
```

§**6.** The constant `AL_BITMAP` has a pleasingly Arabic sound to it – a second-magnitude star, a corrupt arms deal – but is in fact a combination of the meaning codes found in an adjective list. The excerpt parser handles this request in a way specially arranged for us, finding the longest adjective matching at the start of the excerpt.

⟨Parse the longest possible adjective name from the front into ml 6⟩ ≡

```
int sc;
ml = SP_excerpt(AL_BITMAP, fw, w2);
if (ml == NULL) return NULL;
if (unrestricted == FALSE) {
    if (ml_production(ml) == ADJECTIVE_MC) {
        adjectival_phrase *aph = RETRIEVE_POINTER_adjectival_phrase(em_data(ml_meaning(ml)));
        if (aph_applicable_to(aph, domain_kov) == FALSE)
            return NULL;
    } else if (domain_kov) return NULL;
}
sc = ml_match_score(ml);
if (sc == 0) internal_error("Length-scored maximal parse with length 0");
fw += sc;
```

This code is used in §5.

§**7.** Wrapping that into an SP-routine gives:

```
meaning_list *SP_adjective_list(int w1, int w2) {
    begin_SP_routine_skipping_article(w1, w2);
    if ((ml2 = parse_adjective_list(w1, w2, NULL, TRUE))) invoke_1(DC_ADJS_PRODUCTION, ml2);
    on_success_invoke(DC_PRODUCTION);
}
```

The function SP_adjective_list is called from 5/tandv and 5/varc.

§**8. Descriptions.** In most programming languages, commands are like imperative verbs, but their noun phrases are specific. `print X`, say, prints an unambiguously determined quantity `X`. Sometimes wildcards are allowed, as when the Unix shell allows `ls *.txt` to list all text files in the current directory – just as a work of IF allows TAKE ALL. Inform goes further than this, and – in some circumstances at least – permits the `X` to be a more or less vague description of a collection of values, such that only at run-time can it be determined what values `X` refers to.

It might look as if a description is a generalisation of a value: that is, every value is a description (a completely specific one). In fact, that isn't true. "100", for instance, is a value but not a description. The only values allowed as descriptions are the constant world objects. This is done in order to make Inform a richer language for describing states of objects, just as we saw that the domain of an adjective can be a single object. In other words, "rusty iron door" is allowed as a description in order that "open rusty iron door" can also be a description, and therefore:

```
Instead of throwing something at the open rusty iron door: ...
```

can work as a rule. "Open rusty iron door" describes a set which contains either one object (the door, if it happens to be open) or none (if the door is currently closed). We don't allow the same thing with specific values for a variety of reasons – it would read badly, it would be much less efficient to parse quickly – and in any case it's not very useful. Adjectives applied to values tend not to be very dynamic, and source text like

```
if X is the even 3, ...
```

would make little sense.

§**9.** Whereas a value makes a simple meaning list, just a single leaf, a description is so much richer that it needs a larger tree to represent it. For example:

exactly one closed door (called the Portal)

results in the meaning list:

```
DC_PRODUCTION / "exactly one closed door ( called the portal )"
    DC_ADJSNOUN_PRODUCTION / "closed door"
        AL_PRODUCTION / "closed"
            {closed = ADJECTIVE_MC}
        {door = WORLD_OBJECT_MC}
    CALLED_PRODUCTION / "portal"
    DETERMINER_PRODUCTION => Card=1 / "exactly one"
```

§**10.** A description is a sequence of the following four elements, some of which are optional:

(a) *specifier*, which will be a determiner and/or an article (optional);

(b) *qualifier*, which for Inform means adjectives of the various kinds described above (optional);

(c) *noun*, which because these are physical descriptions will refer to a particular object or kind of object (compulsory unless the `allow_nounless` call parameter is set, which it only is to handle one peculiar exception – see "Late Parameters.w"); and

(d) *subordinate clause*, such as "in ..." or "which are on ..." (optional).

For the most part the sequence must be (a), (b), (c), (d), as in:

six of the / open / containers / in the Attic

but the composite words made up from quantifiers and kinds – something, anywhere, everybody, and such – force us to make an exception to this:

something / open / in the Attic

which takes the sequence (a) and (c), (b), (d).

Just occasionally both readings are possible, because words like "something" have a tendency to be used in the source text as part of proper nouns – if the author creates an item called "something your aunt gave you", or "everything you ever wanted". We allow the (a)-and-(c) words only if there is no more explicit determiner to play the role of (a), and even then if that doesn't work out then we backtrack and try again.

Note that we try not to reach (d). If we can parse the whole excerpt without need of relative clauses, we do so, thus preferring the simpler reading.

```
meaning_list *SP_description(int w1, int w2, int allow_nounless) {
    int cw1 = -1, cw2 = -1, original_w1 = w1, original_w2 = w2, rewind_point;
    quantifier *quantifier_used = NULL; int which_N = -1, determiner_w1 = -1, determiner_w2 = -1;
    world_object *some_kind = NULL;
    meaning_list *ml, *final_ml;
    if ((w1<0) || (w2<w1)) return NULL;
    if (word_range_ends_with_calling(w1, w2, &w1, &w2, &cw1, &cw2))
        LOGIF(S_GRAMMAR, "SP_description detects calling <$W>\n", cw1, cw2);
    ⟨Advance past any initial quantifier 11⟩;
    ⟨Advance past any single article 12⟩;
    rewind_point = w1;
    if (quantifier_used == NULL) ⟨Advance past any composite noun-and-quantifier 13⟩;
    ⟨Try to match the remaining text with qualifier and/or noun 14⟩;
    quantifier_used = NULL; cw1 = -1; cw2 = -1;
    if (some_kind) {
```

```
        w1 = rewind_point; some_kind = NULL;
        ⟨Try to match the remaining text with qualifier and/or noun 14⟩;
    }
    ⟨Try to match the original text as having a relative clause 18⟩;
    return NULL;
    Accept:
    final_ml = new_ml_with_words(DC_PRODUCTION, original_w1, original_w2);
    ⟨Post-process the meaning list tree for the physical description 19⟩;
    LOGIF(S_GRAMMAR, "SP_description on <$W>, %s nounless: $m\n",
        original_w1, original_w2, allow_nounless?"allowing":"forbidding", final_ml);
    return final_ml;
}
```

The function SP_description is called from 5/tandv and 5/varc.

§**11.** See "Determiners and Quantifiers.w" for how this is done. (We exclude "no one" because we want to handle that below as if it were "no-one"; we don't want to consider it as the determiner "no" plus the common noun "one", because we don't want to tell Inform that English sometimes considers "one" to be a person rather than a number.)

⟨Advance past any initial quantifier 11⟩ ≡

```
    if ((w1<w2) && (![[w1, w2 == no one ***]])) {
        int x1 = quant_parse_against_text(w1, w2, &which_N, &quantifier_used);
        if (x1 >= 0) {
            determiner_w1 = w1; determiner_w2 = x1-1; w1 = x1;
        } else quantifier_used = NULL;
    }
```

This code is used in §10.

§**12.** Note that an article can follow a determiner, as in "six of the people", where "six of" is a determiner. At this point we don't need to notice whether the article is definite or not, and we're similarly turning a blind eye to singular vs plural, so we just skip over it.

⟨Advance past any single article 12⟩ ≡

```
    if ((w1<w2) && (vocab_test_flags(w1, ARTICLE_MC))) w1++;
```

This code is used in §10.

§**13.** Words like "something" or "everywhere" combine a common noun – thing, and implicitly room – with a determiner – one thing, all rooms. When we detect them, we set both `quantifier_used` and `some_kind` appropriately. None can be recognised if the basic kinds are not created yet, which we check for by inspecting `kind_thing`. (Note that the S-parser may indeed be asked to parse "something" before this point, as when it scans the domains of adjective definitions, but that it's okay that it produces a null result.)

With the "some-" words, no quantifier is set because the meaning here is the `exists_quantifier`. Since this is the default behaviour for unquantified descriptions anyway – "a door is in the Great Hall" means that such a door exists – we needn't set the variable.

"Nothing" is conspicuously absent from the possibilities below. It gets special treatment elsewhere since it can also double as a value (the "not an object" pseudo-value).

⟨Advance past any composite noun-and-quantifier 13⟩ ≡

```
if (kind_thing) {
    determiner_w1 = w1; determiner_w2 = w1;
    if [[word w1 == something/anything]] {
        w1++; some_kind = kind_thing;
    } else if [[word w1 == somewhere/anywhere]] {
        w1++; some_kind = kind_room;
    } else if [[word w1 == someone/anyone/somebody/anybody]] {
        w1++; some_kind = kind_person;
    } else if [[word w1 == everything]] {
        w1++; quantifier_used = for_all_quantifier; some_kind = kind_thing;
    } else if [[word w1 == everywhere]] {
        w1++; quantifier_used = for_all_quantifier; some_kind = kind_room;
    } else if [[word w1 == everyone/everybody]] {
        w1++; quantifier_used = for_all_quantifier; some_kind = kind_person;
    } else if [[word w1 == nowhere]] {
        w1++; quantifier_used = not_exists_quantifier; some_kind = kind_room;
    } else if [[word w1 == nobody]] {
        w1++; quantifier_used = not_exists_quantifier; some_kind = kind_person;
    } else if [[word w1 == no_one]] {
        w1++; quantifier_used = not_exists_quantifier; some_kind = kind_person;
    } else if [[w1, w2 == no one ***]] {
        w1 += 2; determiner_w2++;
        quantifier_used = not_exists_quantifier; some_kind = kind_person;
    }
    if (some_kind) {
        if (w1 > w2) invoke_1(DC_NOUN_PRODUCTION, ml_from_wo(some_kind));
    } else {
        determiner_w1 = -1; determiner_w2 = -1;
    }
}
```

This code is used in §10.

§**14.** It is especially important not to spend time in this routine when what we have is not a description after all, so filtering with the following bitmaps makes a huge time saving:

```
define QUALIFIED_NOUN_BITMAP (WORLD_OBJECT_MC+DESIGNED_TYPE_MC+BUILTINTYPE_MC)
define DESCRIPTION_BITMAP ((NOT_MC+ARTICLE_MC+ADJECTIVE_MC+INORON_MC) | QUALIFIED_NOUN_BITMAP)
```

⟨Try to match the remaining text with qualifier and/or noun 14⟩ ≡

```
int i;
int only_qualifier_or_noun_words_left = TRUE;
for (i=w1; i<=w2; i++)
    if ((vocab_test_flags(i, DESCRIPTION_BITMAP)) == 0)
        only_qualifier_or_noun_words_left = FALSE;
if (only_qualifier_or_noun_words_left) {
    int first_possible_split, last_possible_split;
    int hopeless = FALSE;
    ⟨Find first and last possible splits between qualifier and noun part 15⟩;
    if (hopeless == FALSE)
        ⟨Try all possible splits within this range 16⟩;
}
```

This code is used in §10.

§**15.** The "split" is the word number at which the noun part begins. For instance, if "open transparent containers" is the text of words 10 to 12, then there are four possible split positions: 10 (entirely noun), 11 (open plus two words of noun), 12 (open transparent plus one word of noun) and 13 (entirely adjectives). But using that the adjective words have to match at least part of the `AL_BITMAP`, whereas the noun words have to have the `WORLD_OBJECT_MC` bit (indicating that they occur in excerpt meanings associated with objects or kinds), we can cut down the possible splits considerably – indeed usually to a single possibility, or even none at all, whereupon the `hopeless` flag is set. This is very well worthwhile, because the test at each split is fairly slow.

⟨Find first and last possible splits between qualifier and noun part 15⟩ ≡

```
int i, adjectival_start = -1, adjectival_end = -1, noun_start = -1, noun_end = -1;
for (i=w1; i<=w2; i++)
    if (vocab_test_flags(i, AL_BITMAP)) {
        if (adjectival_start<0) adjectival_start = i;
        adjectival_end = i;
    } else break;
if (some_kind == NULL)
    for (i=w2; i>=w1; i--) {
        if (vocab_test_flags(i, QUALIFIED_NOUN_BITMAP)) {
            if (noun_end<0) noun_end = i;
            noun_start = i;
        } else break;
    }
if (noun_start<0) {
    first_possible_split = w2+1;                          no noun words: purely adjectival
} else {
    first_possible_split = noun_start;                    as we can't split before the first noun
}
if (adjectival_start<0) {
    if (first_possible_split != w1) hopeless = TRUE;      begins with neither sort of word
    last_possible_split = w1;                             no adjectival words: purely noun
} else {
```

```
        if (adjectival_end+1 < first_possible_split) hopeless = TRUE;          gap in the middle
        last_possible_split = adjectival_end+1;                          after the adjectives, that is
    }
```

This code is used in §14.

§**16.** In cases of ambiguity, the earliest split wins: that is, the one maximising the length of the noun. This means that if the source text actually names a dark room, the text "dark room" will not be confused with "dark (i.e., the property) room (i.e, the kind)", since that splits later.

⟨Try all possible splits within this range 16⟩ ≡

```
    int split;
    for (split = first_possible_split; split <= last_possible_split; split++)
        ⟨Try splitting here 17⟩;
```

This code is used in §14.

§**17.** At each split, we test the noun first, because it is a quicker test and also the one less likely to succeed. (Since most adjectives are single-word, and the words up to the split all have `AL_BITMAP` bit(s) set, it's very likely that those words will successfully parse as an adjective list.)

⟨Try splitting here 17⟩ ≡

```
    meaning_list *ml2 = NULL, *ml3 = NULL;
    kind_of_value *restrict_to = NULL;
    if (some_kind) ml2 = ml_from_wo(some_kind);
    if (split <= w2) {
        ml2 = SP_excerpt(WORLD_OBJECT_MC, split, w2);
        if ((ml2 == NULL) && (![[split, w2 == object/objects]]))
            ml2 = SP_KOV_name(split, w2, QUALIFIED_NOUN_BITMAP, &restrict_to, TRUE);
        if (ml2 == NULL) continue;
    }
    if (split > w1) {
        ml3 = parse_adjective_list(w1, split-1, restrict_to, (ml2)?FALSE:TRUE);
        if (ml3 == NULL) continue;
    }
    if (ml2 == NULL) {
        if (allow_nounless == FALSE) continue;
        invoke_1(DC_ADJS_PRODUCTION, ml3);
    }
    if (ml3 == NULL) invoke_1(DC_NOUN_PRODUCTION, ml2);
    invoke_2(DC_ADJSNOUN_PRODUCTION, ml3, ml2);
```

This code is used in §16.

§**18.** To reach this possibility is nearly to admit defeat. `SP_description` has failed to match, and the only salvation would be if the excerpt contains a relative clause – "female people in the Atrium". We only bother to check this if one of the words in the excerpt is flagged as a possible verb or preposition; a verb is a possibility because of excerpts like "animals which carry things", where the word "carry" is the trigger.

But the actual parsing is handled by `SP_sentence` alone. Any work we have done up to now is thrown away, even if some part of it might have been successful. Should `SP_sentence` go well, of course, it's quite likely to call us again on sub-excerpts of the original.

⟨Try to match the original text as having a relative clause 18⟩ ≡

```
int i, might_contain_relative_clause = FALSE;
for (i=original_w1+1; i<original_w2; i++)
    if ((vocab_test_flags(i, (PREPOSITION_MC+CVERB_MC))) != 0)
        might_contain_relative_clause = TRUE;
if (might_contain_relative_clause)
    try_production(SP_sentence(original_w1, original_w2, SN_PRODUCTION));
```

This code is used in §10.

§**19.** If we reach this point, it's good news: success. We add extra nodes to the meaning list tree, though, to record any "calling" name and any determiner used.

⟨Post-process the meaning list tree for the physical description 19⟩ ≡

```
meaning_list *attach_point;
ml_set_down(final_ml, ml);
attach_point = ml;
if (cw1 >= 0) {
    if [[cw1, cw2 == a/an/the/some ...]] cw1++;
    ml_set_right(attach_point, new_ml_with_words(CALLED_PRODUCTION, cw1, cw2));
    attach_point = ml_right(attach_point);
}
if (quantifier_used)
    ml_set_right(attach_point,
        make_determiner_ml(quantifier_used, which_N, determiner_w1, determiner_w2));
```

This code is used in §10.

§**20. KOV names.** These are all converted into meaning lists consisting of a single leaf node, so for instance "object" becomes the meaning list:

```
TYPE_PRODUCTION => (G)VALUE_FMY/CONSTANT_SPC(<null>)-OBJECT_TY-KOV
```

The notation on the right denotes a generic constant value of KOV "object". Singular and plural are equivalent here, so "objects" would make an identical meaning list.

Names of KOVs come from three sources:

(a) The "built-in KOVs", that is, those defined in the "Types.i6t" template file, have single word names. They all represent base KOVs which can be indexed by an ID number, and for speed this ID number is attached to the vocabulary entry for the single word – thus avoiding the need to call the excerpt parser.

(b) The "designed KOVs", that is, those created by the source text. These have multi-word names and are registered with the excerpt parser but are still in the end base KOVs.

(c) Non-base KOVs made using KOV constructors, such as "list of numbers" – the "list of" constructor applied to the base KOV "numbers". These are parsed by `kov_parse_long_name` rather than here.

```
meaning_list *SP_KOV_name(int w1, int w2, int conjunction, kind_of_value **set_kov,
    int data_types_only) {
    if (conjunction & DESIGNED_TYPE_MC) {
        meaning_list *ml = SP_excerpt(DESIGNED_TYPE_MC, w1, w2);
        if (ml) {
            single_integer *sint = RETRIEVE_POINTER_single_integer(em_data(ml_meaning(ml)));
            int type_ID = sint_get(sint);
            if (type_ID > 1) {
                if (set_kov) *set_kov = kova(type_ID);
                return make_type_ml_from_ID(type_ID);
            }
        }
    }
    if (w1 == w2) {
        if (vocab_test_flags(w1, BUILTINTYPE_MC)) {
            int type_ID = vocab_get_literal_number_value(lw_array[w1].lw_identity);
            if ((type_ID > 1) &&
                ((data_types_only == FALSE) || (type_ID_is_data_type(type_ID)))) {
                if (set_kov) *set_kov = kova(type_ID);
                return make_type_ml_from_ID(type_ID);
            }
        }
    } else {
        kind_of_value *kov = kov_parse_long_name(w1, w2);
        if (kov) {
            if (set_kov) *set_kov = kov;
            return make_type_ml_from_kov(kov);
        }
        if (data_types_only == FALSE) {
            int x1 = w1, x2 = w2, c = parse_constructor_name(&x1, &x2);
            if (c != UNKNOWN) {
                if (SP_KOV_name(x1, x2,
                    DESIGNED_TYPE_MC+BUILTINTYPE_MC, &kov, data_types_only)) {
                    if (kov) {
                        if (set_kov) *set_kov = kovcon(c, kov);
                        return make_type_ml_from_kov(kovcon(c, kov));
                    }
```

```
                }
                world_object *k = parse_world_object(x1, x2, TRUE);
                if (k) {
                    if (set_kov) *set_kov = kovcon(c, kovko(k));
                    return make_type_ml_from_kov(kovcon(c, kovko(k)));
                }
            }
        }
    }
    return NULL;
}
```

The function SP_KOV_name is called from 5/tandv.

Type Expressions and Values 5/tandv

Purpose

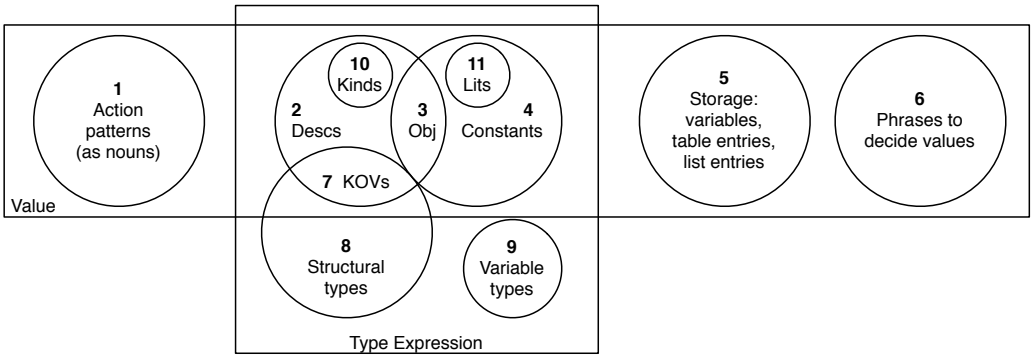
To parse two forms of noun: a noun phrase in a sentence, and a description of what text can be written in a given situation.

5/tandv.§1-2 Type expressions; §3-19 Values; §20-22 Delegated constructs; §23-28 Table references

---

Definitions

¶1. Inform recognises many noun-like constructions, some of which – out of a noun context – look like adjectives, actions or other excerpts which aren't at all evidently nouns. These many ways to describe nouns are gathered up into two central constructions. A "type expression" specifies what sort of excerpt should appear in a given place, whereas a "value" means anything which can be a noun phrase for a verb. There is considerable overlap between the two, but they are not the same, as the following Venn diagram shows:



The following example sentences have the relevant phrases in bold.

[1] if the idea of the gizmo is **taking the fish**, ...

[2] if there are **three women** in the Nunnery, ...

[3a: as description] Before taking **the harmonium**, ...

[3b: as constant] let X be **the harmonium**;

[4] now Y is **the can't reach inside rooms rule**;

[5] now Z is **the time of day**;

[6] let N be **the number of entries in L**;

[7] Understand "turn to [**number**]" as combination-setting.

[8] To repeat until (C - **condition**): ...

[9] The Zeppelin countdown is a **number that varies**.

[10] The little red car is a **vehicle**.

[11] The weight of the Space Shuttle is **68585 kg**.

¶2. A rough measure of complexity is how many times the S-parser has to try parsing a noun phrase, and we cut off (really as a defensive measure against bugs) if this exceeds a threshold:

```
define S_PARSER_COMPLEXITY_THRESHOLD 1000000

int no_calls_to_SP_noun_phrase = 0;
```

---

§**1. Type expressions.** This is a concept which does not exist for conventional programming languages, which would see it as a sort of half-way position between "value" and "type". A "type expression" is a possible specification for a parameter in a phrase definition, though it has other uses elsewhere. That certainly includes cases which traditional programming languages would call types, so

To adjust (X - closed door) by (N - number): ...

includes two type expressions, "closed door" and "number". Similarly "text", "list of rules" and so forth, and the special case of "value", the broadest possible type.

But a type expression can also be a constant, which C (for instance) would consider a value and not a type at all:

To adjust (X - closed door) by (N - 11): ...

gives a definition to be used only where the second parameter has the value 11. In this way any constant value is regarded as being a type – the narrow type representing only its own value.

Note that a list of adjectives with no noun does not always qualify as a type expression, according to the routine as written below. It looks as if it never should, on the face of it – "opaque" does not make clear what kind of object is to be opaque – but in practice English is a little fuzzy on the difference between nouns and adjectives. For instance, this:

To adjust (X - scenery): ...

is allowed even though "scenery" is an adjective in Inform. Bare adjective lists are in practice allowed in all cases except when defining kinds of variables: so "scenery variable" is impossible.

```
meaning_list *SP_type_expression(int w1, int w2, int allow_nounless) {
    begin_SP_routine_skipping_article(w1, w2);
    if (allow_nounless) try_production(SP_adjective_list(w1, w2));
    if (w2>w1) ⟨Try type expressions representing categories of variables 2⟩;
    try_production(SP_KOV_name(w1, w2, conjunction, NULL, FALSE));
    try_production(SP_description(w1, w2, FALSE));
    try_production(SP_constant_value(w1, w2));
    on_success_invoke(TE_PRODUCTION);
}
```

The function SP_type_expression is called from 7/ttts.

§**2.** Another form of type expression is exemplified by "number variable" (meaning: any name of a number variable can go here), and so on. Note that these forms recurse by calling `SP_type_expression` again, so that *syntactically* we allow "T that varies" for any type expression T. This would include contradictions in terms such as "15 that varies", but we want to allow the parse here so that a problem message can be issued higher up in Inform.

⟨Try type expressions representing categories of variables 2⟩ ≡

```
int v1 = -1, v2 = -1;
if ([[w1, w2 == ... variable/variables --> v1, v2]] ||
    [[w1, w2 == ... that/which vary/varies --> v1, v2]]) {
    if [[v1, v2 == existing]] invoke_0(TE_EX_VAR_PRODUCTION);
    if ([[v1, v2 == existing ...]] && (ml2 = SP_type_expression(v1+1, v2, FALSE)))
        invoke_1(TE_EX_VAR_PRODUCTION, ml2);
    if [[v1, v2 == nonexisting]] invoke_0(TE_NEW_VAR_PRODUCTION);
    if ([[v1, v2 == nonexisting ...]] && (ml2 = SP_type_expression(v1+1, v2, FALSE)))
        invoke_1(TE_NEW_VAR_PRODUCTION, ml2);
    if [[v1, v2 == global]] invoke_0(TE_GL_VAR_PRODUCTION);
    if ([[v1, v2 == global ...]] && (ml2 = SP_type_expression(v1+1, v2, FALSE)))
        invoke_1(TE_VAR_PRODUCTION, ml2);
    if ((ml2 = SP_type_expression(v1, v2, FALSE))) invoke_1(TE_VAR_PRODUCTION, ml2);
}
```

This code is used in §1.

§**3. Values.** As noted above, `SP_value` is used to parse a noun phrase arising in a typical phrase, or on either side of an assertion sentence. The boldface terms here are all parsed as values:

The cat is in **the bag**. The **time of day** is **11:10 AM**.

award **six** points;

if **more than three animals** are in **the kennel**, ...

```
kind_of_value *probable_noun_phrase_context = NULL;
meaning_list *SP_value(int w1, int w2) {
    begin_SP_routine(w1, w2);
    LOGIF(S_GRAMMAR, "PV on <$W> in context $u\n", w1, w2, probable_noun_phrase_context);
    if (no_calls_to_SP_noun_phrase >= S_PARSER_COMPLEXITY_THRESHOLD) return NULL;
    if (paired_brackets(w1, w2)) return SP_value(w1+1, w2-1);
    ⟨Value, priority 1: a non-global variable name 4⟩;
    ⟨Value, priority 2: a constant value 5⟩;
    ⟨Value, priority 3: a global variable name 8⟩;
    ⟨Value, priority 4: a property name used as noun 9⟩;
    ⟨Value, priority 5: a table column name, but only if we are expecting it 10⟩;
    ⟨Value, priority 6: an action pattern 11⟩;
    ⟨Value, priority 8: a value computed by a phrase at run-time 13⟩;
    ⟨Value, priority 7: a description which doesn't involve kinds of value 12⟩;
    ⟨Value, priority 9: a reference to entry or entries in a table 14⟩;
    ⟨Value, priority 10: "member of" used explicitly to make a description 15⟩;
    ⟨Value, priority 11: a value property 16⟩;
    ⟨Value, priority 12: a list entry 17⟩;
    ⟨Value, priority 13: a description which does involve kinds of value 18⟩;
    ⟨Value, priority 14: a table column name when we aren't expecting it 19⟩;
    LOGIF(S_GRAMMAR, "PV on <$W> failed\n", w1, w2);
    on_success_invoke(VAL_PRODUCTION);
}
```

The function SP_value is called from 5/varc, 5/candp and 7/ttts.

§**4.** Because such a wide range of text can pass `SP_value`, the order of matching is very important. Local and not-local-but-not-global-either variables come first, so that they can have names overlapping with globally-defined names of other constructs – this avoids namespace clashes, especially when using extensions.

⟨Value, priority 1: a non-global variable name 4⟩ ≡

```
    try_production(SP_local_variable(w1, w2));
    try_production(SP_stacked_variable(w1, w2));
```

This code is used in §3.

§**5.** Constants come next; in case of doubt, if text specified a constant then that ought to be the interpretation. Thus in the sentence:

let X be red;

where "red" is a value of "colour" which is a property of things, we read "red" as a noun – the actual hue – and as a result create "X" as a temporary colour variable; rather than reading "red" as an adjective – the behaviour of having the colour red – and making "X" a description. (We will sometimes be wrong about this: for instance, in "now the canvas is red", it is indeed the adjectival use that's meant. But this is dealt with when simplifying the resultant proposition, later on.)

⟨Value, priority 2: a constant value 5⟩ ≡

```
try_production(SP_constant_value(w1, w2));
⟨Value, priority 2a: an equation written with a "where" clause 6⟩;
⟨Value, priority 2b: an equation written inline 7⟩;
```

This code is used in §3.

§**6.** Equations are normally referred to by name, but they sometimes have "where..." caveats added:

⟨Value, priority 2a: an equation written with a "where" clause 6⟩ ≡

```
int i, eq1 = w1, eq2 = w2, wh1 = -1, wh2 = -1;
if ([[eq1, eq2 == ... where ... : i --> eq1, eq2 ... wh1, wh2]] &&
    ((ml2 = SP_value(eq1, eq2)) != NULL)) {
    switch (ml_production(ml_down(ml2))) {
        case EQUATION_INLINE_PRODUCTION:
        case EQUATION_MC:
            invoke_2(EQUATION_WHERE_PRODUCTION, ml_down(ml2), SP_plain_text(wh1, wh2));
            break;
    }
}
```

This code is used in §5.

§**7.** They can also be written "inline", that is, explicitly; we can tell this by the presence of an equals sign, and the run-up text "...be given by". (We have to be pretty cautious here.)

⟨Value, priority 2b: an equation written inline 7⟩ ≡

```
int pre1 = w1-3, pre2 = w1-1;
if ((pre1 >= 0) && [[pre1, pre2 == be given by]]) {
    int i, j;
    for (i=w1; i<=w2; i++) {
        char *p = lw_array[i].lw_rawtext;
        for (j=0; p[j]; j++)
            if (p[j] == '=')
                invoke_1(EQUATION_INLINE_PRODUCTION, SP_plain_text(w1, w2));
    }
}
```

This code is used in §5.

§**8.** Now global variables. In theory, a registered `QUANTITY_MC` excerpt might be the name of an enumerated constant or a stacked variable, but both of those have been parsed already, so if we reach this then it must be a global.

⟨Value, priority 3: a global variable name 8⟩ ≡
```
if (disjunction & QUANTITY_MC) {
    try_production(SP_excerpt(QUANTITY_MC, w1, w2));
    if [[w1, w2 == the ...]]
        try_production(SP_excerpt(QUANTITY_MC, w1+1, w2));
}
```

This code is used in §3.

§**9.** Property names are only rarely used as nouns, but here is an example:

if the bartered item provides colour, ...

where "colour" is a property name used as a noun. This example is easy to parse, but others are more ambiguous:

if the bartered item provides open, ...

Here "open" is a property name, but it could also be parsed (by `SP_description`) as a description of all items which are open. This is why property names have a higher priority here than descriptions do.

⟨Value, priority 4: a property name used as noun 9⟩ ≡
```
if (disjunction & PROPERTY_MC) {
    try_production(SP_excerpt(PROPERTY_MC, w1, w2));
    if [[w1, w2 == the ...]]
        try_production(SP_excerpt(PROPERTY_MC, w1+1, w2));
}
```

This code is used in §3.

§**10.** Because of Inform's feature allowing objects or enumerated kinds of value to be created by table, it's often the case that column 1 in a table has a name which clashes with the name of a kind of object or value. For instance, in the example "Tour des Maillots", we have:

A jersey is a kind of thing. Some jerseys are defined by the Table of Honorary Jerseys.

and column 1 in the Table is called "jersey". Now in fact column names are also registered with the word "column" suffixed, so that the writer only has to spell out "jersey column" to be unambiguous that he means the column, not the kind. But we don't want to insist on this in cases where the context clearly indicates that we're talking about the table, as here:

sort the Table of Honorary Jerseys in jersey order;

So in cases like this we allow "jersey" to be read as the column name, and in all other cases we fall through into lower-priority description parsing below, so that "jersey" is parsed as a description of the kind of object.

⟨Value, priority 5: a table column name, but only if we are expecting it 10⟩ ≡
```
if ((is_kova(probable_noun_phrase_context, TABLE_COLUMN_TY))
    && (disjunction & TABLE_COLUMN_MC)) {
    try_production(SP_excerpt(TABLE_COLUMN_MC, w1, w2));
    if [[w1, w2 == the ...]]
        try_production(SP_excerpt(TABLE_COLUMN_MC, w1+1, w2));
}
```

This code is used in §3.

§**11.** In practice an action pattern used as a noun will probably need to be specific ("taking the duck") rather than descriptive ("taking an animal") but we don't make syntactic distinctions and allow both here.

⟨Value, priority 6: an action pattern 11⟩ ≡
```
try_production(SP_action_pattern(w1, w2));
```
This code is used in §3.

§**12.** We finally allow descriptions to be matched, but only where they consist of lists of adjectives ("closed fixed in place"), objects ("open Weiss Safe") or kinds ("open container in the Dining Room").

⟨Value, priority 7: a description which doesn't involve kinds of value 12⟩ ≡
```
try_production(SP_adjective_list(w1, w2));
try_production(SP_purely_physical_description(w1, w2));
```
This code is used in §3.

§**13.** Now text like "number of rows in the Table of Ranks" which specifies a value that can only be determined during play, using a "To decide which..." phrase.

It's a little surprising, perhaps, that this comes only around half-way down the priority listing.

It isn't higher up the list because, if it were, a definition such as:

To decide which object is the open door: ...

would effectively redefine a description like "open door", undermining the language; similarly, we don't want a phrase to override a variable name, or worse still a literal –

To decide which number is 11: decide on 22.

But it isn't lower down the list because a phrase when invoked tends to contain secondary clauses, and it's important for those clauses to take priority over the other secondary clauses which appear lower down. For instance:

change the hunger of Ogg to **the hunger of Ogg plus 1**;

Because phrases have higher priority than property values, we read the new value as "(the hunger of (Ogg)) plus (1)" rather than "the hunger of (Ogg plus 1)".

⟨Value, priority 8: a value computed by a phrase at run-time 13⟩ ≡
```
if ((ml2 = SP_excerpt(VALUE_PHRASE_MC, w1, w2)) != NULL) {
    invoke_1(VALUE_PHRASE_PRODUCTION, ml2);
}
if [[w1, w2 == the ...]]
    if ((ml2 = SP_excerpt(VALUE_PHRASE_MC, w1+1, w2)) != NULL)
        invoke_1(VALUE_PHRASE_PRODUCTION, ml2);
```
This code is used in §3.

§**14.** Because `SP_table_reference` is a little slow, we try not to call it for excerpts which obviously can't pass.

⟨Value, priority 9: a reference to entry or entries in a table 14⟩ ≡
```
int try_tr = 0;
for (i=w1; i<=w2; i++) {
    if [[word i == table/entry/listed/row]] try_tr += 2;
    if [[word i == in/of]] try_tr += 1;
}
if (try_tr >= 2) try_production(SP_table_reference(w1, w2));
```
This code is used in §3.

§**15.** The "member of D" construction, where D is a description, can be useful to resolve ambiguities, but also allows us to use a description known only at run-time, since it matches some subset of objects using a routine whose address is stored in a local variable. This allows "To..." phrases to have descriptions as arguments.

⟨Value, priority 10: "member of" used explicitly to make a description 15⟩ ≡

```
int d1, d2;
if [[w1, w2 == member/members of ... --> d1, d2]] {
    if ((ml2 = SP_description(d1, d2, FALSE)) != NULL) {
        ml = new_ml(MEMBER_OF_PRODUCTION);
        ml_set_down(ml, ml2);
        LOGIF(S_GRAMMAR, "PV found member-of + description <$W>\n", d1, d2);
        goto Accept;
    }
    if ((ml2 = SP_local_variable(d1, d2)) != NULL) {
        ml = new_ml(MEMBER_OF_PRODUCTION);
        ml_set_down(ml, new_ml(VAL_PRODUCTION));
        ml_set_down(ml_down(ml), ml2);
        LOGIF(S_GRAMMAR, "PV found member-of + local <$W>\n", d1, d2);
        goto Accept;
    }
}
```

This code is used in §3.

§**16.** For instance, "the carrying capacity of the box", or – providing we are in a context where "it" meaningfully describes an object – "its colour".

Note that the property name is allowed to be unrecognised if we are parsing early in Inform's run. (It's by looking at clauses like this that Inform finds out what the property names are going to be.)

⟨Value, priority 11: a value property 16⟩ ≡

```
for (i=w1+1; i<=w2-1; i++)
    if [[word i == of]] {
        int j = i+1;
        [[j, w2 == the ... --> j, w2]];
        if ((ml3 = SP_value(j, w2)) != NULL) {
            ml2 = SP_excerpt(PROPERTY_MC, w1, i-1);
            if ((ml2 == NULL) && (model_world_constructed == FALSE))
                ml2 = SP_plain_text(w1, i-1);
            if (ml2) invoke_2(VAL_PROP_OF_PRODUCTION, ml2, ml3);
        }
    }
if ((enable_its >= 0) && [[w1, w2 == its/his/her/their ...]]) {
    ml2 = SP_excerpt(PROPERTY_MC, w1+1, w2);
    if (ml2) {
        specification *spec = new_LOCAL_VARIABLE_spec(-1, -1, enable_its);
        ml3 = new_ml(VAL_PRODUCTION);
        ml_set_down(ml3, new_ml(LOCAL_PRODUCTION));
        ml_attach_spec(ml_down(ml3), spec);
        invoke_2(VAL_PROP_OF_PRODUCTION, ml2, ml3);
    }
}
```

This code is used in §3.

§**17.** This is an explicit entry in a list – for instance, "entry 12 in L". Because of the tell-tale word "entry" it is much less tricky to handle.

⟨Value, priority 12: a list entry 17⟩ ≡
```
    if [[word w1 == entry]] {
        for (i=w1+1; i<=w2-1; i++)
            if [[word i == of/in/from]] {
                int j = i+1;
                [[j, w2 == the ... --> j, w2]];
                    if ((ml3 = SP_value(w1+1, i-1)) && (ml2 = SP_value(j, w2)))
                        invoke_2(VAL_LIST_ENTRY_PRODUCTION, ml2, ml3);
            }
    }
```
This code is used in §3.

§**18.** All other descriptions have gone by now; we are left with those, like "even number", which involve kinds of value rather than kinds of object.

⟨Value, priority 13: a description which does involve kinds of value 18⟩ ≡
```
    try_production(SP_description(w1, w2, FALSE));
```
This code is used in §3.

§**19.** And now that names of kinds and kinds of value have been taken care of, we can safely match anything registered as a table column name; it will be unambiguous at this point.

⟨Value, priority 14: a table column name when we aren't expecting it 19⟩ ≡
```
    if (disjunction & TABLE_COLUMN_MC) {
        try_production(SP_excerpt(TABLE_COLUMN_MC, w1, w2));
        if [[w1, w2 == the ...]]
            try_production(SP_excerpt(TABLE_COLUMN_MC, w1+1, w2));
    }
```
This code is used in §3.

§**20. Delegated constructs.** The S-parser doesn't parse every word of the text fed to it: some constructions are delegated to specific code in other chapters. To begin with, local variable names are not registered as excerpts, and are parsed from data on the current stack frame:

```
meaning_list *SP_local_variable(int w1, int w2) {
    int lvn = parse_name_local_to_current_stack_frame(w1, w2);
    if (lvn >= 0) {
        meaning_list *ml;
        specification *spec = new_LOCAL_VARIABLE_spec(-1, -1, lvn);
        ml = new_ml(LOCAL_PRODUCTION);
        ml_attach_spec(ml, spec);
        return ml;
    }
    return NULL;
}
```

§**21.** Stacked variables, which also lack global scope, are similarly context-dependent:

```
meaning_list *SP_stacked_variable(int w1, int w2) {
    ph_stack_frame *phsf = current_stack_frame();
    stacked_variable *stv;
    if (phsf == NULL) return NULL;
    stv = stvol_parse(phsf_get_stvol(phsf), w1, w2);
    if (stv) {
        meaning_list *ml = new_ml(STV_PRODUCTION);
        specification *spec = new_QUANTITY_spec(stv_get_quantity(stv));
        ml_attach_spec(ml, spec);
        return ml;
    }
    return NULL;
}
```

§**22.** And action patterns, such as "taking a container" or "opening a closed door", are parsed by code in the chapter on Actions:

```
meaning_list *SP_action_pattern(int w1, int w2) {
    action_pattern ap = parse_action_pattern(w1, w2, IS_TENSE);
    if (ap_is_valid(&ap)) {
        meaning_list *ml;
        specification *spec = new_TEST_ACTION_spec(store_ap(ap));
        ml = new_ml(AP_PRODUCTION);
        ml_attach_spec(ml, spec);
        return ml;
    }
    return NULL;
}
```

§**23. Table references.** The next parsing routine looks (and is) a little slow, but see `SP_value` above for why it is called only when success is at least plausible.

Table references come in five different forms:

```
meaning_list *SP_table_reference(int w1, int w2) {
    begin_SP_routine(w1, w2);
    LOGIF(S_GRAMMAR, "Possible table reference $W\n", w1, w2);
    ⟨Try an abbreviated table reference, naming only the column 24⟩;
    for (i=w1+1; i<=w2-2; i++) {
        ⟨Try an explicit identification of a cell in the table 25⟩;
        ⟨Try a conditional search of a column in the table 26⟩;
        ⟨Try an associative identification of a cell in the table 27⟩;
        ⟨Try an existential identification of a cell in the table 28⟩;
    }
    on_success_invoke(TR_PRODUCTION);
}
```

§**24.** For instance, "atomic number entry", meaning the entry in that column and implicitly in the table and row currently selected.

⟨Try an abbreviated table reference, naming only the column 24⟩ ≡
```
if ([[w1, w2 == ... entry]] &&
    ((ml2 = SP_excerpt(TABLE_COLUMN_MC, w1, w2-1)) != NULL))
    invoke_1(TR_ENTRY_PRODUCTION, ml2);
```

This code is used in §23.

§**25.** For instance, "atomic number in row 4 of the Table of Elements".

⟨Try an explicit identification of a cell in the table 25⟩ ≡
```
if ([[i, w2 == in row ...]] &&
    ((ml2 = SP_excerpt(TABLE_COLUMN_MC, w1, i-1)) != NULL))
    for (j=i+3; j<w2; j++)
        if ([[word j == of]] &&
            (ml3 = SP_value(i+2, j-1)) && (ml4 = SP_value(j+1, w2)))
            invoke_3(TR_IN_ROW_PRODUCTION, ml2, ml3, ml4);
```

This code is used in §23.

§**26.** For instance, "an atomic number listed in the Table of Elements" in the sentence "if 101 is an atomic number listed in the Table of Elements". (This is part of a condition, and can't evaluate.)

⟨Try a conditional search of a column in the table 26⟩ ≡
```
if ([[i, w2 == listed in ...]] &&
    ((ml2 = SP_excerpt(TABLE_COLUMN_MC, w1, i-1)) != NULL) &&
    ((ml3 = SP_value(i+2, w2)) != NULL))
    invoke_2(TR_LISTED_IN_PRODUCTION, ml2, ml3);
```

This code is used in §23.

§**27.** For instance, "atomic weight corresponding to an atomic number of 57 in the Table of Elements".

⟨Try an associative identification of a cell in the table 27⟩ ≡
```
if ([[i, w2 == corresponding to ...]] &&
    ((ml2 = SP_excerpt(TABLE_COLUMN_MC, w1, i-1)) != NULL))
    for (j=i+3; j<w2; j++)
        if ([[word j == of]] &&
            (ml3 = SP_excerpt(TABLE_COLUMN_MC, i+2, j-1)))
            for (k=j+2; k<w2; k++)
                if ([[word k == in]] &&
                    ((ml4 = SP_value(j+1, k-1)) != NULL) &&
                    ((ml5 = SP_value(k+1, w2)) != NULL))
                    invoke_4(TR_CORR_PRODUCTION, ml2, ml3, ml4, ml5);
```

This code is used in §23.

§**28.** For instance, “atomic weight of 20 in the Table of Elements” in the sentence “if there is an atomic weight of 20 in the Table of Elements”. Again, this is part of a condition, and can't evaluate.

⟨Try an existential identification of a cell in the table 28⟩ ≡

```
if ([[word i == of]] && ((ml2 = SP_excerpt(TABLE_COLUMN_MC, w1, i-1)) != NULL))
    for (j=i+2; j<w2; j++)
        if [[word j == in]] {
            ml3 = SP_value(i+1, j-1);
            ml4 = SP_value(j+1, w2);
            if (ml3 && ml4) invoke_3(TR_OF_IN_PRODUCTION, ml2, ml3, ml4);
        }
```

This code is used in §23.

Verbal and Relative Clauses 5/varc

Purpose

To break down an excerpt into NP and VP-like clauses, perhaps with a primary verb (to make a sentence), perhaps only a relative clause (to make a more complex NP).

---

§**1. The top level of the S-grammar.** English is an SVO language, where the main parts of the sentence occur in the order subject, verb, object. The following routine parses that crucial division, and note that it can be used either to form a complete sentence, where there is an active verb –

now the silver bars are in the Hall of Mists;

where the relevant excerpt parses to:

```
SV_PRODUCTION / "silver bars are in the hall of mists"
    NP_PRODUCTION / "silver bars"
        ...
    VP_PRODUCTION
        VERB_PRODUCTION => VU: are IS_TENSE -> is
            PREP_PRODUCTION => PU: in -> is-in
        NP_PRODUCTION / "the hall of mists"
            ...
```

or alternatively to make a more elaborate noun phrase, using a relative clause, where there is no active verb:

a woman who carries the silver bars;

```
SN_PRODUCTION / "woman who carries the silver bars"
    NP_PRODUCTION / "woman"
        ...
    VP_PRODUCTION
        VERB_PRODUCTION => VU: carries IS_TENSE -> carries
        NP_PRODUCTION / "the silver bars"
            ...
```

We sometimes also have to deal with English's use of "there" as a meaningless placeholder to stand for a missing noun phrase:

if there is an open door, ...

```
SV_PRODUCTION / "there is an open door"
    THERE_PRODUCTION
    VP_PRODUCTION
        VERB_PRODUCTION => VU: is IS_TENSE -> is
        NP_PRODUCTION / "an open door"
            ...
```

Note that we recognise "there" as a placeholder only in the subject position. As an object, it mainly functions in English as a pronoun referring to a specific place – "I go into the lobby. Julia is there." (This is a pronoun Inform doesn't try to understand. "There" as a subject can also function that way – "There is Julia." – but we won't try to disentangle such uses, since they don't arise in sentences with a conditional use: one would never write "if there is Julia" to mean "if Julia is in the lobby".)

§**2.** At any rate here is the SP-routine to parse such sentences. It needs to run quickly, but in principle also needs to try splitting the excerpt with the verb or preposition phrase at any intervening position. We optimise by trying to split only at words with a vocabulary bit identifying them as belonging to verb or preposition uses. Not every "of" is meant as a preposition, so there will still be plenty of false tries, but at least we can skip over "mists", "hall", and so on.

Note that we allow a preposition to be negated, as in this example:

a woman not in the Hall of Mists

(An author naming something which ends with "not" might have trouble here, but trouble is what such an author deserves.)

```
meaning_list *SP_sentence(int w1, int w2, int desired_outcome) {
    int bit_to_spot;
    begin_SP_routine(w1, w2);
    if (no_calls_to_SP_noun_phrase >= S_PARSER_COMPLEXITY_THRESHOLD) return NULL;
    LOGIF(S_GRAMMAR, "SP_sentence on <$W> seeking $p\n", w1, w2, desired_outcome);
    if ((desired_outcome != SN_PRODUCTION) && (desired_outcome != SV_PRODUCTION))
        internal_error("bad call to SP_sentence");
    if (desired_outcome == SN_PRODUCTION) bit_to_spot = PREPOSITION_MC;
    else bit_to_spot = CVERB_MC;
    for (i = w1; i<=w2; i++) if (vocab_test_flags(i, bit_to_spot)) {
        verb_usage *vu;
        int prep_only, w3 = i-1;
        if (desired_outcome == SN_PRODUCTION) prep_only = TRUE; else prep_only = FALSE;
        if [[i, w2 == which/who/that ... --> i, w2]] prep_only = FALSE;
        if (prep_only) {
            j = i; vu = regular_to_be;
            if ((i>w1) && [[word w3 == not]]) { vu = negated_to_be; w3--; }
            ⟨Attempt division into noun phrases for verb vu and position j 3⟩;
        } else {
            LOOP_OVER(vu, verb_usage) {
                j = vu_parse_text_against(i, w2, vu);
                if (j >= 0) ⟨Attempt division into noun phrases for verb vu and position j 3⟩;
            }
        }
    }
    return NULL;
    Accept: ml_set_text(ml, w1, w2);
    correct_S_subtree_for_adjectives(ml_down(ml));
    LOGIF(S_GRAMMAR, "SP_sentence on <$W> succeeds with:\n$m", w1, w2, ml);
    return ml;
}
```

The function SP_sentence is called from 5/candd and 5/candp.

§**3.** In English, the verb "to be" is considered "copular" because it acts to combine its subject and object: "X is 5", "Y is blue", and so on, refer to just one thing but make a statement about its nature or identity. Other verbs – "to carry", say – normally refer to two different things, at least in their most general forms: "X carries the briefcase".

The main complication here is "there". We must read

> there is a woman in the Dining Room

as if it read

> a woman is in the Dining Room

In other words, after "there is" or "there are", we should read a NP with a relative clause but break it up as a VP: "there is NP PU NP" must become "NP is PU NP", where PU is the prepositional usage. We do this only with the copular verb: although English occasionally uses "there" to fill the gap where a NP should be for other verbs ("there dwells in England a man who", and so on) the effect is archaic and not very useful. We don't allow "there exists" – its technical usage in mathematical logic is familiar to mathematical logicians, but the resulting text reads back strangely to anyone else, and "there is" means the same thing anyway.

In the case of "There is a button on the radio", or similar, a special placeholder leaf – `THERE_PRODUCTION` – is entered into the meaning list where the subject should be; the "object" of the sentence is required to be a description (as "a button on the radio" is).

⟨Attempt division into noun phrases for verb vu and position j 3⟩ ≡

```
int copular_flag = FALSE, there_flag = FALSE;
preposition_usage *preposition_used = NULL;
meaning_list *subject_part = NULL, *object_part = NULL;
if ([[w1, w3 == there]] &&
    (vu_get_meaning(vu) == a_is_b_predicate) &&
    (desired_outcome == SV_PRODUCTION)) there_flag = TRUE;
else subject_part = SP_noun_phrase(w1, w3, prep_only);
if (vu_get_meaning(vu) == a_is_b_predicate) {
    copular_flag = TRUE;
    ⟨Look for a preposition immediately after the copular verb 4⟩;
}
if ((prep_only == FALSE) || (preposition_used)) {
    if (object_part == NULL) object_part = SP_noun_phrase(j, w2, copular_flag);
    if (there_flag) {
        if ((object_part == NULL) ||
            (ml_production(ml_down(ml_down(object_part))) != DC_PRODUCTION))
            continue;
        subject_part = new_ml(THERE_PRODUCTION);
    }
    if ((object_part) && (subject_part))
        ⟨Construct the meaning list and invoke as a successful sentence 6⟩;
}
```

This code is used in §2.

§**4.** Some prepositions imply the player as object: "carried", in the sense of "to be carried", for instance – "The briefcase is carried". We fill the `object_part` subtree with a representation of the player-object for those.

⟨Look for a preposition immediately after the copular verb 4⟩ ≡

```
preposition_usage *pu;
LOOP_OVER(pu, preposition_usage) {
    k = pu_parse_text_against(j, w2, pu, TRUE);
    if (k >= 0) {
        if ((pu_implies_player(pu)) && (k > w2)) {
            object_part = new_ml(NP_PRODUCTION);
            ml_set_down(object_part, new_ml(VAL_PRODUCTION));
            ml_set_down(ml_down(object_part), new_ml(QUANTITY_MC));
            ml_set_meaning(ml_down(ml_down(object_part)), meaning_of_player);
        } else {
            object_part = SP_noun_phrase(k, w2, FALSE);
        }
        if (object_part) {
            preposition_used = pu;
            ⟨Allow a preposition to behave as a noun qualified by adjectives, in rare cases 5⟩;
            break;
        }
    }
}
```

This code is used in §3.

§**5.** The subject part is normally expected to include a noun: for instance,

> all of the opaque containers in the item

has as subject "all of the opaque containers" and object "the item", with "in" as the prepositional usage. But in rare cases the preposition is itself also noun-like in behaviour. Consider:

> all of the flame-retardant parts of the item

Here "parts of" is the preposition, but "parts" is also functioning as the noun governing the subject, or at least that is what the author intended. But Inform will have tried to parse "all of the flame-retardant" as subject, and returned `NULL` as a result. So we re-parse the subject, but allow it to contain a nounless adjective list this time.

This is surprisingly rarely necessary. In the whole test suite (as of July 2008) only a single sentence falls into this case.

⟨Allow a preposition to behave as a noun qualified by adjectives, in rare cases 5⟩ ≡

```
if ((pu_implicitly_behaves_as_noun(pu)) &&
    (subject_part == NULL) && (there_flag == FALSE))
    subject_part = SP_description(w1, w3, TRUE);
```

This code is used in §4.

§**6.** At this point there is no work remaining except to construct the tree: success is now certain.

⟨Construct the meaning list and invoke as a successful sentence 6⟩ ≡

```
meaning_list *VP_part = new_ml(VP_PRODUCTION);
ml_set_down(VP_part, new_ml(VERB_PRODUCTION));
ml_attach_data(ml_down(VP_part), STORE_POINTER_verb_usage(vu));
if (preposition_used) {
    ml_set_down(ml_down(VP_part), new_ml(PREP_PRODUCTION));
    ml_attach_data(ml_down(ml_down(VP_part)),
        STORE_POINTER_preposition_usage(preposition_used));
}
ml_set_right(ml_down(VP_part), object_part);
invoke_2(desired_outcome, subject_part, VP_part);
```

This code is used in §3.

§**7. Tidying up a sentence subtree.** This checks, in a paranoid sort of way, that a subtree is properly formed, and also makes one useful correction when it sees a wrong guess as to whether an adjective is meant as a noun.

```
void correct_S_subtree_for_adjectives(meaning_list *ml) {
    meaning_list *subject_phrase_subtree, *object_phrase_subtree, *verb_phrase_subtree;
    if (ml == NULL) internal_error("SV childless");
    if ((ml_right(ml) == NULL) && (ml_production(ml) != DC_PRODUCTION))
        internal_error("SV with only one child, which isn't a DC");
    subject_phrase_subtree = ml;
    verb_phrase_subtree = ml_right(ml);
    if (ml_down(verb_phrase_subtree) == NULL)
        internal_error("SV childless");
    if (ml_right(ml_down(verb_phrase_subtree)) == NULL)
        internal_error("SV only one child");
    object_phrase_subtree = ml_right(ml_down(verb_phrase_subtree));
    ⟨Modify the object from a noun to an adjective if the subject is also a noun 8⟩;
    if (ml_production(verb_phrase_subtree) != VP_PRODUCTION)
        internal_error("SV not a VP");
    if (ml_production(ml_down(verb_phrase_subtree)) != VERB_PRODUCTION)
        internal_error("child of SV not a verb");
}
```

The function correct_S_subtree_for_adjectives is called from 5/mlc.

§**8.** The following is used to correct the SV-subtree for something like "painting is orange" so that "orange" will be used not as a noun but as an adjective.

⟨Modify the object from a noun to an adjective if the subject is also a noun 8⟩ ≡

```
if ((ml_down(object_phrase_subtree)) && (ml_down(ml_down(object_phrase_subtree))) &&
    (ml_production(ml_down(ml_down(object_phrase_subtree))) == QUANTITY_MC) &&
    (ml_down(subject_phrase_subtree)) && (ml_down(ml_down(subject_phrase_subtree))) &&
    (ml_production(ml_down(ml_down(subject_phrase_subtree))) == DC_PRODUCTION)) {
    meaning_list *adjq = ml_down(ml_down(object_phrase_subtree));
    quantity *q = RETRIEVE_POINTER_quantity(em_data(ml_meaning(adjq)));
    if (qty_get_adjectival_phrase(q)) {
        ml_set_production(adjq, ADJECTIVE_MC);
        ml_set_meaning(adjq,
            em_new(ADJECTIVE_MC, 0,
                STORE_POINTER_adjectival_phrase(qty_get_adjectival_phrase(q))));
        ml_set_down(ml_down(object_phrase_subtree),
            new_ml(DC_PRODUCTION));
        ml_set_down(ml_down(ml_down(object_phrase_subtree)),
            new_ml(DC_ADJS_PRODUCTION));
        ml_set_down(ml_down(ml_down(ml_down(object_phrase_subtree))),
            new_ml(AL_PRODUCTION));
        ml_set_down(ml_down(ml_down(ml_down(ml_down(object_phrase_subtree)))), adjq);
    }
}
```

This code is used in §7.

§**9. Values as noun phrases.** It is very nearly true that the subject and object noun phrases are parsed by `SP_value`, which was given in "Type Expressions and Values". But there is a technicality: for reasons to do with ambiguities, `SP_value` needs to be able to try descriptions which involve only physical objects at one stage, and then later to try other descriptions.

Note that `SP_purely_physical_description` calls `SP_description` which in turn may, if there's a relative clause, call `SP_sentence` and thus `SP_noun_phrase`. Rather than passing endless copies of a flag down the call stack, we simply give `SP_noun_phrase` a global mode of operation.

```
int force_all_SP_noun_phrases_to_be_physical = FALSE;

meaning_list *SP_purely_physical_description(int w1, int w2) {
    meaning_list *ml;
    int s = force_all_SP_noun_phrases_to_be_physical;
    force_all_SP_noun_phrases_to_be_physical = TRUE;
    ml = SP_description(w1, w2, FALSE);
    force_all_SP_noun_phrases_to_be_physical = s;
    return ml;
}
```

The function SP_purely_physical_description is called from 5/tandv.

§**10.** The upshot of this is that `SP_noun_phrase` is only ever called in "purely physical mode" when it will later be called outside that mode in any event, and that therefore the set of excerpts matched by `SP_noun_phrase` genuinely is the same as that matched by `SP_value`.

```
meaning_list *SP_noun_phrase(int w1, int w2, int allow_nounless) {
    begin_SP_routine(w1, w2);
    LOGIF(S_GRAMMAR, "SP_noun_phrase on <$W>, %s nounless\n", w1, w2,
        allow_nounless?"allowing":"forbidding");
    if (no_calls_to_SP_noun_phrase++ >= S_PARSER_COMPLEXITY_THRESHOLD) return NULL;
    if (force_all_SP_noun_phrases_to_be_physical) {
        try_production(SP_description(w1, w2, allow_nounless));
    } else {
        try_production(SP_value(w1, w2));
    }
    on_success_invoke(NP_PRODUCTION);
}
```

§**11.** Finally, the following routine constructs an `SN_PRODUCTION` subtree for a noun-governed description or an adjective list. It is needed only for conditions ("if fixed in place scenery, ...") where the object referred to is understood from context.

```
meaning_list *SP_descriptive_NP(int w1, int w2) {
    begin_SP_routine(w1, w2);
    ml2 = SP_description(w1, w2, FALSE);
    if (ml2 == NULL) ml2 = SP_adjective_list(w1, w2);
    if (ml2) {
        if (ml_production(ml_down(ml2)) == SN_PRODUCTION) {
            ml = ml_down(ml2); goto Accept;
        }
        invoke_1(SN_PRODUCTION, ml2);
    }
    return NULL;
    Accept: ml_set_text(ml, w1, w2);
    return ml;
}
```

The function SP_descriptive_NP is called from 5/candp.

Conditions and Phrases 5/candp

Purpose

To parse the text of To... phrases, say phrases and conditions.

5/candp.§1-6 Conditions; §7-12 Command phrases; §13-18 Say phrases

---

Definitions

¶1. For the most part, the meaning-list scheme is modeless – no context is needed to determine what to do; all contextual work of interpretation is shifted later on, to the type-checking stage. But I have not quite been able to maintain this theoretically neat position. For one thing, "otherwise (P - phrase)" is handled as an independent phrase, and this perhaps questionable decision means that the meaning list converter needs to know whether there has just been an "if" or not – since "otherwise" can only be valid if there has. (To be fair, "else" is funny in all compiler grammars.)

```
int last_parsed_phrase_was_if = FALSE;
int last_parsed_phrase_opened_a_block = FALSE;
```

---

§**1. Conditions.** Inform's syntax would be purer if all conditions were the result of parsing `SP_sentence`. In general they are, but there two operations which enrich conditions, and three other sources of basic conditions: phrase options, phrases to decide, action patterns.

The reason a literal number is explicitly not allowed to be a condition is that if something is created called (say) "Room 62" then "62" might be read by `SP_description` as an abbreviated reference to that room.

```
meaning_list *SP_condition(int w1, int w2, int allow_bare_description) {
    begin_SP_routine(w1, w2);
    make_necessary_callings(w1, w2);
    if (paired_brackets(w1, w2)) return SP_condition(w1+1, w2-1, allow_bare_description);
    ⟨Allow two conditions to be joined with AND and OR 2⟩;
    ⟨Trim a stipulation on the chronology away from the condition 3⟩;
    if ((w1 == w2) && (vocab_test_flags(w1, NUMBER_MC))) return NULL;
    ⟨If inside a phrase, read the name of a phrase option as an implicit condition 4⟩;
    if (![[w1, w2 == there is/are ...]]) ⟨Try an invocation of a phrase-to-decide 5⟩;
    ⟨Read an action pattern as an implicit condition 6⟩;
    try_production(SP_sentence(w1, w2, SV_PRODUCTION));
    if (allow_bare_description) try_production(SP_descriptive_NP(w1, w2));
    if [[w1, w2 == there is/are ...]] ⟨Try an invocation of a phrase-to-decide 5⟩;
    on_success_invoke(COND_PRODUCTION);
}
```

The function SP_condition is called from 7/ttts and 13/test.

§**2.** Logical "and" and "or" are implemented directly right here, rather than being phrases defined in the Standard Rules.

⟨Allow two conditions to be joined with AND and OR 2⟩ ≡

```
int bl;
for (bl=0, i=w1; i<w2; i++) {
    int prd = 0, upto = i-1;
    if [[word i == OPENBRACKET]] bl++;
    if [[word i == CLOSEBRACKET]] bl--;
    if (bl > 0) continue;
    if [[word i == and]] prd = COND_AND_PRODUCTION;
    if [[word i == or]] prd = COND_OR_PRODUCTION;
    if ((prd != 0) && (upto>=w1)) {
        if ((upto>w1) && [[word upto == COMMA]]) upto--;
        if ((ml2 = SP_condition(w1, upto, FALSE)) &&
            (ml3 = SP_condition(i+1, w2, FALSE)))
            invoke_2(prd, ml2, ml3);
    }
}
```

This code is used in §1.

§**3.** This removes suffixes like "...for the third time" from a condition:

⟨Trim a stipulation on the chronology away from the condition 3⟩ ≡

```
time_period tp = parse_time_period(w1, w2);
int end_of_non_time_part = tp_is_valid(&tp);
if ((end_of_non_time_part >= w1) &&
    (ml2 = SP_condition(w1, end_of_non_time_part, allow_bare_description))) {
    ml3 = make_time_ml(tp);
    invoke_2(COND_PAST_PRODUCTION, ml2, ml3);
}
```

This code is used in §1.

§**4.** The option to use "not..." to test a phrase option negatively is parsed here only after the positive sense has been ruled out – people do sometimes create phrase options like "not printing anything" which begin with the word "not".

⟨If inside a phrase, read the name of a phrase option as an implicit condition 4⟩ ≡

```
if (phrase_being_compiled != NULL) {
    if ((i = ph_To_parse_phrase_option_used(phrase_being_compiled, w1, w2)) >= 0)
        try_production(make_option_ml(i, TRUE));
    if ([[w1, w2 == not ...]]
        && ((i = ph_To_parse_phrase_option_used(phrase_being_compiled, w1+1, w2)) >= 0))
        try_production(make_option_ml(i, FALSE));
}
```

This code is used in §1.

§**5.** As usual, we try to get better sensitivity to ambiguities by dividing the test for a phrase-to-decide into two, so that the following is used at a different point if the excerpt begins "there is" than if it doesn't. The point of this is that some phrases to decide have wording which coincides with a description, and in general the phrase should win, but in the case of "there is" we make the presumption that the author intends a sentence testing the existence of something.

⟨Try an invocation of a phrase-to-decide 5⟩ ≡

```
if ((ml2 = SP_excerpt(COND_PHRASE_MC, w1, w2)) != NULL)
    invoke_1(COND_PHRASE_PRODUCTION, ml2);
if ([[w1, w2 == not ...]] && (SP_excerpt(COND_PHRASE_MC, w1+1, w2))) {
    ml2 = SP_condition(w1+1, w2, FALSE);
    invoke_1(COND_NOT_PRODUCTION, ml2);
}
```

This code is used in §1.

§**6.** As a condition, an action pattern is implicitly considered as a test of what the current action is:

if examining an open door, ...

This wouldn't work so well for the past tense form:

if examined an open door, ...

because it seems too clunky as neither quite active nor passive. Who examined the open door? So Inform uses the following version instead:

if we have examined an open door, ...

thus adopting the "science we". Not very elegant, but the alternatives were difficult to parse. "We are" is allowed for consistency's sake, but does nothing, i.e., "we are taking" and "taking" are synonymous.

⟨Read an action pattern as an implicit condition 6⟩ ≡

```
action_pattern ap;
if [[w1, w2 == we have ...]] {
    ap = parse_action_pattern(w1+2, w2, HASBEEN_TENSE);
    if (ap_is_valid(&ap)) {
        if (ap_makes_callings(&ap)) {
            sentence_problem(_P_(C5PastActionCalled),
                "a description of an action cannot both refer to past "
                "history and also use '(called ...)'",
                "because that would require Inform in general to remember "
                "too much information about past events.");
        } else try_production(make_pastaction_ml(ap));
    }
}
if [[w1, w2 == we are ...]] {
    ap = parse_action_pattern(w1+2, w2, IS_TENSE);
    if (ap_is_valid(&ap)) try_production(make_action_ml(ap));
}
ap = parse_action_pattern(w1, w2, IS_TENSE);
if (ap_is_valid(&ap)) try_production(make_action_ml(ap));
```

This code is used in §1.

§**7. Command phrases.** The final clutch of SP-routines handle individual commands, written in their semicolon-divided list in the body of a rule or "To..." definition.

For instance, in the not very sensible rule:

```
Instead of jumping: now the score is 10; say "Greetings!" instead.
```

Inform will use `SP_command` to parse the text of the two commands in the rule body, with the results:

```
PHRASE_PRODUCTION
    {now # = VOID_PHRASE_MC} / "now the score is 10"
        UNPARSED_PRODUCTION / "the score is 10"
```

and, at greater length:

```
PHRASE_PRODUCTION
    INSTEAD_PRODUCTION
        SAY_PRODUCTION
            [1/22] {# = SAY_PHRASE_MC} / ""Greetings!""
                UNPARSED_PRODUCTION / ""Greetings!""
            ...
```

Note that `SP_command` passes the text with no attempt to judge whether the parameters of the phrase match; instead it records all possibilities at this point (case 1 of 22 is that a number is supplied, etc., etc.) for typechecking to resolve much later on.

```
meaning_list *SP_command(int w1, int w2) {
    begin_SP_routine(w1, w2);
    if (paired_brackets(w1, w2)) return SP_command(w1+1, w2-1);
    ⟨Police phrases beginning with else or otherwise 8⟩;
    ⟨Detect a switch case indication 9⟩;
    ⟨Detect the use of a To... phrase 10⟩;
    try_production(SP_rule_outcome(w1, w2));
    on_success_invoke(CMD_PRODUCTION);
}
```

The function SP_command is called from 7/ttts.

§**8.** "Else" or "otherwise" as a single word on its own is a divider in a long "if", and this has its own production (rather than being defined as a To... phrase in the Standard Rules). If a condition is added, though, we are in a more substantial construction which does indeed get defined in the Standard Rules. But we reject some obviously wrong cases now, to force a problem message to appear.

⟨Police phrases beginning with else or otherwise 8⟩ ≡

```
    if [[w1, w2 == else/otherwise ***]] {
        int c;
        if (w1 == w2) invoke_0(OTHERWISE_PRODUCTION);
        if ((last_parsed_phrase_was_if) &&
            (last_parsed_phrase_opened_a_block)) return NULL;                    to force error
        if ((last_parsed_phrase_was_if == FALSE) &&
            ((([[w1, w2 == else/otherwise if/unless ***]] == FALSE)
            || [[w1, w2 == else/otherwise if/unless ... begin]]
            || [[w1, w2 == ... COMMA ... : c]]))
                return NULL;                                                     to force error
        if [[w1, w2 == else/otherwise if/unless ... begin]]
            return NULL;                                                         to force error
    }
```

This code is used in §7.

§**9.** Switch cases are another form of divider, again with a production of their own rather than being defined as phrases in the SR.

⟨Detect a switch case indication 9⟩ ≡
```
    if [[w1, w2 == DASHDASH otherwise]]
        invoke_0(CASE_PRODUCTION);
    if ([[w1, w2 == DASHDASH ...]] && (ml2 = SP_value(w1+1, w2)))
        invoke_1(CASE_PRODUCTION, ml2);
```
This code is used in §7.

§**10.** This is the case we almost always fall into. Note that the phrase text can be prefixed or suffices with the "instead" keyword, but not both.

⟨Detect the use of a To... phrase 10⟩ ≡
```
    int v1 = -1, v2 = -1;
    if [[w1, w2 == instead ... --> v1, v2]] ;
    else if [[w1, w2 == ... instead --> v1, v2]] ;
    if (v1 >= 0) try_production(SP_command_phrase(v1, v2, TRUE));
    try_production(SP_command_phrase(w1, w2, FALSE));
```
This code is used in §7.

§**11.** Text substitutions ("say phrases") and void phrases have independent namespaces, as the following demonstrates.

```
meaning_list *SP_command_phrase(int w1, int w2, int instead_flag) {
    meaning_list *ml, *ml2, *ml4, *ml5;
    if ([[w1, w2 == say ...]] && (ml5 = SP_say_phrase(w1+1, w2))) {
        ml2 = new_ml(SAY_PRODUCTION); ml_set_down(ml2, ml5);
    } else {
        ml2 = SP_excerpt(VOID_PHRASE_MC + END_PHRASE_MC, w1, w2);
    }
    if (ml2) {
        if (instead_flag) {
            ml4 = ml2; ml2 = new_ml(INSTEAD_PRODUCTION); ml_set_down(ml2, ml4);
        }
        ml = new_ml(PHRASE_PRODUCTION); ml_set_down(ml, ml2);
        return ml;
    }
    return NULL;
}
```

§**12.** Rule outcomes are such a small linguistic category that they don't get a meaning code to themselves, so they share the miscellaneous category.

```
meaning_list *SP_rule_outcome(int w1, int w2) {
    meaning_list *ml = SP_excerpt(MISCELLANEOUS_MC, w1, w2);
    if ((ml) && (em_get_secondary_code(ml_meaning(ml)) == RULE_OUTCOME_SMC))
        return ml;
    return NULL;
}
```

§13. Say phrases. Uniquely, a say phrase takes the form of a comma-separated list, and is compiled by regarding each entry as an independent entry. Double-quoted text is literal if it contains no square brackets, but is expanded if it includes text substitutions in squares: thus the following routine ensures that

say "Look, [the noun] said."

is parsed as if it had read:

say "Look, ", the noun, " said."

The result is a flat list of `SAY_PHRASE_MC` leaves as siblings in the meaning list tree, one for each non-trivial part of the list. (We discard the empty text for efficiency's sake; the expansion of square bracket substitutions does sometimes produce these, so it is not as pointless an optimisation as it might look.)

```
meaning_list *SP_say_phrase(int w1, int w2) {
    int i;
    if ((w1<0) || (w2<w1)) return NULL;
    if ((i = is_word_intermediate_unbracketed(COMMA_V, w1, w2)) >= 0) {
        if ((compare_word_by_strcmp(w1, "\"\"")) && (i==w1+1))
            return SP_say_phrase(w1+2, w2);                          ignore empty initial string
        if ((compare_word_by_strcmp(w2, "\"\"")) && (i==w2-1))
            return SP_say_phrase(w1, w2-2);                          ignore empty final string
        ⟨Divide the say list at this first non-trivial comma 14⟩;
    }
    if ((w1 == w2) && (vocab_test_flags(w1, TEXTWITHSUBS_MC)))
        ⟨Unpack quoted text containing substitutions in square brackets and parse again 15⟩;
    return SP_excerpt(SAY_PHRASE_MC, w1, w2);
}
```

§14. Because we looked for commas left to right, the left-hand term is without commas, and will parse to a single leaf in the meaning list; the right-hand term may still be a comma-separated list.

⟨Divide the say list at this first non-trivial comma 14⟩ ≡

```
    meaning_list *ml = SP_say_phrase(w1, i-1);          otherwise take first term in comma list
    meaning_list *ml2 = SP_say_phrase(i+1, w2);                  and then recurse for the rest
    if (ml && ml2) {
        meaning_list *ml_last = ml;
        while (ml_right(ml_last)) ml_last = ml_right(ml_last);
        ml_set_right(ml_last, ml2);
        return ml;
    }
```

This code is used in §13.

§**15.** We ask the lexer to read the quoted text again, but this time in its mode which breaks up text at square brackets:

⟨Unpack quoted text containing substitutions in square brackets and parse again 15⟩ ≡

```
int lw1, lw2; char *p = lw_array[w1].lw_rawtext;
⟨Check that substitution does not contain suspicious punctuation 16⟩;
lw1 = lexer_wordcount;
feed_into_lexer(p, TRUE, FALSE);                    expand unquoted text substitution
lw2 = lexer_wordcount - 1;
feed_into_lexer(" . ", FALSE, FALSE);
for (i=lw1; i<=lw2; i++) if [[word i == FULLSTOP]]
    ⟨Issue problem message for unexpected punctuation in a substitution 17⟩;
return SP_say_phrase(lw1, lw2);                     ...and parse it
```

This code is used in §13.

§**16.** It would of course also be an error for the text to contain nested or mismatched square brackets, but if it did, then the text would not have been flagged as `TEXTWITHSUBS_MC` by the lexer.

⟨Check that substitution does not contain suspicious punctuation 16⟩ ≡

```
int k, sqb = 0;
for (k=0; p[k]; k++) {
    switch (p[k]) {
        case '[': sqb++; break;
        case ']': sqb--; break;
        case ':': if ((k>0) && (isdigit(p[k-1])) && (isdigit(p[k+1]))) break;
        case ';':
            if (sqb > 0) ⟨Issue problem message for unexpected punctuation in a substitution 17⟩;
            break;
        case ',':
            if (sqb > 0) ⟨Issue problem message for comma in a substitution 18⟩;
            break;
    }
}
```

This code is used in §15.

§**17.** So now just the problem messages:

⟨Issue problem message for unexpected punctuation in a substitution 17⟩ ≡

```
sentence_problem(_P_(C5TSWithPunctuation),
    "a substitution contains a '.', ':' or ';'",
    "which suggests that a close square bracket ']' may have gone astray.");
return NULL;
```

This code is used in §15,16,15,16,15,16.

§**18.** And the more specialised:

⟨Issue problem message for comma in a substitution 18⟩ ≡

```
sentence_problem(_P_(C5TSWithComma),
    "a substitution contains a comma ’,’",
    "which is against the rules, because ’say’ is a special phrase in "
    "which the comma divides items in a list of things to say, and so it "
    "loses its ordinary meanings. Because of this, no text substitution "
    "can contain a comma. "
    "(If you’re trying to use a value produced by a phrase with a phrase "
    "option - say ’the best route from A to B, using even locked doors’ - "
    "you’ll need to put this in a ’let’ variable first and then say that, "
    "or else define a better text substitution to do the job for you.)");
return NULL;
```

This code is used in §16.

Meaning List Conversions 5/mlc

Purpose

To convert meaning lists into specifications, for the use of the rest of NI.

Definitions

¶1. This final section of Chapter 5 is one of a pair of sections making up an interface layer between the S-parser (below) and the rest of Inform (above). The S-parser turned excerpts into a tree structure with both hierarchical depth and alternative readings, which was expansive and easy to generate but not easy to use. The rest of Inform wants to store essentially the same information in a single object (a "specification") with, in some cases, a proposition of predicate calculus attached. This section turns the meaning list into the specification part; the code which produces the proposition is the content of the "Sentence Conversions" section of Chapter 6.

¶2. Some notational conventions. Routines to convert ML subtrees to SPs are all given names in the form `*_to_spec` (and they are the only such routines in Inform). Only four of these are accessed from outside the interface layer, one for each of the four big concepts parsed by the S-parser:

(1) `TE_subtree_to_spec`, which converts a type expression subtree headed by `TE_PRODUCTION`.

(2) `VAL_subtree_to_spec`, which converts a value subtree headed by `VAL_PRODUCTION`.

(3) `CMD_subtree_to_spec`, which converts a command subtree headed by `CMD_PRODUCTION`.

(4) `COND_subtree_to_spec`, which converts a condition subtree headed by `COND_PRODUCTION`.

¶3. Given the nature of the code, it's prudent to make defensive assertions. (See also the meaning list conversion backtrace macro, in "Debugging Log", which is used to produce a meaningful backtrace if something goes wrong.) So:

```
define NOW_CONVERTING(pr)
    specification *spec = NULL;
    RECORD_MLC_BACKTRACE;
    if ((ml == NULL) || (ml_production(ml) != pr))
        internal_error("Non-" #pr " production");
define NOW_CONVERTING_SUBTREE(pr)
    NOW_CONVERTING(pr)
    if (ml_down(ml) == NULL)
        internal_error("Childless " #pr " production");
define NOW_CONVERTING_LEAF(pr)
    NOW_CONVERTING(pr)

---

§**1. Layout.** The code in this conversion layer is arranged in a top-down style as follows:

(I) The four externally used conversion routines described above.

(II) One routine for each possible node in the tree, responsible for converting that node and any subtree hanging from it, except for leaves corresponding to excerpt meanings.

(III) One routine for each possible leaf-node corresponding to an excerpt meaning.

(IV) More difficult code to handle sentences and phrase invocations, needed to support various node types in (II).

§**2. Level I: The four tops.** Command subtrees are all headed by `CMD_PRODUCTION`, which has four possible children, the interesting one being an excerpt-meaning leaf for a rulebook outcome.

Because we expect this to be called sequentially for each command in a rule body, we can preserve a little state from one call to the next: in particular, whether the previous call compiled an "if" or a block opening (detectable with an "else").

We have to be careful in case a phrase which doesn't open a block nevertheless causes another phrase, as here:

> while ... repeatedly if ...

where a "while" iterates a single phrase which happens to be an "if". So we change the sequential state only if we aren't being called in a nested way.

```
int PHRASE_subtree_to_type_nesting = 0;

specification *CMD_subtree_to_spec(meaning_list *ml) {
    if (ml == NULL) return new_UNKNOWN_spec();
    NOW_CONVERTING_SUBTREE(CMD_PRODUCTION);
    PHRASE_subtree_to_type_nesting++;
    if (PHRASE_subtree_to_type_nesting == 1) {
        int w1, w2;
        ml_get_text(ml, &w1, &w2);
        last_parsed_phrase_was_if = [[word w1 == if]];
        last_parsed_phrase_opened_a_block = [[word w2 == begin]];
    }
    ml = ml_down(ml);

                ⟨Give up with a problem message because variables can't have this KOV 50⟩;
            kov = spec_get_kind_of_value(spec);
        }
    }
    return kov;
}
```

§**48.** For instance, "X is a 54 that varies."

⟨Give up with a problem message because what must vary is constant 48⟩ ≡

```
    quote_source(1, current_sentence);
    handmade_problem(_P_(C5TypeCantVary));
    issue_problem_segment(
        "In %1, '%9' is a contradiction in terms, as this is something that "
        "cannot ever vary.");
    issue_problem_end();
    return kova(OBJECT_TY);                                    to prevent further errors
```

This code is used in §47.

§**49.** For instance, "X is an open door that varies."

⟨Give up with a problem message because what must vary is not maintainable 49⟩ ≡

```
quote_source(1, current_sentence);
handmade_problem(_P_(C5TypeUnmaintainable));
issue_problem_segment(
    "In %1, '%9' is not a kind of value which a variable can safely have, "
    "as it cannot be guaranteed that the contents will always meet "
    "this criterion.");
issue_problem_end();
return kova(OBJECT_TY);                                    to prevent further errors
```

This code is used in §47.

§**50.** For instance, "X is a condition that varies."

⟨Give up with a problem message because variables can't have this KOV 50⟩ ≡

```
handmade_problem(_P_(C5BadVariableKind1));
quote_source(1, current_sentence);
issue_problem_segment(
    "In %1, '%9' is not a kind of value which a variable is allowed to "
    "have. (See the table at the end of the Kinds index for a list of "
    "the kinds allowed.)");
issue_problem_end();
return kova(NUMBER_TY);                                    to prevent further errors
```

This code is used in §47.

§**51.** Secondly, there are three basic kinds of phrase: those used as commands (i.e., void procedures in C terms), those used as values (returning values other than true/false) and those used as conditions (returning true or false). These are stored in a way making basically the same use of a specification's references, so all three are handled by the following code.

The usage of a phrase is called an "invocation" of it, and sometimes more than one invocation appears, for two reasons: a "say" phrase can contain a sequence of invocations to follow, one after another; and sometimes it will only be clear at run-time which of several possible definitions is to apply, so the possibilities will all be invoked.

```
specification *general_phrase_to_spec(meaning_list *ml) {
    int instead_flag = FALSE, group_count = 0, mw1, mw2;
    specification *spec;
    RECORD_MLC_BACKTRACE;
    ml_get_text(ml, &mw1, &mw2);
    switch(ml_production(ml)) {
        case PHRASE_PRODUCTION: spec = new_TO_PHRASE_spec(); break;
        case COND_PHRASE_PRODUCTION: spec = new_PHRASE_TO_DECIDE_IF_spec(); break;
        case VALUE_PHRASE_PRODUCTION: spec = new_PHRASE_TO_DECIDE_VALUE_spec(); break;
        default: CHILD_UNCONVERTIBLE(TE_PRODUCTION);
    }
    if (mw1 >= 0) { spec->word_ref1 = mw1; spec->word_ref2 = mw2; }
    ml = ml_down(ml);
    if (ml_production(ml) == INSTEAD_PRODUCTION) { instead_flag = TRUE; ml = ml_down(ml); }
    switch(ml_production(ml)) {
        case SAY_PRODUCTION: ⟨Build the invocation list for a say phrase 53⟩; break;
```

```
        case END_PHRASE_MC: ⟨Make an end phrase, with no invocation list 56⟩; break;
        default: ⟨Build the invocation list for a non-say phrase 52⟩; break;
    }
    int len = length_of_invocation_list(spec_invocation_list(spec));
    if (len >= MAX_INVOCATIONS_PER_PHRASE)
        ⟨Issue overcomplicated phrase problem message 58⟩;
    if (len > 0) {
        ⟨Set the instead flag on invocations in the final group 57⟩;
        sort_spec_invocation_list(spec_invocation_list(spec));
    }
    return spec;
}
```

§**52.** Here there is just one invocation group, but it may contain multiple invocations, each produced from another node in the meaning list tree as we run sideways through the alternative readings.

⟨Build the invocation list for a non-say phrase 52⟩ ≡

```
    for (; ml; ml = ml_sideways(ml)) {
        phrase *ph;
        if (ml_meaning(ml) == NULL) internal_error("Blank phrase meaning");
        ph = RETRIEVE_POINTER_phrase(em_data(ml_meaning(ml)));
        if (parse_against_PHTD(spec, ph, ml) == FALSE) {
            coerce_spec_to_UNKNOWN(spec);
            break;
        }
    }
    group_count = 1;                                    since just one group was added
```

This code is used in §51.

§**53.** The case of a say phrase is more interesting, because now there are multiple invocation groups, identified by numbers counting upwards from 0. Each group corresponds to a rightwards sibling in the meaning tree; each of the nodes can have sideways siblings too, though, which is why each group can have multiple invocations in it, one for each sideways alternative.

We convert each group in succession.

⟨Build the invocation list for a say phrase 53⟩ ≡

```
    for (ml=ml_down(ml); ml; group_count++, ml=ml_right(ml)) {
        specification* this_group = new_TO_PHRASE_spec();
        ⟨Fill references with the single invocation group at ML 54⟩;
        ⟨Copy the new group's references to the tail of SP, setting their group numbers 55⟩;
    }
```

This code is used in §51.

§**54.** Each single group is handled much as in the "non-say" case.

⟨Fill references with the single invocation group at ML 54⟩ ≡
```
meaning_list *ml2;
for (ml2 = ml; ml2; ml2 = ml_sideways(ml2)) {
    phrase *ph = RETRIEVE_POINTER_phrase(em_data(ml_meaning(ml2)));
    if (parse_against_PHTD(this_group, ph, ml2) == FALSE) {
        coerce_spec_to_UNKNOWN(this_group);
        break;
    }
}
```

This code is used in §53.

§**55.**

⟨Copy the new group's references to the tail of SP, setting their group numbers 55⟩ ≡
```
INVOCATION_VARIABLE(inv);
LOOP_THROUGH_INVOCATION_LIST(inv, spec_invocation_list(this_group))
    inv_set_group(inv, group_count);
append_invocation_list(spec_invocation_list(spec), spec_invocation_list(this_group));
```

This code is used in §53.

§**56.** An end phrase, like "end if", carries with it a reference to what is ending ("if", in this case).

⟨Make an end phrase, with no invocation list 56⟩ ≡
```
spec = new_END_BLOCK_spec(RETRIEVE_POINTER_phrase(em_data(ml_meaning(ml))));
```

This code is used in §51.

§**57.** It's important to set the instead flag only in the final group of invocations, or else (if set) it will prevent later groups from having any effect. Consider:

```
instead say "The score is ", score, "."
```

The effect of "instead" is to halt the current rule, so if the instead flag were set for every invocation then the rule would halt after only "The score is " has been printed (that being the effect of group 0: groups 1 and 2 would have no effect). Instead, in this example, only group 2 is flagged.

⟨Set the instead flag on invocations in the final group 57⟩ ≡
```
INVOCATION_VARIABLE(inv);
LOOP_THROUGH_INVOCATION_LIST(inv, spec_invocation_list(spec))
    if (inv_get_group(inv) == group_count-1)
        inv_set_instead_flag(inv, instead_flag);
```

This code is used in §51.

§**58.** This is in practice only ever experienced for long say phrases in a situation where many kinds of value have been created, so that "say V" for a value V is heavily ambiguous – pumping up the number of invocations generated. The limit is intentionally set high, but one day it should perhaps be removed altogether.

⟨Issue overcomplicated phrase problem message 58⟩ ≡

```
    log_invocation_list(spec_invocation_list(spec));
    coerce_spec_to_UNKNOWN(spec);
    spec->word_ref1 = current_sentence->word_ref1; spec->word_ref2 = current_sentence->word_ref2;
    quote_source(1, current_sentence);
    handmade_problem(_P_(C5OverlongSay));
    issue_problem_segment(
        "In %1, the phrase being constructed is just too "
        "long and complicated, and will need to be simplified. (This "
        "sometimes happens with a 'say', or a piece of text, containing "
        "many text substitutions in succession: if so, it may be worth "
        "defining some more powerful text substitutions - for instance "
        "writing 'To say super-duper: ...', giving the gory details, "
        "and then using the single substitution '[super-duper]' in the "
        "original phrase.");
    issue_problem_end();
    return spec;
```

This code is used in §51.

§**59.** Various forms of the DC conversion boil down to this: we have one or both of a noun (say "door") and an adjective list qualifying it (say "open fixed in place"). We need to combine these into a single specification.

```
specification *qualified_noun_to_spec(meaning_list *adjlist, meaning_list *noun) {
    specification *spec = NULL;
    if (noun) {
        switch (ml_production(noun)) {
            case WORLD_OBJECT_MC:
                ⟨Create type for a physical headword 60⟩;
                break;
            case TYPE_PRODUCTION:
                ⟨Create type for an abstract headword 61⟩;
                break;
            default: internal_error("Unknown noun production type");
        }
    } else spec = new_DESCRIPTION_spec();
    if (adjlist) ⟨Incorporate the adjectives from the list 62⟩;
    return spec;
}
```

§**60.** The noun is usually going to be a common noun (a kind or kind of value), but not always, because Inform allows proper nouns which represent objects to be qualified by adjectives ("the open Marble Door"). Note that we treat both of the possible noun productions differently from their treatment as values, though in the case of a specific object name unqualified by adjectives (just "Marble Door", say) the result does agree and is not a `DESCRIPTION` spec.

⟨Create type for a physical headword 60⟩ ≡

```
world_object *wo = disambiguate_world_object(noun, FALSE);
if (wo == NULL) internal_error("no WO follows disambiguation");
else if (wo->kind_flag) {
    spec = new_DESCRIPTION_spec();
    spec_set_described_kind(spec, wo);
} else if (adjlist) {
    spec = new_DESCRIPTION_spec();
    spec_set_described_object(spec, wo);
} else
    spec = world_object_to_OBJECT_spec(wo);
```

This code is used in §59.

§**61.** The abstract value case is simpler, since here only kinds of value are allowed (and there are no proper nouns).

⟨Create type for an abstract headword 61⟩ ≡

```
kind_of_value *kov = spec_get_kind_of_value(ml_get_attached_spec(noun));
spec = new_DESCRIPTION_spec();
spec_set_described_kov(spec, kov);
```

This code is used in §59.

§**62.**

⟨Incorporate the adjectives from the list 62⟩ ≡

```
meaning_list *ml = adjlist;
int mw1, mw2; ml_get_text(ml, &mw1, &mw2);
if (ml_production(ml) != AL_PRODUCTION) internal_error("Non-AL production");
ml = ml_down(ml);
if (ml == NULL) internal_error("Empty AL production");
while (ml) {
    adjective_list_entry *ale = adj_to_adjective_list_entry(ml);
    add_to_adjective_list(ale, spec);
    ml = ml_right(ml);
}
```

This code is used in §59.

§**63.** A utility to convert what is either an adjective node, or a negation marker with its adjective node as only child, into an entry suitable for a SP's list.

```
adjective_list_entry *adj_to_adjective_list_entry(meaning_list *ml) {
    adjective_list_entry *ale = NULL;
    int negate = FALSE;
    meaning_list *ml2 = ml;
    RECORD_MLC_BACKTRACE;
    RetrySwitch:
    switch(ml_production(ml2)) {
        case ADJ_NOT_PRODUCTION:
            ml2 = ml_down(ml); negate = TRUE;
            goto RetrySwitch;
        case ADJECTIVE_MC:
            ale = new_adjective_list_entry(
                RETRIEVE_POINTER_adjectival_phrase(em_data(ml_meaning(ml2))),
                    (negate)?FALSE:TRUE);
            break;
        default: internal_error("Unexpected AL production");
    }
    return ale;
}
```

§**64.** The last difficult case to handle is that of sentence-like constructions.

```
specification *general_sentence_to_spec(meaning_list *ml) {
    specification *spec;
    meaning_list *subject_noun_phrase = NULL, *verb_phrase = NULL;
    verb_usage *vu = NULL; preposition_usage *pu = NULL;
    int mw1, mw2; ml_get_text(ml, &mw1, &mw2);
    RECORD_MLC_BACKTRACE; s_subtree_error_set_position(ml);
    LOGIF(S_GRAMMAR, "general_sentence_to_spec applied to:\n$m", ml);
    ⟨Reconstruct a bare description as a sentence with an implied absent subject 65⟩;
    ⟨Check that the top structure of the tree is in order, and obtain the verb 66⟩;
    switch(ml_production(ml)) {
        case SN_PRODUCTION:
            spec = new_DESCRIPTION_spec();
            spec_set_proposition(spec, S_subtree_to_proposition(ml, NULL));
            s_subtree_accumulate_headword(spec, ml);
            break;
        case SV_PRODUCTION:
            spec = new_TEST_PROPOSITION_spec(S_subtree_to_proposition(ml, NULL));
            break;
        default: CHILD_UNCONVERTIBLE(VAL_PRODUCTION);
    }
    if (mw1 >= 0) { spec->word_ref1 = mw1; spec->word_ref2 = mw2; }
    if (vu_get_tense_used(vu) != IS_TENSE) ⟨Attach tense marker to the SP 67⟩;
    return spec;
}
```

§**65.** For instance, "if an open door" can contain a valid condition generating an SV-subtree: the implied subject is whatever is being discussed (the I6 `self` object, in practice) and the implied verb is "is", in the present tense.

⟨Reconstruct a bare description as a sentence with an implied absent subject 65⟩ ≡

```
if (ml_right(ml_down(ml)) == NULL) {
    switch(ml_production(ml_down(ml))) {
        case DC_PRODUCTION: {
            meaning_list *ml2 = ml_down(ml);
            ml_set_down(ml, new_ml(NP_PRODUCTION));
            ml_set_down(ml_down(ml), new_ml(ABSENT_SUBJECT_PRODUCTION));
            ml_set_right(ml_down(ml), new_ml(VP_PRODUCTION));
            verb_phrase = ml_right(ml_down(ml));
            ml_set_down(verb_phrase, new_ml(VERB_PRODUCTION));
            ml_set_right(ml_down(verb_phrase), ml2);
            ml_attach_data(ml_down(verb_phrase),
                STORE_POINTER_verb_usage(regular_to_be));
            ml_set_production(ml, SV_PRODUCTION);
            correct_S_subtree_for_adjectives(ml_down(ml));
            break;
        }
        default:
            s_subtree_error("only one child with no assumed subject");
    }
}
```

This code is used in §64.

§**66.** Having performed that manoeuvre, we can be certain that the top of the tree has the standard form, but we check it anyway.

⟨Check that the top structure of the tree is in order, and obtain the verb 66⟩ ≡

```
subject_noun_phrase = ml_down(ml);
verb_phrase = ml_right(ml_down(ml));
if (ml_down(verb_phrase) == NULL) s_subtree_error("VP childless");
if (ml_right(ml_down(verb_phrase)) == NULL)
    s_subtree_error("VP only one child");
if (ml_production(verb_phrase) != VP_PRODUCTION)
    s_subtree_error("VP not a VP");
if (ml_production(ml_down(verb_phrase)) != VERB_PRODUCTION)
    s_subtree_error("child of VP not a verb");
vu = RETRIEVE_POINTER_verb_usage(ml_get_attached_data(ml_down(verb_phrase)));
if (vu == NULL) s_subtree_error("verb null");
if (ml_down(ml_down(verb_phrase))) {
    if (ml_production(ml_down(ml_down(verb_phrase))) != PREP_PRODUCTION)
        s_subtree_error("child of VERB not a PREP");
    pu = RETRIEVE_POINTER_preposition_usage(
        ml_get_attached_data(ml_down(ml_down(verb_phrase))));
    if (pu == NULL) s_subtree_error("PREP null");
}
```

This code is used in §64.

§**67.** It's in order to detect past tense usage that we needed to extract the VU above.

⟨Attach tense marker to the SP 67⟩ ≡
```
    if (ml_production(ml) == SN_PRODUCTION) {
        sentence_problem(_P_(C5DescSubordinatePast),
            "subordinate clauses have to be in the present tense",
            "so 'the Black Door was open' is fine, but not 'something which "
            "was open'. Only the main verb can be in the past tense.");
    } else if (prop_detect_locals(spec_get_proposition(spec)) > 0) {
        sentence_problem(_P_(C5DescLocalPast),
            "conditions written in the past tense cannot refer to "
            "temporary values",
            "because they have no past. For instance, the name given in a "
            "'repeat...' can't be talked about as having existed before.");
    } else spec_attach_tense(spec, vu_get_tense_used(vu));
```
This code is used in §64.

§**68.** The idea of "accumulation" is to extract the maximum information we can about the headword noun to which a subtree refers – what its kind is, and what adjectives it satisfies. We will never get all of the information this way – "the open containers which have been in lighted rooms" cannot be summed up so simply, and has to be accumulated merely as "open containers". But we want to extract the maximum amount that we can, since this improves the fine sorting of rules by applicability.

```
void s_subtree_accumulate_headword(specification *spec,
    meaning_list *s_ml) {
    world_object *subtree_wo;
    specification *subtree_spec;
    LOGIF(S_GRAMMAR, "s_subtree_accumulate_headword applied to:\n$m", s_ml);
    if (ml_production(s_ml) == DC_PRODUCTION)
        subtree_spec = DC_subtree_to_spec(ml_down(s_ml), FALSE);
    else
        subtree_spec = NP_subtree_to_spec(ml_down(s_ml));
    subtree_wo = wo_of_CONSTANT_OBJECT_if_any(subtree_spec);
    if (subtree_wo) {
        restrict_DESCRIPTION_domain(spec, subtree_wo);
        ⟨Also accumulate descriptive matter from a relative clause applying to this 70⟩;
        return;
    }
    if (species_is(subtree_spec, DESCRIPTION_SPC)) {
        ⟨Copy all references over from the subtree SP to the headword SP 69⟩;
        if (spec_get_described_object(subtree_spec))
            restrict_DESCRIPTION_domain(spec, spec_get_described_object(subtree_spec));
        else if (spec_get_described_kind(subtree_spec))
            restrict_DESCRIPTION_domain(spec, spec_get_described_kind(subtree_spec));
        ⟨Also accumulate descriptive matter from a relative clause applying to this 70⟩;
        return;
    }
    if ((species_is(subtree_spec, CONSTANT_SPC)) ||
        (spec_get_storage_form(subtree_spec) == LOCAL_VARIABLE_SPC) ||
        (spec_get_storage_form(subtree_spec) == NONLOCAL_VARIABLE_SPC))
        return;
    coerce_spec_to_UNKNOWN(spec);
}
```

§**69.** These references all represent adjectives which the subtree SP is required to satisfy, so we copy them over to the SP being accumulated.

⟨Copy all references over from the subtree SP to the headword SP 69⟩ ≡
```
adjective_list_entry *tr_from;
LOOP_THROUGH_ADJECTIVE_LIST(tr_from, subtree_spec) {
    adjective_list_entry *tr_new = copy_adjective_list_entry(tr_from);
    add_to_adjective_list(tr_new, spec);
}
```

This code is used in §68.

§**70.** We use recursion to continue accumulating anything we can find in a relative clause, provided it is connected by the copular verb and in the present tense. The effect is that, e.g., "containers which are open" can be simplified into the simpler description "open containers": likewise "things which are people who are women" would collapse to "people who are women" and then "women", the noun at the head specialising from things to people to women.

⟨Also accumulate descriptive matter from a relative clause applying to this 70⟩ ≡
```
if (ml_production(s_ml) == SN_PRODUCTION) {
    verb_usage *vu;
    meaning_list *verb_phrase = ml_right(ml_down(s_ml));
    if (verb_phrase == NULL) s_subtree_error("no VP");
    if (ml_down(verb_phrase) == NULL) s_subtree_error("VP childless");
    if (ml_right(ml_down(verb_phrase)) == NULL)
        s_subtree_error("VP only one child");
    if (ml_production(verb_phrase) != VP_PRODUCTION)
        s_subtree_error("VP not a VP");
    if (ml_production(ml_down(verb_phrase)) != VERB_PRODUCTION)
        s_subtree_error("child of VP not a verb");
    vu = RETRIEVE_POINTER_verb_usage(ml_get_attached_data(ml_down(verb_phrase)));
    if (vu == NULL) s_subtree_error("verb null");
    if ((vu_get_meaning(vu) == a_is_b_predicate) &&
        (ml_down(ml_down(verb_phrase)) == NULL) &&
        (vu_get_tense_used(vu) == IS_TENSE)) {
        s_subtree_accumulate_headword(spec, ml_right(ml_down(verb_phrase)));
    }
}
```

This code is used in §68.

§**71.** That completes the interface layer handling meaning list conversions, except for the difficult part: the routine `S_subtree_to_proposition`, found in Chapter 6, which translates a sentence subtree to a proposition. It is time to leave the world of parsing behind for a while, and enter the less textual domain of predicate calculus.

6 Predicate Calculus

`6/iprc`: *Introduction to Predicate Calculus.w* An exposition of the form of predicate calculus used by Inform.

`6/term`: *Terms.w* Terms are the representations of values in predicate calculus: variables, constants or functions of other terms.

`6/aprop`: *Atomic Propositions.w* To build and modify atoms, the syntactic pieces from which propositions are built up.

`6/prop`: *Propositions.w* To build and modify structures representing propositions in predicate calculus.

`6/vars`: *Binding and Substitution.w* To substitute constants into propositions in place of variables, and to apply quantifiers to bind any unbound variables.

`6/pform`: *Propositional Form.w* The first of the three sources of propositions to conjure with: those which arise by conversion of existing data, in the form of type specifications.

`6/treec`: *Tree Conversions.w* The second of the three sources of propositions to conjure with: those which arise from subtrees constructed by the A-parser.

`6/sconv`: *Sentence Conversions.w* The third of the three sources of propositions to conjure with: those which arise by the parsing of complex sentence trees in the S-grammar.

`6/simp`: *Simplifications.w* A set of operations each of which takes a proposition and either leaves it unchanged or replaces it with a simpler one logically equivalent to the original.

`6/tcpr`: *Type Check Propositions.w* Predicate calculus is a largely symbolic exercise, and its rules of working tend to assume that all predicates are meaningful for all terms: this means, for instance, that "if blue is 14" is likely to make a well-formed sentence in predicate calculus. In this section we reject such propositions on the grounds that they violate type-checking requirements on relations – in this example, the equality relation.

`6/equal`: *The Equality Relation.w* To define that prince among predicates, the equality relation.

`6/asp`: *Assert Propositions.w* To declare that a given proposition is a true statement about the state of the world when play begins.

`6/sch`: *I6 Schemas.w* To create, and later expand upon, short prototypes of I6 syntax for such run-time tasks as the setting, unsetting or testing of a relation.

`6/atoms`: *Compile Atoms.w* In this section, given an atom of a proposition we compile I6 code as required for any of three possible outcomes: (i) to test whether it is true, (ii) to make it henceforth true, or (iii) to make it henceforth false.

`6/defer`: *Deciding to Defer.w* To decide whether a proposition can be compiled immediately, in the body of the current routine, or whether it must be deferred to a routine of its own, which is called from the current routine.

`6/cind`: *Cinders and Deferrals.w* To compile terms, having carefully preserved any constants which might have been lost in the process of deferring a proposition (such tricky constants being called "cinders").

`6/cdefp`: *Compile Deferred Propositions.w* To compile the I6 routines needed to perform the tests or tasks deferred as being too difficult in their original contexts.

Introduction to Predicate Calculus 6/iprc

Purpose

An exposition of the form of predicate calculus used by Inform.

---

§**1.** "Again and again Haddon thought he had found the key to the strange writings, but always he was disappointed. And then one day – he was an old man of seventy now – he fed a trial programme into his computer, and for the first time a translated sentence was delivered – his life-long task was rewarded. Yes, but for the fact that one man had been prepared to devote every spare hour of his life to solving the riddle, the amazing story of the Trigan Empire would never have been given to the world. WHAT FOLLOWS IS THAT STORY." (*The Rise and Fall of the Trigan Empire*, 1965)

§**2. Why predicate calculus.** Most attempts to codify the meaning of sentences in any systematic way involve predicate calculus, and most people generally seem to agree that linguistic concepts (like verbs, adjectives, and determiners) correspond uncannily well with logical ones (like binary predicates, unary predicates, and quantifiers). Since today's mathematical logic has its roots in work on the philosophy of language (chiefly by Frege and Wittgenstein), this is not altogether a coincidence. All the same, it is striking how good the fit is, considering that human language is so haphazard and logic so regular.

At any rate Inform goes along with this consensus, and converts the difficult passages in its source text into mathematical propositions – lines written in logical notation. This is useful partly as a well-defined way to store complicated meanings inside the program, but also because these propositions can then be simplified by logical rules. We can change their form so long as we do not change their meaning, in the hope of finding ways to carry out the same tasks but more efficiently than a simple-minded reading of the text would suggest.

There are four main tasks to perform:

(a) Building propositions from the other Inform data structures;

(b) Simplifying, rearranging and type-checking propositions;

(c) Asserting that certain propositions are true at the start of play;

(d) Compiling certain propositions to I6 code which can test them, make them true, or make them false.

In this chapter, we take these tasks in order. Because it contains all of Inform's predicate calculus lore in one place, it necessarily contains little pieces of algorithms from other chapters: a piece of the type-checker, a piece of the code for asserting the initial state of play, and so on. Well: but the overlap had to go somewhere.

§**3.** A glimpse of Inform's inner workings can be made by writing a test instruction like so:

```
Laboratory is a room. The box is a container.

Test sentence (internal) with a man can see the box in the Laboratory.
```

At the start of play, the compiled story file will print a textual form of the proposition in predicate calculus which that became:

```
1. a man can see the box in the Laboratory
[ Exists x : man(x) & thing('box') & is('laboratory', ContainerOf('box')) & can-see(x, 'box') ]
x - object.
```

(The `intest` test case `Calculus` runs about 200 sentences like this.) One can similarly "Test description (internal) with..." for any description, such as "animals which are in lighted rooms".

§**4. Formal description.** There are many flavours of predicate calculus, and though they behave in broadly similar ways, the details vary in practice. Inform's calculus is unusual in several respects, so here is its definition.

The terms "constant", "variable" and "function" below are used in their predicate-calculus senses, *not* their Inform ones. In the excerpt

> a container in the location of Nicole contains the second noun

the text "location of Nicole" is a phrase deciding an object – a function – and "the second noun" is an object that varies – a variable. But if we are looking at the sentence only for its logical meaning, we have to forget about the passage of time and think about what the sentence means at any single moment. "Location of Nicole" and "the second noun" are both fixed, in this instant; the only thing which varies is the identity of the possible container, because we might have to look at hundreds of different containers to see if the sentence is true. One logical translation might be

$$\exists x : \mathit{container}(x) \wedge \mathit{in}(x, C_1) \wedge \mathit{in}(C_2, x)$$

where C_1 and C_2 are constants ("location of Nicole" and "second noun" respectively), while the only variable is x, the mysterious container. (The symbol $\exists$ means "there exists".) Because objects move around in play, and C_1 and C_2 have different values at different moments, this sentence is sometimes true and sometimes false. But its *meaning* does not change.

§**5.** The propositions in our predicate calculus are those which can be made using the following ingredients and recipes.

1. There are 26 variables, which we print to the debugging log as `x`, `y`, `z`, `a`, `b`, `c`, ..., `w`.

2. The constants are specifications with family `VALUE` – that is, all literal constants, variables, list and table entries, or phrases which decide values.

3. A "predicate" P is a statement $P(a, b, c, ...)$ which is either true or false for any given combination $a, b, c, ...$ The "arity" of a predicate is the number of terms it looks at. There is speculative talk of allowing higher-order predicates in future (and Inform's data structures have been built with one eye on this), but for now we use only unary predicates $U(x)$ or binary predicates $B(x, y)$, of arity 1 and 2 respectively. The predicates in our calculus are as follows:

(a) The special binary predicate $\mathit{is}(x, y)$, true if and only if $x = y$.
(b) Every kind K (of value or of object) corresponds to a unary predicate $K(x)$.
(c) Every state of an either/or property corresponds to a unary predicate, e.g., $\mathit{open}(x)$.
(d) Every possible value of an enumerated kind of value which corresponds to a property similarly corresponds to a unary predicate: e.g., if we have defined "colour" as a kind of value and made it a property of things, then $\mathit{green}(x)$, $\mathit{red}(x)$, and $\mathit{blue}(x)$ might all be unary predicates.
(e) Every adjectival phrase, to which a definition has been supplied in the source, likewise produces a unary predicate: for example, $\mathit{visible}(x)$.
(f) An adjective given a definition which involves a threshold for a numeric property also produces a binary predicate for its comparative form: for instance, a definition for "tall" gives not only a unary predicate $\mathit{tall}(x)$ (as in (e) above) but also a binary predicate $\mathit{taller}(x, y)$.
(g) A special unary predicate $\mathit{everywhere}(x)$ which asserts that the backdrop x can be found in every room.
(h) Each table column name C gives rise to a binary predicate $\mathit{listed\text{-}in\text{-}C}(x, y)$, which tests whether value x is listed in the C column of table y. (This looks as if it should really be a single ternary predicate, but since we never need to quantify over choice of column, nothing would be gained by that.)
(i) Every value property P gives rise to a binary predicate $\mathit{same\text{-}P\text{-}value}(x, y)$, testing whether objects x and y have the same value of P. (Again, it would not be useful to quantify over P.)
(j) Every direction D gives rise to a binary predicated $\mathit{mapped\text{-}D}(x, y)$, testing whether there is a map connection from x to y in direction D.
(k) Each new relation defined in the source text is a binary predicate.

(l) The basic stock of spatial containment relations built into Inform – $in(x, y)$, $on(x, y)$, etc. – are similarly binary predicates.

(m) If P is a binary predicate present in Inform then so automatically is its "reversal" R, defined by $R(x, y)$ if and only if $P(y, x)$. For instance, the existence of *carries*(x, y) ensures that we also have *carried-by*(x, y), its reversal. The equality predicate $x = y$ is its own reversal, but all other binary predicates are formally different from their reversals, even if they always mean the same in practice. (The reversal of *same-carrying-capacity-as*(x, y) is true if and only if the original is true, but we regard them as different predicates just the same.)

4. If a binary predicate B has the property that for any x there is at most one y such that $B(x, y)$ (for instance, *carried-by* has this property) then we write f_B for the function which maps x to either the unique value y such that $B(x, y)$, or else to a zero value. (In the case where y is an object, we interpret this as "nothing", which for logical purposes is treated as if it were a valid object, so that f_B maps the set of objects to itself.) Another way of saying this is that f_B, if it exists, is defined by:

$$B(x, y) \Leftrightarrow y = f_B(x).$$

These are the only functions allowed in our predicate calculus, and they are always functions of just one variable.

5. A "quantifier" Qx is a logical expression for the range of values of a given variable x: for instance, $\forall x$ (read "for all x") implies that x can have any value, whereas $\exists x$ (read "there exists an x") means only that at least one value works for x. In our calculus, we allow not only these quantifiers but also the following generalised quantifiers, where n is a non-negative integer:

(a) The quantifier $V_{=n}x$ – meaning "for exactly n values of x".
(b) The quantifier $V_{\geq n}x$ – meaning "for at least n values of x".
(c) The quantifier $V_{\leq n}x$ – meaning "for at most n values of x".
(d) The quantifier $P_{\geq n}x$ – meaning "for at least a percentage of n values of x".
(e) The quantifier $P_{\leq n}x$ – meaning "for at most a percentage of n values of x".

Note that "for all x" corresponds to $P_{\geq 100}x$, and "there exists x" to $V_{\geq 1}x$, so the above scheme does indeed generalise the standard pair of quantifiers $\forall$ and $\exists$.

6. A "term" must be a constant, a variable or a function $f_B(t)$ of another term t. So x, "Miss Marple", $f_B(x)$ and $f_A(f_B(f_C(6)))$ are all examples of terms. We are only allowed to apply functions a finite number of times, so any term has the form:

$$f_{B_1}(f_{B_2}(...f_{B_n}(s)...))$$

for at most a finite number n of function usages (possibly $n = 0$), where at bottom s must be either a constant or a variable.

7. A proposition is defined by the following rules:

(a) The empty expression is a proposition. This is always true, so in these notes it will be written $\top$.
(b) For any unary predicate U and any term t, $U(t)$ is a proposition.
(c) For any binary predicate B and any terms s, t, $B(s, t)$ is a proposition.
(d) For any proposition ϕ, the negation $\neg(\phi)$ is a proposition. This is by definition true if and only if ϕ is false.
(e) For any propositions ϕ and ψ, the conjunction $\phi \wedge \psi$ – true if and only if both are true – is a proposition so long as it is well-formed (see below).
(f) For any variable v, the quantifier $\exists v$ is a proposition.
(g) For any variable v, any quantifier Q other than $\exists$, and any proposition ϕ in which v is a "free" variable (see below), $Qv \in \{v \mid \phi(v)\}$ is a proposition. The set denotes all possible values of v matching the condition $\phi(v)$, and this specifies the range of the quantifier.

§**6.** Note that there are two ways in which propositions can appear in brackets in a bigger proposition: negation (d), and specifying a quantification domain (g). We sometimes call the bracketed part a "subexpression" of the whole.

In particular, note that – unusually – we do not bracket quantification itself. Most definitions would say that given v and a proposition $\phi(v)$, we can form $\exists v : (\phi(v))$ – in other words that quantification is a way to modify an already created proposition, but that $\exists v$ is not a proposition in its own right, just as $\neg$ is not a proposition. Inform disagrees. Here $\exists v$ is a meaningful sentence: it means "an object exists". We can form "there is a door" by rule (e), conjoining $\exists x$ and $door(x)$ to form $\exists x : door(x)$. (As a nod to conventional mathematical notation, we write a colon after a quantifier instead of a conjunction sign $\wedge$. But Inform stores it as just another conjunction.)

We *do* bracket the domain of quantification. Most simple predicate calculuses (predicates calculus?) have no need, since their only quantifiers are $\forall$ and $\exists$, and there is a single universe set from which all values are drawn. But in Inform, some quantifiers range over doors, some over numbers, and so on. In most cases, a quantifier must specify its domain. For example,

$$\forall x \in \{x \mid number(x)\} : even(x)$$

("all numbers are even" – false, of course) specifies the domain of $\forall$ as the set of all x such that $number(x)$. $\exists$ is the one exception to this. The statement

$$\exists x \in \{x \mid number(x)\} : even(x)$$

("a number is even" – true this time) could equally be written

$$\exists x : number(x) \wedge even(x)$$

("there is an even number"). We take advantage of this, and Inform never specifies a domain for a $\exists$ quantifier.

§**7. Free and bound variables, well-formedness.** In any proposition ϕ, we say that a variable v is "bound" if it appears as the variable governed by a quantifier: it is "free" if it does appear somewhere in ϕ – either directly as a term or indirectly through a function application – and is not bound. For instance, in

$$\forall x : K(x) \wedge B(x, f_C(y))$$

the variable x is bound and the variable y is free. In most accounts of predicate calculus we say that a proposition is a "sentence" if all of its variables are bound, but Inform often needs to parse English text to a proposition with one free variable remaining in it, so we are not too picky about this.

A well-formed proposition is one in which a variable v is quantified at most once: and in which, if it is quantified, then it occurs only after (to the right of) its quantifier, and only within the subexpression containing its quantifier. Thus the following are not well-formed:

$$\exists v : open(v) \wedge \exists v : closed(v)$$

(v is quantified twice),

$$open(v) \wedge \exists v : closed(v)$$

(v occurs before its quantifier),

$$\neg(\exists v : closed(v)) \wedge openable(v)$$

(v occurs outside the subexpression containing the quantifier – in this case, outside the negation brackets).

§**8. The scope of quantifiers.** A quantifier introduces a variable into a proposition which would not otherwise be there, and it exists only for a limited range. For instance, in the proposition

$$open(x) \wedge \neg(\exists y : in(x, y)) \wedge container(x)$$

the variable y exists only within the negation brackets; it ceases to exist as soon as we move back out to the *container* atom. This range is called the "scope" of the quantifier. In general, scopes are always as large as possible in Inform: a variable lasts until the end of the subexpression in which it is created. If the quantifier is outside of any brackets, then the variable lasts until the end of the proposition.

§**9.** Earlier drafts of Inform played games with moving quantifiers around, in order to try to achieve more efficiently compiled propositions. The same thing is now done by building propositions in a way which places quantifiers as far forwards as possible, so we no longer actively move them once they are in place. But it seems still worth preserving the rule which says when this can be done:

Lemma. *Suppose that x is a variable; ϕ is a proposition in which x is unused; $\psi(x)$ is a proposition in which x is free; and that Q is a generalised quantifier. Then*

$$\phi \wedge Qx : \psi(x) \quad \Leftrightarrow \quad Qx : \phi \wedge \psi(x)$$

provided that Q requires at least one case in its range to be satisfied.

Proof. In any given evaluation, either ϕ is true, or it is false. Suppose it is true. Since $T \wedge \theta \Leftrightarrow \theta$, both sides reduce to the same expression, $Qx : \psi(x)$. On the other hand, suppose ϕ is false. Then $\phi \wedge Qx : \psi(x)$ is false, since $F \wedge \theta = F$ for any θ. But the other side is $Qx : F$. Since we know that Q can only be satisfied if at least one case of x works, and here every case of x results in falsity, $Qx : F$ is also false. So the two expressions have the same evaluation in this case, too.

§**10. What is not in our calculus.** The significant thing missing is disjunction. In general, the disjunction $\phi \vee \psi$ – "at least one of ϕ and ψ holds" – is not a proposition.

Natural language does not seem to share the general even-handedness of Boolean logic as between "and" and "or", perhaps because of the way that speech is essentially a one-dimensional stream of discourse. Talking makes it easier to reel off a linear list of requirements than to describe a deep tree structure.

Of course, the operations "not" and "and" are between them sufficient to express all other operations, and in particular we could imitate disjunction like so:

$$\neg(\neg(\phi) \wedge \neg(\psi))$$

("they are not both false" being equivalent to "at least one is true"), but Inform does not at present make use of this.

Terms 6/term

Purpose

Terms are the representations of values in predicate calculus: variables, constants or functions of other terms.

Definitions

¶1. Recall that a "term" can be anything which is a constant, can be a variable, or can be a function $f_B(t)$ of another term t. Our representation of this as a data structure therefore falls into three cases. At all times exactly one of the three relevant fields, `variable`, `constant` and `function` is used.

(a) Variables are represented by the numbers 0 to 25, and `-1` means "not a variable".

(b) Constants are pointers to `specification` structures of main type `VALUE`, and `NULL` means "not a constant".

(c) Functions are pointers to `pcalc_func` structures (see below), and `NULL` means "not a function".

Cinders are discussed in "Cinders and Deferrals", and can be ignored for now.

In order to verify that a proposition makes sense and does not mix up incompatible kinds of value, we will need to type-check it, and one part of that involves assigning a kind of value K to every term t occurring in the proposition. This calculation does involve some work, so we cache the result in the `term_checked_as_kov` field, in order that we only have to work it out once.

```
typedef struct pcalc_term {
    int variable;                                    0 to 25, or -1 for "not a variable"
    struct specification *constant;                  or NULL for "not a constant"
    struct pcalc_func *function;                     or NULL for "not a function of another term"
    int cinder;                                      complicated, this: used to worry about scope of I6 local variables
    struct kind_of_value *term_checked_as_kov;       or NULL if unchecked
} pcalc_term;
```

The structure pcalc_term is shared with 6/aprop, 6/vars, 6/sconv, 6/simp, 6/tcpr, 6/equal, 6/asp, 6/sch, 6/atoms, 6/cind, 6/cdefp and 9/provr.

¶2. The `pcalc_func` structure represents a usage of a function inside a term. Terms such as $f_A(f_B(f_C(x)))$ often occur, so a typical term might be stored as

(1) A `pcalc_term` structure which has a `function` field pointing to
(2) A `pcalc_func` structure whose `bp` field points to A, and whose `fn_of` field is
(3) A `pcalc_term` structure which has a `function` field pointing to
(4) A `pcalc_func` structure whose `bp` field points to B, and whose `fn_of` field is
(5) A `pcalc_term` structure which has a `function` field pointing to
(6) A `pcalc_func` structure whose `bp` field points to C, and whose `fn_of` field is
(7) A `pcalc_term` structure which has a `variable` field set to 0 (which is x).

```
typedef struct pcalc_func {
    struct binary_predicate *bp;                     the predicate B such that this is f_B(t)
    struct pcalc_term fn_of;                         the term t such that this is f_B(t)
    int from_term;                                   whether t is term 0 or 1 of B
} pcalc_func;
```

The structure pcalc_func is shared with 6/vars, 6/simp, 6/tcpr, 6/asp, 6/atoms, 6/cind and 6/cdefp.

§1. Creating new terms.

```
pcalc_term term_new_variable(int v) {
    pcalc_term pt; ⟨Make new blank term structure pt 2⟩;
    pt.variable = v;
    return pt;
}
pcalc_term term_new_constant(specification *c) {
    pcalc_term pt; ⟨Make new blank term structure pt 2⟩;
    pt.constant = c;
    return pt;
}
pcalc_term term_new_function(binary_predicate *bp, pcalc_term ptof, int t) {
    pcalc_term pt; ⟨Make new blank term structure pt 2⟩;
    pcalc_func *pf = CREATE(pcalc_func);
    pf->bp = bp; pf->fn_of = ptof; pf->from_term = t;
    pt.function = pf;
    return pt;
}
```

The function term_new_variable is called from 6/aprop, 6/prop, 6/pform, 6/treec, 6/sconv, 6/simp and 6/cdefp.
The function term_new_constant is called from 5/aph, 6/aprop, 6/vars, 6/treec, 6/sconv, 6/simp and 12/cinv.
The function term_new_function is called from 6/simp.

§2. Where, in all three cases:

⟨Make new blank term structure pt 2⟩ ≡

```
    pt.variable = -1;
    pt.constant = NULL;
    pt.function = NULL;
    pt.cinder = -1;                                   that is, no cinder
    pt.term_checked_as_kov = NULL;
```

This code is used in §1.

§3. Variable letters. The variables 0 to 25 are referred to by the letters $x, y, z, a, b, c, ..., w$: this convention is followed both in the debugging log and in functions compiled into I6 code.

The number 26 turns up quite often in this chapter, and while it's normally good style to define named constants, here we're not going to. 26 is a number which anyone other than a string theorist will immediately associate with the size of the alphabet. Moreover, we can't really raise the total, because there are only 26 single-character local variable names in I6, `a` to `z`. (Well, strictly speaking there is also `_`, but we won't go there.) To have a variable limit lower than 26 would be artificial, since there are no memory constraints arguing for it; and in any case a proposition with 27 or more variables would be so huge that it could not be evaluated at run-time in any remotely plausible length of time. So although the 26-variables-only limit is embedded in Inform, it really is not any restriction, and it greatly simplifies the code.

```
char *pcalc_vars = "xyzabcdefghijklmnopqrstuvw";
```

§**4. Underlying terms.** Routines to see if a term is a constant C, or if it is a chain of functions at the bottom of which is a constant C; and similarly for variables.

```
specification *term_constant_underlying(pcalc_term *t) {
    if (t->constant) return t->constant;
    if (t->function) return term_constant_underlying(&(t->function->fn_of));
    return NULL;
}
int term_variable_underlying(pcalc_term *t) {
    if (t->variable >= 0) return t->variable;
    if (t->function) return term_variable_underlying(&(t->function->fn_of));
    return -1;
}
```

The function term_constant_underlying is called from 6/simp, 6/tcpr and 6/atoms.
The function term_variable_underlying is called from 6/prop, 6/vars, 6/sconv and 6/simp.

§**5. Adjective-noun conversions.** As we shall see, a general unary predicate stores a type-reference pointer to an adjectival phrase – the adjective it tests. But sometimes the same word acts both as adjective and noun in English. In "the green door", clearly "green" is an adjective; in "the door is green", it is possibly a noun; in "the colour of the door is green", it must surely be a noun. Yet these are all really the same meaning. To cope with this ambiguity, we need a way to convert the adjectival form of such an adjective into its noun form, and back again.

```
pcalc_term prop_adj_to_noun_conversion(adjective_list_entry *tr) {
    adjectival_phrase *aph = get_adjective_from_list_entry(tr);
    quantity *q = aph_has_ENUMERATIVE_meaning(aph);
    if (q) return term_new_constant(new_QUANTITY_spec(q));
    property_name *prn = aph_has_EORP_meaning(aph);
    if (prn) return term_new_constant(property_name_to_PROPERTY_spec(prn));
    return term_new_variable(0);
}
```

The function prop_adj_to_noun_conversion is called from 6/prop.

§**6.** And conversely:

```
adjective_list_entry *prop_noun_to_adj_conversion(pcalc_term pt) {
    kind_of_value *kov;
    adjectival_phrase *aph;
    specification *spec = pt.constant;
    if (spec_is_actual_CONSTANT(spec) == FALSE) return NULL;
    kov = spec_get_kind_of_value(spec);
    if (kov_get_coinciding_property(kov) == NULL) return NULL;
    quantity *q = RETRIEVE_FROM_SPEC(spec, quantity);
    aph = qty_get_adjectival_phrase(q);
    return new_adjective_list_entry(aph, TRUE);
}
```

The function prop_noun_to_adj_conversion is called from 6/tcpr.

§**7. Debugging terms.** The art of this is to be unobtrusive; when a proposition is being logged, we don't much care about the constant terms, and want to display them concisely and without fuss.

```
void log_pcalc_term(pcalc_term *pt) {
    if (pt == NULL) {
        LOG("<null-term>");
    } else if (pt->constant) {
        specification *spec = pt->constant;
        if (pt->cinder >= 0) { LOG("const_%d", pt->cinder); return; }
        if (spec->word_ref1 >= 0) { LOG("'$W'", spec->word_ref1, spec->word_ref2); return; }
        if (species_is(spec, CONSTANT_SPC)) {
            world_object *wo = wo_of_CONSTANT_OBJECT_if_any(spec);
            if (wo) { LOG("$O", wo); return; }
        }
        if (spec->word_ref1 >= 0) { LOG("<$W>", spec->word_ref1, spec->word_ref2); return; }
        LOG("$S", spec);
    } else if (pt->function) {
        binary_predicate *bp = pt->function->bp;
        i6_schema *fn = bp_get_term_as_function_of_other(bp, 0);
        if (fn == NULL) fn = bp_get_term_as_function_of_other(bp, 1);
        if (fn == NULL) internal_error("Function of non-functional predicate");
        if (logging_to_I6_text) {
            log_i6_schema_applied(fn, &(pt->function->fn_of));
        } else {
            LOG("{$i:$0}", fn, &(pt->function->fn_of));
        }
    } else if (pt->variable >= 0) {
        int j = pt->variable;
        if (j<26) LOG("%c", pcalc_vars[j]); else LOG("<bad-var=%d>", j);
    } else {
        LOG("<bad-term>");
    }
}
```

The function log_pcalc_term is called from 2/dl, 6/aprop and 6/cind.

Atomic Propositions 6/aprop

Purpose

To build and modify atoms, the syntactic pieces from which propositions are built up.

Definitions

¶1. As the description in the Introduction showed, propositions are complicated data structures. Roughly speaking, they are made up of small independent pieces which can be combined in a variety of ways into larger assemblies. In this section, we look at the smallest pieces: some of these could be propositions in their own right, others are only structural items needed to form up the larger collections. But each individual piece, or "atom", is stored in a `pcalc_prop` structure.

The question of how these are joined together is left until the next section.

```
define MAX_ATOM_ARITY 2                                          for the moment, at any rate

typedef struct pcalc_prop {
    int element;                                          one of the constants below: always 1 or greater
    int arity;                                  1 for quantifiers and unary predicates; 2 for BPs; 0 otherwise
    struct general_pointer predicate;                   usually indicates which predicate structure is meant
    struct pcalc_term terms[MAX_ATOM_ARITY];                          terms to which the predicate applies
    struct kind_of_value *assert_kind_of_value;          KIND_ATOM: the kind of value of a variable
    int calling_data;                                    CALLED_ATOM: compacted form of a word range
    struct pcalc_prop *next;                                  next atom in the list for this proposition
} pcalc_prop;
```

The structure pcalc_prop is shared with 6/prop, 6/vars, 6/sconv, 6/simp, 6/tcpr, 6/asp, 6/atoms, 6/defer, 6/cind and 6/cdefp.

¶2. The Universe is filled with atoms, but they come in different kinds, called elements. For us, an "element" is the identifying number, stored in the `element` field, which tells Inform what kind of atom something is. The following is our Periodic Table of all possible elements:

```
define QUANTIFIER_ATOM 1                                                  any generalised quantifier

define PREDICATE_ATOM 10                  a property-based unary predicate, or any predicate of higher arity
define KIND_ATOM 11                                  a unary predicate K(x) associated with a kind K
define ISAKIND_ATOM 12                  a unary predicate asserting that x is the world-object for a kind
define ISAKOV_ATOM 13                    a unary predicate asserting that x is the generic SP for a KOV
define ISAVAR_ATOM 14                  a unary predicate asserting that x is the SP for a global variable
define EVERYWHERE_ATOM 15                                  a unary predicate asserting omnipresence
define HERE_ATOM 16                                      a unary predicate asserting presence "here"
define CALLED_ATOM 17                                 to keep track of "(called the intruder)"-style names

define NEGATION_OPEN_ATOM 20                          logical negation ¬ applied to contents of group
define NEGATION_CLOSE_ATOM 30                                                  end of logical negation ¬
define DOMAIN_OPEN_ATOM 21                            logical negation ¬ applied to contents of group
define DOMAIN_CLOSE_ATOM 31                                                    end of logical negation ¬
```

¶3. And as with columns in the Periodic Table, these elements come in what are called "groups", because it often happens that atoms of different elements behave similarly when the elements have something in common.

```
define STRUCTURAL_GROUP 10
define PREDICATES_GROUP 20
define OPEN_OPERATORS_GROUP 30
define CLOSE_OPERATORS_GROUP 40
```

---

§**1. The elements.** Given an element, the following returns the group to which it belongs.

```
int element_get_group(int element) {
    if (element <= 0) return 0;
    if (element < STRUCTURAL_GROUP) return STRUCTURAL_GROUP;
    if (element < PREDICATES_GROUP) return PREDICATES_GROUP;
    if (element < OPEN_OPERATORS_GROUP) return OPEN_OPERATORS_GROUP;
    if (element < CLOSE_OPERATORS_GROUP) return CLOSE_OPERATORS_GROUP;
    return 0;
}
```

The function element_get_group is called from 6/prop, 6/vars, 6/simp and 6/cdefp.

§**2.** Some atoms occur in pairs, which have to match like opening and closing parentheses. The following returns 0 for an element code which does not behave like this, or else returns the opposite number to any element code which does.

```
int element_get_match(int element) {
    switch (element) {
        case NEGATION_OPEN_ATOM: return NEGATION_CLOSE_ATOM;
        case NEGATION_CLOSE_ATOM: return NEGATION_OPEN_ATOM;
        case DOMAIN_OPEN_ATOM: return DOMAIN_CLOSE_ATOM;
        case DOMAIN_CLOSE_ATOM: return DOMAIN_OPEN_ATOM;
        default: return 0;
    }
}
```

The function element_get_match is called from 6/prop.

§**3. Creating atoms.** Every atom is created by the following routine:

```
pcalc_prop *atom_new(int element) {
    pcalc_prop *prop = CREATE(pcalc_prop);
    prop->next = NULL;
    prop->element = element;
    prop->assert_kind_of_value = NULL;
    prop->arity = 0;
    prop->predicate = NULL_GENERAL_POINTER;
    return prop;
}
```

The function atom_new is called from 6/prop, 6/pform, 6/treec, 6/sconv, 6/simp and 8/imp.

§**4. The STRUCTURAL group.** Some convenient routines to handle atoms of specific elements now follow: first, `QUANTIFIER` atoms. These have arity 1, and the single term must always be a variable, the one which is being bound. The parameter is a number needed for some `quantifier` types to identify the range: for instance, it would be 7 in the case of $V_{=7}$.

Tying specific variables to quantifiers seems to be out of fashion in modern computer science. Contemporary theorem-proving assistants mostly use de Bruijn's numbering scheme, in which numbers 1, 2, 3, ..., refer to variables being quantified in an indirect way. The advantage is that propositions are easier to construct, since the same numbers can be used in different subexpressions of the same proposition, and there's no worrying about clashes. But it all just moves the difficulty elsewhere, by making it less obvious how to pair up the numbers with variables at compilation time, and less obvious even how many variables are needed. So we stick to the old-fashioned way of imitating $\forall x : P(x)$ rather than $\forall 1.P$.

```
pcalc_prop *atom_QUANTIFIER_new(quantifier *quant, int v, int parameter) {
    pcalc_prop *prop = atom_new(QUANTIFIER_ATOM);
    prop->arity = 1;
    prop->terms[0] = term_new_variable(v);
    prop->predicate = STORE_POINTER_quantifier(quant);
    prop->calling_data = parameter;
    return prop;
}
```

The function atom_QUANTIFIER_new is called from 6/vars, 6/pform, 6/treec and 6/simp.

§**5.** Quantifier atoms can be detected as follows:

```
int atom_is_quantifier(pcalc_prop *prop) {
    if ((prop) && (prop->element == QUANTIFIER_ATOM)) return TRUE;
    return FALSE;
}
int atom_is_existence_quantifier(pcalc_prop *prop) {
    if ((prop) && (prop->element == QUANTIFIER_ATOM) &&
        (RETRIEVE_POINTER_quantifier(prop->predicate) == exists_quantifier))
        return TRUE;
    return FALSE;
}
int atom_is_nonexistence_quantifier(pcalc_prop *prop) {
    if ((prop) && (prop->element == QUANTIFIER_ATOM) &&
        (RETRIEVE_POINTER_quantifier(prop->predicate) == not_exists_quantifier))
        return TRUE;
    return FALSE;
}
int atom_is_forall_quantifier(pcalc_prop *prop) {
    if ((prop) && (prop->element == QUANTIFIER_ATOM) &&
        (RETRIEVE_POINTER_quantifier(prop->predicate) == for_all_quantifier))
        return TRUE;
    return FALSE;
}
int atom_is_notall_quantifier(pcalc_prop *prop) {
    if ((prop) && (prop->element == QUANTIFIER_ATOM) &&
        (RETRIEVE_POINTER_quantifier(prop->predicate) == not_for_all_quantifier))
        return TRUE;
    return FALSE;
}
```

```
int atom_is_for_all_x(pcalc_prop *prop) {
    if ((atom_is_forall_quantifier(prop)) && (prop->terms[0].variable == 0)) return TRUE;
    return FALSE;
}
```

The function atom_is_quantifier is called from 6/prop and 6/simp.
The function atom_is_existence_quantifier is called from 6/prop, 6/simp and 6/defer.
The function atom_is_nonexistence_quantifier is called from 6/simp.
The function atom_is_forall_quantifier is called from 6/simp.
The function atom_is_notall_quantifier is called from 6/simp.
The function atom_is_for_all_x is called from 6/prop.

§**6.** See "Determiners and Quantifiers" for what a now-assertable quantifier is:

```
int atom_is_now_assertable_quantifier(pcalc_prop *prop) {
    if (prop->element != QUANTIFIER_ATOM) return FALSE;
    return quant_is_now_assertable(RETRIEVE_POINTER_quantifier(prop->predicate));
}
```

The function atom_is_now_assertable_quantifier is called from 6/defer.

§**7. The PREDICATES group.** Next, unary predicates, beginning with the `EVERYWHERE` special case.

```
pcalc_prop *atom_EVERYWHERE_new(pcalc_term pt) {
    pcalc_prop *prop = atom_new(EVERYWHERE_ATOM);
    prop->arity = 1;
    prop->terms[0] = pt;
    return prop;
}
```

The function atom_EVERYWHERE_new is called from 6/treec and 6/simp.

§**8.** And `HERE`:

```
pcalc_prop *atom_HERE_new(pcalc_term pt) {
    pcalc_prop *prop = atom_new(HERE_ATOM);
    prop->arity = 1;
    prop->terms[0] = pt;
    return prop;
}
```

The function atom_HERE_new is called from 6/treec.

§**9.** And `ISAKIND`:

```
pcalc_prop *atom_ISAKIND_new(pcalc_term pt) {
    pcalc_prop *prop = atom_new(ISAKIND_ATOM);
    prop->arity = 1;
    prop->terms[0] = pt;
    return prop;
}
```

The function atom_ISAKIND_new is called from 6/treec.

§**10.** And `ISAKOV`:

```
pcalc_prop *atom_ISAKOV_new(pcalc_term pt) {
    pcalc_prop *prop = atom_new(ISAKOV_ATOM);
    prop->arity = 1;
    prop->terms[0] = pt;
    return prop;
}
```

The function atom_ISAKOV_new is called from 6/treec.

§**11.** And `ISAVAR`:

```
pcalc_prop *atom_ISAVAR_new(pcalc_term pt) {
    pcalc_prop *prop = atom_new(ISAVAR_ATOM);
    prop->arity = 1;
    prop->terms[0] = pt;
    return prop;
}
```

The function atom_ISAVAR_new is called from 6/treec.

§**12.** `CALLED` atoms are interesting because they exist only for their side-effects: they have no effect at all on the logical status of a proposition (well, except that they should not be applied to free variables referred to nowhere else). They can therefore be added or removed freely. In the phrase

> if a woman is in a lighted room (called the den), ...

we need to note that the value of the bound variable corresponding to the lighted room will need to be kept and to have a name ("the den"): this will probably mean the inclusion of a `CALLED=den(y)` atom.

The calling data for a `CALLED` atom is the textual name by which the variable will be called: a word range packed into a single `int` field.

```
pcalc_prop *atom_CALLED_new(int w1, int w2, pcalc_term pt, kind_of_value *kov) {
    pcalc_prop *prop = atom_new(CALLED_ATOM);
    prop->arity = 1;
    prop->terms[0] = pt;
    prop->calling_data = w1 + ((w2-w1) << 20);
    prop->assert_kind_of_value = kov;
    return prop;
}
void atom_CALLED_get_name(pcalc_prop *prop, int *w1, int *w2) {
    *w1 = prop->calling_data & ((1<<20)-1);
    *w2 = (prop->calling_data >> 20) + *w1;
}
```

The function atom_CALLED_new is called from 6/pform and 6/treec.
The function atom_CALLED_get_name is called from 6/asp, 6/atoms and 6/defer.

§**13.** Now for a KIND atom. At first sight, it looks odd that a unary predicate for a kind is represented differently from other predicates. Isn't it a unary predicate just like any other? Well: it is, but then again, we want to compile propositions to reasonably efficient I6 code which determines whether or not they are true. We particularly want to look out for patterns like

$$\forall x : ... \wedge container(x) \wedge ...$$

since they allow us to consider x ranging over a smaller, and therefore more efficiently searchable, domain: most objects aren't containers. So KIND_ATOM atoms are useful in ways which other unary predicate atoms are not.

Once again, this atom has arity 1, but the term no longer has to be a variable; when Inform reads a sentence like

> Viper Pit is a room.

the resulting proposition will include a KIND atom whose term is the constant value for the Viper Pit.

Any kind of value can be assigned, but the commonest case involves a kind of object, so a special routine exists just to create KIND atoms in that case.

```
pcalc_prop *atom_KIND_object_new(world_object *k, pcalc_term pt) {
    pcalc_prop *prop = atom_new(KIND_ATOM);
    prop->arity = 1;
    prop->assert_kind_of_value = kovko(k);
    prop->terms[0] = pt;
    return prop;
}
pcalc_prop *atom_KIND_value_new(kind_of_value *kov, pcalc_term pt) {
    pcalc_prop *prop = atom_new(KIND_ATOM);
    prop->arity = 1;
    prop->assert_kind_of_value = kov;
    prop->terms[0] = pt;
    return prop;
}
```

The function atom_KIND_object_new is called from 6/pform, 6/treec and 6/simp.
The function atom_KIND_value_new is called from 6/pform, 6/treec, 6/sconv and 6/simp.

§**14.** That just leaves the general sort of unary predicate. In principle we ought to be able to create $U(t)$ for any term t, but in practice we only ever need $t = x$, that is, variable 0.

```
pcalc_prop *atom_unary_PREDICATE_from_aph(adjectival_phrase *aph, int negated) {
    pcalc_prop *prop = atom_new(PREDICATE_ATOM);
    prop->arity = 1;
    prop->terms[0] = term_new_variable(0);
    prop->predicate = STORE_POINTER_adjective_list_entry(
        new_adjective_list_entry(aph, (negated)?FALSE:TRUE));
    return prop;
}
```

The function atom_unary_PREDICATE_from_aph is called from 6/pform, 6/treec, 6/sconv, 8/creat and 8/imp.

§**15.** And binary predicates are pretty well the same:

```
pcalc_prop *atom_binary_PREDICATE_new(binary_predicate *bp,
    pcalc_term pt1, pcalc_term pt2) {
    pcalc_prop *prop = atom_new(PREDICATE_ATOM);
    prop->arity = 2;
    prop->predicate = STORE_POINTER_binary_predicate(bp);
    prop->terms[0] = pt1; prop->terms[1] = pt2;
    return prop;
}
binary_predicate *atom_is_binary_predicate(pcalc_prop *prop) {
    if (prop == NULL) return NULL;
    if (prop->element != PREDICATE_ATOM) return NULL;
    if (prop->arity != 2) return NULL;
    return RETRIEVE_POINTER_binary_predicate(prop->predicate);
}
int atom_is_equality_predicate(pcalc_prop *prop) {
    binary_predicate *bp = atom_is_binary_predicate(prop);
    if (bp == a_is_b_predicate) return TRUE;
    return FALSE;
}
```

The function atom_binary_PREDICATE_new is called from 6/treec, 6/sconv and 6/simp.
The function atom_is_binary_predicate is called from 6/simp.
The function atom_is_equality_predicate is called from 6/simp.

§**16.** Given C, return the proposition $is(x, C)$:

```
pcalc_prop *prop_x_is_constant(specification *spec) {
    return atom_binary_PREDICATE_new(a_is_b_predicate,
        term_new_variable(0), term_new_constant(spec));
}
```

The function prop_x_is_constant is called from 6/pform.

§**17.** And conversely:

```
pcalc_term *atom_is_x_equals(pcalc_prop *prop) {
    if (atom_is_equality_predicate(prop) == FALSE) return NULL;
    if (prop->terms[0].variable != 0) return NULL;
    return &(prop->terms[1]);
}
```

The function atom_is_x_equals is called from 6/sconv.

§18. Validating atoms.

```
char *atom_validate(pcalc_prop *prop) {
    int group;
    if (prop == NULL) return NULL;
    group = element_get_group(prop->element);
    if (group == 0) return "atom of undiscovered element";
    if (prop->arity > MAX_ATOM_ARITY) return "atom with overly large arity";
    if (prop->arity < 0) return "atom with negative arity";
    if (prop->arity == 0) {
        if (group == PREDICATES_GROUP) return "predicate without terms";
        if (prop->element == QUANTIFIER_ATOM) return "quantifier without variable";
    } else {
        if ((prop->element != PREDICATE_ATOM) && (prop->arity != 1))
            return "unary atom with other than one term";
        if ((group == OPEN_OPERATORS_GROUP) || (group == CLOSE_OPERATORS_GROUP))
            return "parentheses with terms";
    }
    if ((prop->element == QUANTIFIER_ATOM) && (prop->terms[0].variable == -1))
        return "missing variable in quantification";
    return NULL;
}
```

The function atom_validate is called from 6/prop.

§19. Debugging log.

Logging atomic propositions divides into cases:

```
void log_pcalc_atom(pcalc_prop *prop) {
    if (prop == NULL) { LOG("<null-atom>"); return; }
    switch(prop->element) {
        case PREDICATE_ATOM:
            switch(prop->arity) {
                case 1: ⟨Log some suitable textual name for this unary predicate 20⟩; break;
                case 2: ⟨Log some suitable textual name for this binary predicate 21⟩; break;
                default: LOG("?exotic-predicate-arity=%d?", prop->arity); break;
            }
            break;
        case QUANTIFIER_ATOM: {
            quantifier *quant = RETRIEVE_POINTER_quantifier(prop->predicate);
            log_quantifier(quant, prop->calling_data);
            LOG(" "); ⟨Log a comma-separated list of terms for this atomic proposition 22⟩;
            return;
        }
        case CALLED_ATOM: {
            int w1, w2;
            atom_CALLED_get_name(prop, &w1, &w2);
            LOG("called='$W'", w1, w2);
            break;
        }
        case KIND_ATOM: {
            world_object *k = kovko_get_kind(prop->assert_kind_of_value);
            if (logging_to_I6_text == FALSE) LOG("kind=");
            if ((k) && (k->word_ref1 >= 0)) LOG("$W", k->word_ref1, k->word_ref2);
            else LOG("$u", prop->assert_kind_of_value); break;
```

```
        }
        case ISAKIND_ATOM: LOG("is-a-kind"); break;
        case ISAKOV_ATOM: LOG("is-a-KOV"); break;
        case ISAVAR_ATOM: LOG("is-a-var"); break;
        case EVERYWHERE_ATOM: LOG("everywhere"); break;
        case HERE_ATOM: LOG("here"); break;
        case NEGATION_OPEN_ATOM: LOG("NOT["); break;
        case NEGATION_CLOSE_ATOM: LOG("NOT]"); break;
        case DOMAIN_OPEN_ATOM: LOG("IN["); break;
        case DOMAIN_CLOSE_ATOM: LOG("IN]"); break;
        default: LOG("?bad-atom?"); break;
    }
    if (prop->arity > 0) {
        LOG("("); ⟨Log a comma-separated list of terms for this atomic proposition 22⟩; LOG(")");
    }
}
```

The function log_pcalc_atom is called from 2/dl and 6/prop.

§**20.**

⟨Log some suitable textual name for this unary predicate 20⟩ ≡

```
    adjective_list_entry *tr = RETRIEVE_POINTER_adjective_list_entry(prop->predicate);
    if (adjective_used_positively(tr) == FALSE) LOG("not-");
    log_adjectival_phrase(get_adjective_from_list_entry(tr));
```

This code is used in §19.

§**21.** And more easily:

⟨Log some suitable textual name for this binary predicate 21⟩ ≡

```
    binary_predicate *bp = RETRIEVE_POINTER_binary_predicate(prop->predicate);
    if (bp == NULL) LOG("?bad-bp?"); else LOG(bp_get_log_name(bp));
```

This code is used in §19.

§**22.** Just a diagnostic way of printing the terms in an atomic proposition, by their index numbers. (They are numbered from 0 to $A-1$, where A is the arity.)

⟨Log a comma-separated list of terms for this atomic proposition 22⟩ ≡

```
    int t;
    for (t=0; t<prop->arity; t++) {
        if (t>0) LOG(", ");
        log_pcalc_term(&(prop->terms[t]));
    }
```

This code is used in §19.

Propositions 6/prop

Purpose

To build and modify structures representing propositions in predicate calculus.

Definitions

¶1. We now begin on the data structures to hold propositions. Now a properly constructed proposition has a natural tree structure – one can regard quantification, negation, and conjunction as higher nodes, and predicates as leaves. So the idea of storing propositions as trees has a certain elegance. At first it seems an advantage that any such tree is necessarily a valid proposition. But in fact this is not so helpful, because we want to build propositions gradually, and in particular intermediate states need to exist which are not yet valid but will be. If we used a tree representation, we would also need some cursor-position-like marker for the region of current growth, and that could all become complicated. We will also find that the main operation we need to perform is a depth-first traverse of the tree, which is a little tiresome to do in a conventional loop (it lends itself to recursion, but that's inconvenient).

So we will instead store propositions in a linked list, imitating the notation used by mathematicians who write them along in a single line. Now there's a natural way to store incomplete propositions and a natural build-point (at the end), and depth-first traverses are easy – just work along from left to right. The disadvantage is that it's also easy to make malformed propositions, so we have to build carefully.

For instance, "Test sentence (internal) with no man can see the box." produces:

```
1. no man can see the box
[ DoesNotExist x IN[ man(x) IN] : can-see(x, 'box') ]
```

The proposition is stored as a linked list of atoms, of elements like so:

```
QUANTIFIER --> DOMAIN_OPEN --> PREDICATE --> DOMAIN_CLOSE --> PREDICATE
```

In short: a proposition is a linked list of `pcalc_prop` atoms, joined by their `next` fields. The present section contains routines to help build and edit such lists.

¶2. In particular:

(a) The empty list, a `NULL` pointer, represents the universally true proposition $\top$. Asserting it does nothing; testing it at run-time always evaluates to `true`.

(b) The conjunction $\phi \wedge \psi$ is just the concatenation of their linked lists.

(c) Negation $\neg(\phi)$ is the concatenation `NEGATION_OPEN --> P --> NEGATION_CLOSE`, where `P` is the linked list for ϕ.

(d) The quantifier $Qv \in \{v \mid \phi(v)\}$ is `QUANTIFIER --> DOMAIN_OPEN --> P --> DOMAIN_CLOSE`.

In this section, we'll call a segment of the list representing a pair of matched brackets, like `DOMAIN_OPEN --> P --> DOMAIN_CLOSE`, a "group".

¶3. We sometimes need to indicate a position within a proposition – a position not of an atom, but between atoms. Consider the possible places where letters could be inserted into the word "rap": before the "r" (trap), between "r" and "a" (reap), between "a" and "p" (ramp), after the "p" (rapt). Though "rap" is a three-letter word, there are four possible insertion points – so they can't exactly correspond to letters. The convention used with Inform propositions is that a position marker points to the `pcalc_prop` structure for the atom *before* the position meant: and a `NULL` pointer in this context means the front position, before the opening atom.

¶4. The code needed to perform a depth-first traverse of a proposition is abstracted by the following macros. Note that we often need to remember the atom before the current one, so we keep that in a spare variable during each traverse. (This saves us having to maintain the proposition data structure as a doubly linked list, which would be harder to edit.)

One macro declares the name of a marker variable to be used when traversing; the other is the necessary loop head. Note that we do not assume that `p` will still be non-`NULL` at the end of a loop iteration, just because it was at the beginning: local edits are sometimes performed in the traverse, and it can happen that an edit truncates the proposition so savagely that the loop finds its ground cut out from under it.

```
define TRAVERSE_VARIABLE(p)
    pcalc_prop *p = NULL, *p##_prev = NULL;
    int p##_repeat = FALSE;
define TRAVERSE_PROPOSITION(p, start)
    for (p=start, p##_prev=NULL, p##_repeat = FALSE;
        p;
        (p##_repeat == FALSE)?(p##_prev=p, p=(p)?(p->next):NULL):0, p##_repeat = FALSE)
```

¶5. An edit which happens during a traverse is permitted to make any change to the proposition at and beyond the marker position `p`, but not allowed to change what came before. Since such an edit might leave `p` pointing to an atom which has been cut, or moved later, we must perform the following macro after edits to restore `p`. We know that the atom which was before `p` at the start of the loop has not been changed – since edits aren't allowed there – so `p_prev` must be correct, and we therefore restore `p` to the next atom after `p_prev`.

There is a catch, however: if our edit consists only of deleting some atoms then using `PROPOSITION_EDITED` correctly resets `p` to the current atom at the marker position, and that will be the first atom after the ones deleted. If we then just go around the loop, we move on to the next atom; as a result, the first atom after the deleted ones is skipped over. We can avoid this by using `PROPOSITION_EDITED_REPEATING_CURRENT` instead.

Every routine which simplifies a proposition is expected to have an `int *` argument called `changed`: on exit, the `int` variable this points to should be set if and only if a change has been made to the proposition.

```
define PROPOSITION_EDITED(p, prop)
    if (p##_prev == NULL) p = prop; else p = p##_prev->next;
    *changed = TRUE;
define PROPOSITION_EDITED_REPEATING_CURRENT(p, prop)
    PROPOSITION_EDITED(p, prop)
    p##_repeat = TRUE;
```

---

§**1. Implied conjunction.** Conjunction (logical "and") occurs so densely in propositions arising from natural language that our data structures would grow large and unmanageable if we wrote all of them out. So we adopt a convention similar to the one in algebra, where the formula

$$xy + w(v - 1)$$

is understood to mean multiplication of x by y, and of w by $(v - 1)$. Note that if we were to write it out as a sequence of symbols

```
x y + w ( v - 1 )
```

then multiplication would only be understood at two positions, not between every pair of symbols. In the same way, the following routine looks at a pair of adjacent atoms and decides whether or not conjunction should be understood between them.

```
int implied_conjunction_between(pcalc_prop *p1, pcalc_prop *p2) {
    if ((p1 == NULL) || (p2 == NULL)) return FALSE;
    if (element_get_group(p1->element) == OPEN_OPERATORS_GROUP) return FALSE;
    if (element_get_group(p2->element) == CLOSE_OPERATORS_GROUP) return FALSE;
    if (p1->element == QUANTIFIER_ATOM) return FALSE;
    if (p1->element == DOMAIN_CLOSE_ATOM) return FALSE;
    return TRUE;
}
```

The function implied_conjunction_between is called from 6/defer.

§**2.** Purely decoratively, we print some punctuation when logging a proposition; this is chosen to look like standard mathematical notation.

```
char *debugging_log_text_between(pcalc_prop *p1, pcalc_prop *p2) {
    if ((p1 == NULL) || (p2 == NULL)) return "";
    if (p1->element == QUANTIFIER_ATOM) {
        if (p2->element == DOMAIN_OPEN_ATOM) return "";
        return ":";
    }
    if (p1->element == DOMAIN_CLOSE_ATOM) return ":";
    if (implied_conjunction_between(p1, p2)) {
        if (logging_to_I6_text) return("&");                    since ^ in I6 strings means newline
        return ("^");
    }
    return "";
}
```

§**3.** So we may as well complete the debugging log code now. Note that $\top$ is logged as just `[ ]`.

```
void log_pcalc_prop(pcalc_prop *prop) {
    TRAVERSE_VARIABLE(p);
    LOG("[ ");
    TRAVERSE_PROPOSITION(p, prop) {
        char *bridge = debugging_log_text_between(p_prev, p);
        if (bridge[0]) LOG("%s ", bridge);
        log_pcalc_atom(p);
        LOG(" ");
    }
    LOG("]");
}
```

The function log_pcalc_prop is called from 2/dl.

§**4. Validity.** Since the proposition data structure lets us build all kinds of nonsense, we'll be much safer if we can check our working – if we can verify that a proposition is valid. But what does that mean? We might mean:

(i) a proposition is good if its sequence of `next` pointers all correctly point to `pcalc_prop` structures, and don't loop around into a circle;
(ii) a proposition is good if (i) is true, and it is correctly punctuated;
(iii) a proposition is good if (ii) is true, and it never confuses together two different variables by giving both the same letter;
(iv) a proposition is good if (iii) is true, and all of its predicates can safely be applied to all of their terms, and we can identify what kind of value each variable ranges over.

These are steadily stronger conditions. The first is a basic invariant of our data structures: nothing failing (i) will ever be allowed to exist, provided the routines in this section are free of bugs. Condition (ii) is called *syntactic validity*; (iii) is *well-formedness*; (iv) is *type safety*. Correct source text eventually makes propositions which have all four properties, but intermediate half-built states often satisfy only (i).

§**5.** The following examples illustrate the differences. This one is not even syntactically valid:

```
DOMAIN_OPEN_ATOM --> NEGATION_CLOSE_ATOM --> NEGATION_CLOSE_ATOM
```

This one is syntactically valid, but not well-formed:

```
EVERYWHERE_ATOM(x) --> QUANTIFIER=for-all(x) --> PREDICATE=open(x)
```

(If `x` ranges over all objects at the middle of the proposition, it had better not already have a value, but if it doesn't, what can that first atom mean? It would be like writing the formula $n + \sum_{n=1}^{10} n^2$, where clearly two different things have been called n.)

And this proposition is well-formed but not type-safe:

```
QUANTIFIER=for-all(x) --> KIND=number(x) --> EVERYWHERE(x)
```

(Here `x` is supposed to be a number, and therefore has no location, but `EVERYWHERE` can validly be applied only to backdrop objects, so what could `EVERYWHERE(x)` possibly mean?)

§**6.** Well-formedness and type safety are left to later sections in this chapter, but we can at least test syntactic validity here.

define MAX_PROPOSITION_GROUP_NESTING 100 *vastly more than could realistically be used*

```
int prop_is_syntactically_valid(pcalc_prop *prop) {
    TRAVERSE_VARIABLE(p);
    int groups_stack[MAX_PROPOSITION_GROUP_NESTING], group_sp = 0;
    TRAVERSE_PROPOSITION(p, prop) {
        (1) each individual atom has to be properly built:
        char *err = atom_validate(p);
        if (err) { LOG("Atom error: %s: $o\n", err, p); return FALSE; }
        (2) every open bracket must be matched by a close bracket of the same kind:
        if (element_get_group(p->element) == OPEN_OPERATORS_GROUP) {
            if (group_sp >= MAX_PROPOSITION_GROUP_NESTING) {
                LOG("Group nesting too deep\n"); return FALSE;
            }
            groups_stack[group_sp++] = p->element;
        }
        if (element_get_group(p->element) == CLOSE_OPERATORS_GROUP) {
            if (group_sp <= 0) { LOG("Too many close groups\n"); return FALSE; }
            if (element_get_match(groups_stack[--group_sp]) != p->element) {
                LOG("Group open/close doesn't match\n"); return FALSE;
            }
        }
        (3) every quantifier except "exists" must be followed by domain brackets, which occur nowhere else:
        if ((atom_is_quantifier(p_prev)) && (atom_is_existence_quantifier(p_prev) == FALSE)) {
            if (p->element != DOMAIN_OPEN_ATOM) { LOG("Quant without domain\n"); return FALSE; }
        } else {
            if (p->element == DOMAIN_OPEN_ATOM) { LOG("Domain without quant\n"); return FALSE; }
        }
        if ((p->next == NULL) &&
            (atom_is_quantifier(p)) && (atom_is_existence_quantifier(p) == FALSE)) {
            LOG("Ends without domain of final quantifier\n"); return FALSE;
        }
    }
    (4) a proposition must end with all its brackets closed:
    if (group_sp != 0) { LOG("%d group(s) open\n", group_sp); return FALSE; }
    return TRUE;
}
```

The function prop_is_syntactically_valid is called from 6/vars.

§**7. Primitive operations on propositions.** First, copying, which means copying not just the current atom, but all subsequent ones.

```
pcalc_prop *prop_copy(pcalc_prop *original) {
    pcalc_prop *first = NULL, *last = NULL, *prop = original;
    while (prop) {
        pcalc_prop *copied_atom = atom_new(0);
        *copied_atom = *prop; copied_atom->next = NULL;
        if (first) last->next = copied_atom;
        else first = copied_atom;
        last = copied_atom;
        prop = prop->next;
    }
    return first;
}
```

The function prop_copy is called from 6/cdefp and 7/vasp.

§**8.** Now to concatenate propositions. If E and T are both syntactically valid, the result will be, too; but the same is not true of well-formedness, so we need to be careful in using this.

```
pcalc_prop *prop_concatenate(pcalc_prop *existing_body, pcalc_prop *tail) {
    pcalc_prop *end = existing_body;
    if (end == NULL) return tail;
    while (end && (end->next)) end = end->next;
    end->next = tail;
    return existing_body;
}
```

The function prop_concatenate is called from 6/pform, 6/treec, 6/sconv, 8/creat, 8/imp and 9/prop.

§**9.** And here is a version which protects us:

```
pcalc_prop *prop_conjoin(pcalc_prop *existing_body, pcalc_prop *tail) {
    vars_renumber_bound(tail, existing_body, -1);
    existing_body = prop_concatenate(existing_body, tail);
    return existing_body;
}
```

The function prop_conjoin is called from 6/treec.

§**10. Inserting and deleting atoms.** Here we insert an atom at a given position, or at the front if the position is NULL.

```
pcalc_prop *prop_insert_atom(pcalc_prop *prop, pcalc_prop *position,
    pcalc_prop *new_atom) {
    if (position == NULL) {
        new_atom->next = prop;
        return new_atom;
    } else {
        if (prop == NULL) internal_error("inserting atom nowhere");
        new_atom->next = position->next;
        position->next = new_atom;
        return prop;
    }
}
```

The function prop_insert_atom is called from 6/vars and 6/simp.

§**11.** And similarly, with the deleted atom the one after the position given:

```
pcalc_prop *prop_delete_atom(pcalc_prop *prop, pcalc_prop *position) {
    if (position == NULL) {
        if (prop == NULL) internal_error("deleting atom nowhere");
        return prop->next;
    } else {
        if (position->next == NULL) internal_error("deleting atom off end");
        position->next = position->next->next;
        return prop;
    }
}
```

The function prop_delete_atom is called from 6/simp and 6/cdefp.

§**12. Inspecting contents.** First, we count the number of atoms in a given proposition. This is used by other parts of Inform as a crude measure of how complicated it is; though in fact it is not all that crude so long as it is applied to a proposition which has been simplified.

```
int prop_length(pcalc_prop *prop) {
    int n = 0;
    TRAVERSE_VARIABLE(p);
    TRAVERSE_PROPOSITION(p, prop) n++;
    return n;
}
```

The function prop_length is called from 7/cosp.

§13. Matching sequences of atoms. The following sneakily variable-argument-length function can be used to detect subsequences within a proposition: say, the sequence

```
QUANTIFIER --> PREDICATE --> anything --> CALLED
```

starting at the current position, which could be tested with:

```
prop_match(p, 4, QUANTIFIER_ATOM, NULL, PREDICATE_ATOM, NULL,
 ANY_ATOM_HERE, NULL, CALLED_ATOM, &cp);
```

As can be seen, each atom is tested with an element number and an optional pointer; when a successful match is made, the optional pointer is set to the atom making the match. (So if the routine returns `TRUE` then we can be certain that `cp` points to the `CALLED_ATOM` at the end of the run of four.) There are two special pseudo-element-numbers:

```
define ANY_ATOM_HERE 0          match any atom, but don't match beyond the end of the proposition
define END_PROP_HERE -1         a sentinel meaning "the proposition must end at this point"
```

```
int prop_match(pcalc_prop *prop, int c, ...) {
    int i, outcome = TRUE;
    va_list ap;                                   the variable argument list signified by the dots
    va_start(ap, c);                              macro to begin variable argument processing
    for (i = 0; i < c; i++) {
        int a = va_arg(ap, int);
        pcalc_prop **atom_p = va_arg(ap, pcalc_prop **);
        if (atom_p != NULL) *atom_p = prop;
        switch (a) {
            case ANY_ATOM_HERE: if (prop == NULL) outcome = FALSE; break;
            case END_PROP_HERE: if (prop != NULL) outcome = FALSE; break;
            default: if (prop == NULL) outcome = FALSE;
                else if (prop->element != a) outcome = FALSE;
                break;
        }
        if (prop) prop = prop->next;
    }
    va_end(ap);                                   macro to end variable argument processing
    return outcome;
}
```

The function prop_match is called from 6/sconv and 6/simp.

§14. Seeking atoms. Here we run through the proposition looking for either a given element, or a given arity, or both:

```
pcalc_prop *prop_seek_atom(pcalc_prop *prop, int atom_req, int arity_req) {
    TRAVERSE_VARIABLE(p);
    TRAVERSE_PROPOSITION(p, prop)
        if (((atom_req < 0) || (p->element == atom_req)) &&
            ((arity_req < 0) || (p->arity == arity_req)))
                return p;
    return NULL;
}
```

§**15.** Seeking different kinds of atom is now easy:

```
int prop_contains_binary_predicate(pcalc_prop *prop) {
    if (prop_seek_atom(prop, PREDICATE_ATOM, 2)) return TRUE; return FALSE;
}
int prop_contains_quantifier(pcalc_prop *prop) {
    if (prop_seek_atom(prop, QUANTIFIER_ATOM, -1)) return TRUE; return FALSE;
}
int prop_contains_nonexistence_quantifier(pcalc_prop *prop) {
    while ((prop = prop_seek_atom(prop, QUANTIFIER_ATOM, 1)) != NULL) {
        quantifier *quant = RETRIEVE_POINTER_quantifier(prop->predicate);
        if (quant != exists_quantifier) return TRUE;
        prop = prop->next;
    }
    return FALSE;
}
int prop_contains_callings(pcalc_prop *prop) {
    if (prop_seek_atom(prop, CALLED_ATOM, -1)) return TRUE; return FALSE;
}
```

The function prop_contains_binary_predicate is called from 8/knowp.

The function prop_contains_quantifier is called from 6/defer and 10/tab.

The function prop_contains_nonexistence_quantifier is called from 6/asp.

The function prop_contains_callings is called from 6/defer and 11/chron.

§**16.** Here we try to find out the kind of value of variable 0 without the full expense of typechecking the proposition:

```
kind_of_value *prop_describes_KOV(pcalc_prop *prop) {
    pcalc_prop *p = prop;
    while ((p = prop_seek_atom(prop, ISAKOV_ATOM, 1)) != NULL) {
        if (term_variable_underlying(&(p->terms[0])) == 0) return p->assert_kind_of_value;
        p = p->next;
    }
    p = prop;
    while ((p = prop_seek_atom(p, KIND_ATOM, 1)) != NULL) {
        if (term_variable_underlying(&(p->terms[0])) == 0) return p->assert_kind_of_value;
        p = p->next;
    }
    return NULL;
}
```

The function prop_describes_KOV is called from 6/defer and 7/tc.

§**17.** Finding an adjective which cannot be construed as an either/or property name used adjectivally (as in "a closed door") is more involved:

```
int prop_contains_adjective(pcalc_prop *prop) {
    while ((prop = prop_seek_atom(prop, PREDICATE_ATOM, 1)) != NULL) {
        adjective_list_entry *tr = RETRIEVE_POINTER_adjective_list_entry(prop->predicate);
        adjectival_phrase *aph = get_adjective_from_list_entry(tr);
        if (aph_has_EORP_meaning(aph) == NULL) return TRUE;
        return TRUE;
        prop = prop->next;
    }
    return FALSE;
}
```

The function prop_contains_adjective is called from 8/knowp.

§**18.** The following searches not for an atom, but for the lexically earliest term in the proposition:

```
pcalc_term prop_get_first_cited_term(pcalc_prop *prop) {
    TRAVERSE_VARIABLE(p);
    TRAVERSE_PROPOSITION(p, prop)
        if (p->arity > 0)
            return p->terms[0];
    internal_error("prop_get_first_cited_term on termless proposition");
    return term_new_variable(0);                    never executed, but needed to prevent gcc warnings
}
```

The function prop_get_first_cited_term is called from 6/sconv.

§**19.** Here we attempt, if possible, to read a proposition as being either $adjective(v)$ or $\exists v : adjective(v)$, where the adjective can be also be read as a noun, and if so we return a constant term t for that noun; or if the proposition isn't in that form, we return $t = x$, that is, variable 0.

```
pcalc_term convert_adj_to_noun(pcalc_prop *prop) {
    pcalc_term pct = term_new_variable(0);
    if (prop == NULL) return pct;
    if (atom_is_existence_quantifier(prop)) prop = prop->next;
    if (prop == NULL) return pct;
    if (prop->next != NULL) return pct;
    if ((prop->element == PREDICATE_ATOM) && (prop->arity == 1)) {
        adjective_list_entry *tr = RETRIEVE_POINTER_adjective_list_entry(prop->predicate);
        return prop_adj_to_noun_conversion(tr);
    }
    return pct;
}
```

The function convert_adj_to_noun is called from 6/sconv.

§**20. Bracketed groups.** The following routine tests whether the entire proposition is a single bracketed group. For instance:

```
NEGATION_OPEN --> PREDICATE --> KIND --> NEGATION_CLOSE
```

would qualify. Note that detection succeeds only if the parentheses match, and that they may be nested.

```
int prop_is_a_group(pcalc_prop *prop, int governing) {
    int match = element_get_match(governing), level = 0;
    if (match == 0) internal_error("prop_is_a_group called on unmatchable");
    TRAVERSE_VARIABLE(p);
    if ((prop == NULL) || (prop->element != governing)) return FALSE;
    TRAVERSE_PROPOSITION(p, prop) {
        if (element_get_group(p->element) == OPEN_OPERATORS_GROUP) level++;
        if (element_get_group(p->element) == CLOSE_OPERATORS_GROUP) level--;
    }
    if ((p_prev->element == match) && (level == 0)) return TRUE;
    return FALSE;
}
```

The function prop_is_a_group is called from 6/defer.

§**21.** The following removes matched parentheses, leaving just the interior:

```
pcalc_prop *prop_remove_topmost_group(pcalc_prop *prop) {
    TRAVERSE_VARIABLE(p);
    if ((prop == NULL) || (prop_is_a_group(prop, prop->element) == FALSE))
        internal_error("tried to remove topmost group which wasn't there");
    LOGIF(WORKINGS, "ungrouping proposition: $D\n", prop);
    prop = prop->next;
    TRAVERSE_PROPOSITION(p, prop)
        if ((p->next) && (p->next->next == NULL)) { p->next = NULL; break; }
    LOGIF(WORKINGS, "to ungrouped result: $D\n", prop);
    return prop;
}
```

The function prop_remove_topmost_group is called from 6/defer.

§**22.** The main application of which is to remove negation:

```
pcalc_prop *prop_unnegate(pcalc_prop *prop) {
    if (prop_is_a_group(prop, NEGATION_OPEN_ATOM))
        return prop_remove_topmost_group(prop);
    return NULL;
}
```

The function prop_unnegate is called from 11/chron.

§**23.** More ambitiously, this removes matched parentheses found at any given point in a proposition (which can continue after the close bracket).

```
pcalc_prop *prop_ungroup_after(pcalc_prop *prop, pcalc_prop *position, pcalc_prop **last) {
    TRAVERSE_VARIABLE(p);
    pcalc_prop *from;
    int opener, closer, level;
    LOGIF(WORKINGS, "removing frontmost group from proposition: $D\n", prop);
    if (position == NULL) from = prop; else from = position->next;
    opener = from->element;
    closer = element_get_match(opener);
    if (closer == 0) internal_error("tried to remove frontmost group which doesn't open");
    from = from->next;
    prop = prop_delete_atom(prop, position);                                  remove opening atom
    if (from->element == closer) {                                  the special case of an empty group
        prop = prop_delete_atom(prop, position);                              remove opening atom
        goto Ungrouped;
    }
    level = 0;
    TRAVERSE_PROPOSITION(p, from) {
        if (p->element == opener) level++;
        if (p->element == closer) level--;
        if (level < 0) {
            if (last) *last = p_prev;
            prop = prop_delete_atom(prop, p_prev);                            remove closing atom
            goto Ungrouped;
        }
    }
    internal_error("tried to remove frontmost group which doesn't close");
    Ungrouped:
    LOGIF(WORKINGS, "to ungrouped result: $D\n", prop);
    return prop;
}
```

The function prop_ungroup_after is called from 6/simp.

§**24.** Occasionally we want to strip away a "for all", and since that is always followed by a domain specification, we must also ungroup this:

```
pcalc_prop *prop_trim_universal_quantifier(pcalc_prop *prop) {
    if ((atom_is_for_all_x(prop)) &&
        (prop_match(prop, 2, QUANTIFIER_ATOM, NULL, DOMAIN_OPEN_ATOM, NULL))) {
        prop = prop_ungroup_after(prop, prop, NULL);
        prop = prop_delete_atom(prop, NULL);
        LOGIF(WORKINGS, "prop_trim_universal_quantifier: $D\n", prop);
    }
    return prop;
}
```

The function prop_trim_universal_quantifier is called from 7/vasp.

§**25.** Less ambitiously:

```
pcalc_prop *prop_remove_final_close_domain(pcalc_prop *prop, int *move_domain) {
    *move_domain = FALSE;
        TRAVERSE_VARIABLE(p);
        TRAVERSE_PROPOSITION(p, prop)
            if ((p->next == NULL) && (p->element == DOMAIN_CLOSE_ATOM)) {
                *move_domain = TRUE;
                return prop_delete_atom(prop, p_prev);
            }
    return prop;
}
```

The function prop_remove_final_close_domain is called from 6/sconv.

Binding and Substitution 6/vars

Purpose

To substitute constants into propositions in place of variables, and to apply quantifiers to bind any unbound variables.

6/vars.§1-5 Well-formedness; §6-9 Renumbering; §10 Binding; §11-14 Substitution; §15-16 A footnote on variable 0

Definitions

¶1. In any given proposition:

(a) a variable is *unused* if it is never mentioned as, or in, any term, and is not the variable of any quantifier;

(b) a variable is *bound* if it appears as the variable of any `QUANTIFIER_ATOM`;

(c) a variable is *free* if it is used but not bound.

These are mutually exclusive (no two can be true at the same time), and in any given proposition, each of the 26 variables is always either unused, bound or free.

In this section we are concerned with three operations applied to propositions:

(a) *substitution* means replacing each mention of a given variable with a given constant: for instance, changing x to 3 throughout ("substituting $x = 3$"). This has no effect if x is unused, and is illegal if x is bound, since it could produce nonsense like "for all 3, 3 is odd".

(b) *binding* means adding a new quantifier to a proposition, ranging some variable v. If v were unused this would be unlikely to be sensible (it would just make an inefficient way to test the size of the domain set), whereas if v were already a bound variable then the result would be a proposition which is no longer well-formed. So binding can only be done to free variables.

(c) *renumbering* means replacing each mention of a given variable v with another variable w. Clearly w needs to be initially unused, or we could accidentally change "v is greater than w" into "w is greater than w". But provided w is unused, the proposition's truth or otherwise remains unchanged.

¶2. Propositions with free variables are vague, and we would like to get rid of them. It can be very difficult to guess their values, just as subtle human understanding seems to be needed to interpret pronouns like "it" (see the enormous literature on the donkey anaphora problem in linguistics). So we aim to translate excerpts of source text into just two kinds of proposition:

(a) an *S-proposition* which has no free variables – such as the result of translating "The tree is in the Courtyard" or "Every door is open";

(b) an *SN-proposition* in which only variable 0 (x) is free – such as the result of translating "open containers which are in lighted rooms", which comes out to a proposition $\phi(x)$ testing whether x is one.

Whole English sentences or conditions make S-propositions, but descriptions make SN-propositions. (By renumbering, any proposition with one free variable can be made into an SN-proposition.)

---

§**1. Well-formedness.** It might seem logical to have a routine which takes a proposition ϕ and a variable v and returns its status – unused, free or bound. But this would be inefficient, since we want to work with all 26 at once, so instead we take a pointer to an array of `int` which needs to have (at least, but probably exactly) 26 entries, and on exit each entry is set to one of the following. In the course of doing that, it's easy to test whether variables are used properly – a bound variable should occur for the first time in its quantification, and should not reoccur once the subexpression holding the quantifier has finished. We set the `valid` flag if all is well.

```
define UNUSED_VST 1
define FREE_VST 2
define BOUND_VST 3
```

```
void vars_determine_status(pcalc_prop *prop, int *var_states, int *valid) {
    TRAVERSE_VARIABLE(p);
    int j, unavailable[26], blevel = 0, dummy;
    if (valid == NULL) valid = &dummy;
    *valid = TRUE;
    for (j=0; j<26; j++) { var_states[j] = UNUSED_VST; unavailable[j] = 0; }
    TRAVERSE_PROPOSITION(p, prop) {
        if (element_get_group(p->element) == OPEN_OPERATORS_GROUP) blevel++;
        if (element_get_group(p->element) == CLOSE_OPERATORS_GROUP) {
            blevel--;
            for (j=0; j<26; j++) if (unavailable[j] > blevel) unavailable[j] = -1;
        }
        for (j=0; j<p->arity; j++) {
            int v = term_variable_underlying(&(p->terms[j]));
            if (v >= 0) {
                if (unavailable[v] == -1) {
                    *valid = FALSE;
                    LOG("$o invalid because of %c unavailable\n", p, pcalc_vars[v]);
                }
                if (p->element == QUANTIFIER_ATOM) {
                    if (var_states[v] != UNUSED_VST) {
                        *valid = FALSE;
                        LOG("$o invalid because of %c Q for F\n", p, pcalc_vars[v]);
                    }
                    var_states[v] = BOUND_VST; unavailable[v] = blevel;
                } else {
                    if (var_states[v] == UNUSED_VST) var_states[v] = FREE_VST;
                }
            }
        }
    }
}
```

The function vars_determine_status is called from 6/tcpr, 6/asp and 6/cdefp.

§**2.** With just a little wrapping, this gives us the test of well-formedness.

```
int prop_is_well_formed(pcalc_prop *prop) {
    int status, var_states[26];
    if (prop_is_syntactically_valid(prop) == FALSE) return FALSE;
    vars_determine_status(prop, var_states, &status);
    if (status == FALSE) { LOG("Variable usage malformed\n"); return FALSE; }
    return TRUE;
}
```

The function prop_is_well_formed is called from 6/sconv, 6/tcpr and 6/defer.

§**3.** Occasionally we really do care only about one of the 26 variables:

```
int status_of_var(pcalc_prop *prop, int v) {
    int var_states[26];
    if (v == -1) return UNUSED_VST;
    vars_determine_status(prop, var_states, NULL);
    return var_states[v];
}
```

The function status_of_var is called from 6/sconv.

§**4.** To distinguish sentences from descriptions, the following can be informative:

```
int vars_number_free(pcalc_prop *prop) {
    int var_states[26], j, c;
    vars_determine_status(prop, var_states, NULL);
    for (j=0, c=0; j<26; j++) if (var_states[j] == FREE_VST) c++;
    LOGIF(WORKINGS, "There %s %d free variable%s in $D\n",
        (c==1)?"is":"are", c, (c==1)?"":"s", prop);
    return c;
}
```

The function vars_number_free is called from 6/sconv, 6/defer, 7/vasp and 8/knowc.

§**5.** While this gives us a new variable which can safely be added to an existing proposition:

```
int vars_find_unused(pcalc_prop *prop) {
    int var_states[26], j;
    vars_determine_status(prop, var_states, NULL);
    for (j=0; j<26; j++) if (var_states[j] == UNUSED_VST) return j;
    return 25;                                          the best we can do: it avoids crashes, at least...
}
```

The function vars_find_unused is called from 6/sconv and 6/simp.

§**6. Renumbering.** Another "vector operation" on variables: to renumber them throughout a proposition according to a map array. If `renumber_map[j]` is -1, make no change; otherwise each instance of variable j should be changed to this new number.

Note that because `QUANTIFIER_ATOM`s store the variable being quantified as a term, the following changes quantification variables as well as predicate terms, which is as it should be.

```
void vars_map(pcalc_prop *prop, int *renumber_map) {
    TRAVERSE_VARIABLE(p);
    int j;
    TRAVERSE_PROPOSITION(p, prop)
        for (j=0; j<p->arity; j++) {
            pcalc_term *pt = &(p->terms[j]);
            while (pt->function) pt=&(pt->function->fn_of);
            if ((pt->variable >= 0) && (renumber_map[pt->variable] >= 0))
                pt->variable = renumber_map[pt->variable];
        }
}
```

§**7.** The following takes any proposition and edits it so that the variables used are the lowest-numbered ones; moreover, variables are introduced in numerical order – that is, the first mentioned will be x, then the next introduced will be y, and so on.

```
void vars_renumber(pcalc_prop *prop) {
    TRAVERSE_VARIABLE(p);
    int j, k, renumber_map[26];
    for (j=0; j<26; j++) renumber_map[j] = -1;
    k = 0;
    TRAVERSE_PROPOSITION(p, prop)
        for (j=0; j<p->arity; j++) {
            int v = term_variable_underlying(&(p->terms[j]));
            if ((v >= 0) && (renumber_map[v] == -1)) renumber_map[v] = k++;
        }
    vars_map(prop, renumber_map);
}
```

The function vars_renumber is called from 6/sconv and 6/simp.

§**8.** This more complicated routine renumbers bound variables in one proposition in order to guarantee that none of them coincides with a variable used in a second proposition. This is needed in order to take the conjunction of two propositions, because "for all x, x is a door" and "there exists x such that x is a container" mean different things by x; they can only be combined in a single proposition if one of the x variables is changed to, say, y.

The surprising thing here is the asymmetry. Why do we only renumber to avoid clashes with bound variables in `prop` – why not free ones as well? The answer is that we use a form of conjunction in Inform which assumes that a free variable in ϕ has the same meaning as it does in ψ; thus in conjoining "open" with "lockable" we assume that the same thing is meant to be both open and lockable. If we renumbered to avoid clashes in free variables, we would produce a proposition meaning that one unknown thing is open, and another one lockable: that would have two free variables and be much harder to interpret.

If we pass a `query` parameter which is a valid variable number, the routine returns its new identity when renumbered.

```
int vars_renumber_bound(pcalc_prop *prop, pcalc_prop *not_to_overlap, int query) {
    int prop_vstates[26], nto_vstates[26], renumber_map[26];
    int j, next_unused;
    vars_determine_status(prop, prop_vstates, NULL);
    vars_determine_status(not_to_overlap, nto_vstates, NULL);
    for (j=0, next_unused=0; j<26; j++)
        if ((prop_vstates[j] == BOUND_VST) && (nto_vstates[j] != UNUSED_VST)) {
            ⟨Advance to the next variable not used in either proposition 9⟩;
            renumber_map[j] = next_unused++;
        } else renumber_map[j] = -1;
    vars_map(prop, renumber_map);
    if (query == -1) return -1;
    if (renumber_map[query] == -1) return query;
    return renumber_map[query];
}
```

The function vars_renumber_bound is called from 6/prop and 6/sconv.

§**9.** Again, we fall back on variable 25 if we run out. (This can only happen if the conjunction of the two propositions had 26 variables.)

⟨Advance to the next variable not used in either proposition 9⟩ ≡

```
    int k;
    for (k=next_unused; (k<26) &&
        (!((prop_vstates[k] == UNUSED_VST) && (nto_vstates[k] == UNUSED_VST))); k++) ;
    if (k == 26) next_unused = 25; else next_unused = k;
```

This code is used in §8.

§**10. Binding.** In this routine, we look for free variables and preface the proposition with ∃ quantifiers to bind them. For instance, $open(x)$ becomes $\exists x : open(x)$.

We first renumber the proposition's variables from left to right, and then quantify in reverse order – thus starting with the innermost free variable and working outwards (i.e., towards the left). Since at each stage we are prefacing the proposition, though, the net effect is that in the final proposition the previously free variables are bound in increasing order. For instance:

$$in(x, y) \quad \rightarrow \quad \exists y : in(x, y) \quad \rightarrow \quad \exists x : \exists y : in(x, y)$$

```
pcalc_prop *vars_bind_existential(pcalc_prop *prop) {
    int var_states[26], j;
    vars_renumber(prop);
    vars_determine_status(prop, var_states, NULL);
    for (j=25; j>=0; j--)
        if (var_states[j] == FREE_VST)
            prop = prop_insert_atom(prop, NULL,
                atom_QUANTIFIER_new(exists_quantifier, j, 0));
    return prop;
}
```

The function vars_bind_existential is called from 6/sconv.

§**11. Substitution.** In the following, we substitute term T (a constant or function) in place of variable v in the given proposition. We begin with two utility routines to substitute into the variable "underneath" a given term.

```
int substitute_v_in_term(pcalc_term *pt, int v, pcalc_term *t) {
    if (pt->variable == v) { *pt = *t; return TRUE; }
    if (pt->function) return substitute_v_in_term(&(pt->function->fn_of), v, t);
    return FALSE;
}
void substitute_nothing_in_term(pcalc_term *pt, pcalc_term *t) {
    if ((pt->constant) && (spec_is_nothing_object_constant(pt->constant))) { *pt = *t; return; }
    if (pt->function) substitute_nothing_in_term(&(pt->function->fn_of), t);
}
void substitute_term_in_term(pcalc_term *pt, pcalc_term *t) {
    if (pt->constant) { *pt = *t; return; }
    if (pt->function) substitute_term_in_term(&(pt->function->fn_of), t);
}
```

The function substitute_nothing_in_term is called from 6/simp.
The function substitute_term_in_term is called from 6/simp.

§**12.** Now the main procedure. This is one of those deceptive problems where the actual algorithm is obvious, but the circumstances when it can validly be applied are less so.

The difficulty depends on the term T being substituted in for the variable v. In general every term is a chain of functions with, right at the end, either a constant or a variable. If a constant is underneath, there is no problem at all. But if there is a variable underneath T – a VUT, as we say below – then it's possible that the substitution introduces circularities which would make it invalid. If that happens, we run into this:

```
define DISALLOW(msg) {
    if (verify_only) { *allowed = FALSE; return prop; }
    internal_error(msg);
}
```

§**13.** So the routine is intended to be called twice: once to ask if the situation looks viable, and once to perform the substitution itself.

```
pcalc_prop *vars_substitute_term(pcalc_prop *prop, int v, pcalc_term t,
    int verify_only, int *allowed, int *changed) {
    TRAVERSE_VARIABLE(p);
    if (verify_only) *allowed = TRUE;
    if ((v<0) || (v>=26)) DISALLOW("variable substitution out of range");
    if (prop_is_well_formed(prop) == FALSE) DISALLOW("substituting into malformed prop");
    ⟨Make sure the substitution would not fail because of a circularity 14⟩;
    if (verify_only) return prop;
    LOGIF(WORKINGS, "Substituting %c = $0 in: $D\n", pcalc_vars[v], &t, prop);
    TRAVERSE_PROPOSITION(p, prop) {
        int i;
        for (i=0; i<p->arity; i++)
            if (substitute_v_in_term(&(p->terms[i]), v, &t))
                *changed = TRUE;
    }
    if (prop_is_well_formed(prop) == FALSE) internal_error("substitution made malformed prop");
    return prop;
}
```

The function vars_substitute_term is called from 6/simp.

§14. The problem we might find, then, is that setting $v = T$ will be circular because T itself depends on v. There are two ways this can happen: first, T might be directly a function of v itself, i.e., the VUT might be v; second, T might be a function of some variable w which, by being quantified after v, is allowed to depend on it, in some way that we can't determine. (For examples of this, see "Simplifications".)

The general rule, then, is that T can contain only constants or variables which are free *within and after the scope of* v. (If w is bound outside the scope of v but after it, this means w didn't exist at the time that v did, and the attempted substitution would produce a proposition which isn't well-formed – w would occur before its quantifier.) We can check this condition pretty easily, it turns out:

⟨Make sure the substitution would not fail because of a circularity 14⟩ ≡

```
    if ((verify_only == FALSE) && (status_of_var(prop, v) == BOUND_VST))
        DISALLOW("substituting bound variable");
    int vut = term_variable_underlying(&t);
    if (vut >= 0) {
        int v_has_been_seen = FALSE;
        if (v == vut) DISALLOW("resubstituting same variable");
        TRAVERSE_PROPOSITION(p, prop) {
            if (v_has_been_seen == FALSE) {
                int i;
                for (i=0; i<p->arity; i++)
                    if (term_variable_underlying(&(p->terms[i])) == v)
                        v_has_been_seen = TRUE;
            }
            if ((p->element == QUANTIFIER_ATOM) && (p->terms[0].variable == vut) &&
                (v_has_been_seen))
                    DISALLOW("substituted value may be circular");
        }
    }
```

This code is used in §13.

§15. A footnote on variable 0. Because of the special status of x (variable 0) – the one allowed to be free in SN-propositions – we sometimes need to know about it. The range of a bound variable can be found by looking at its quantifier, but a free variable can remain ambiguous. The presence of a `KIND` atom will explicitly solve the problem for us; if we don't find one, though, we will simply have to assume that the set of objects is the domain of x. (We return `NULL` here, but that's the assumption which the caller will have to make.)

```
world_object *vars_kind_of_variable_0(pcalc_prop *prop) {
    TRAVERSE_VARIABLE(p);
    TRAVERSE_PROPOSITION(p, prop)
        if ((p->element == KIND_ATOM) && (p->terms[0].variable == 0)) {
            world_object *wo = kovko_get_kind(p->assert_kind_of_value);
            if (wo) return wo;
        }
    return NULL;
}
```

The function vars_kind_of_variable_0 is called from 8/refpt.

§**16.** And a quick way to substitute it:

```
pcalc_prop *substitute_var_0_in(pcalc_prop *prop, specification *spec) {
    int bogus;
    return vars_substitute_term(prop, 0, term_new_constant(spec), FALSE, NULL, &bogus);
}
```

The function substitute_var_0_in is called from 6/defer.

Propositional Form 6/pform

Purpose

The first of the three sources of propositions to conjure with: those which arise by conversion of existing data, in the form of type specifications.

Definitions

¶1. It is of course a sin for the same concept to have two different data representations in one computer program. But natural language subtly blurs the distinction between conditions and nouns in a way which lures us into this sin. Consider the word "closed". It's the name of a property, and as such is a noun; but it's also an adjective, and in a sentence like "if the marble tomb is closed" it clearly represents a condition.

In any case, we have two different needs. Every description must eventually be stored as a proposition, so that we can test or assert it. But we also need to be able to look at the structure of the original form of the description – was it one adjective, or two? With a common noun like "number", or a proper one like "Queen Mary"? And the propositional form disguises that, because of simplification, rearrangement and so on.

We therefore store simpler descriptions, such as "closed lockable door", by attaching a sort of transcription to their specifications; we write "closed, lockable" and "door" into relevant fields of an attached structure called the "description docket" of the SP. This is how such SPs are stored when parsed, and in the early stages of work on them.

More complicated descriptions with relative clauses, such as "women who like Mr Darcy", are stored in propositional form as soon as parsed.

Eventually we need to test or assert that a description applies to something. If the SP is still stored in docket form, we have to perform a conversion of that data into a (fairly simple) proposition before we can proceed. This is the main use for the single routine in this section.

---

§**1.** The following routine takes a SP and returns the best proposition it can, with a single unbound variable, to represent SP. In general, if V is a value, then this will be the proposition $is(x, V)$, but if it is possible to construe V as a list of one or more unary predicates (or `KIND` atoms, which are really unary predicates in disguise) then we return a logical conjunction of these predicates applied to the unbound x. For instance, the SP for the name of the property "closed" would become the proposition $closed(x)$.

```
pcalc_prop *prop_from_spec(specification *spec, int quantify) {
    pcalc_prop *prop = NULL;
    if (spec == NULL) return NULL;                                    the null description is universally true
    if (spec_get_proposition(spec)) return spec_get_proposition(spec);    a propositional form is already made
    int c1, c2;
    spec_get_calling(spec, &c1, &c2);
    if (c1 >= 0) prop = prop_concatenate(prop,
        atom_CALLED_new(c1, c2, term_new_variable(0), spec_get_described_kov(spec)));
    ⟨If this is a named constant for a KOV, but can be used adjectivally, convert it as such 2⟩;
    ⟨If it's an either-or property name, it must be being used adjectivally 3⟩;
    ⟨If it isn't a description at this point, it must be an ordinary noun 4⟩;
    ⟨Begin the proposition for a description-like SP with an atom for the head noun 5⟩;
    ⟨Concatenate atoms for any adjectives in the description 6⟩;
    if (quantify) ⟨Bind with a quantifier if the SP marks for one 7⟩;
    ⟨Typecheck the propositional form, and return 8⟩;
}
```

The function prop_from_spec is called from 6/sconv, 6/defer, 7/cosp, 8/knowc and 11/ap.

§**2.** For example, if we have written:

Colour is a kind of value. The colours are pink, green and black. A thing has a colour.

then "pink" is both a noun and an adjective. If SP is its representation as a noun, we return the proposition testing it adjectivally: *pink*(x).

```
⟨If this is a named constant for a KOV, but can be used adjectivally, convert it as such 2⟩ ≡
    quantity *q = spec_get_constant_quantity_if_any(spec);
    if (q) {
        property_name *pname = kov_get_coinciding_property(qty_kind_of_value(q));
        if (pname) {
            prop = prop_concatenate(prop,
                    atom_unary_PREDICATE_from_aph(qty_get_adjectival_phrase(q), FALSE));
            ⟨Typecheck the propositional form, and return 8⟩;
        }
    }
```

This code is used in §1.

§**3.** For example, if the SP is "scenery", we return the proposition *scenery*(x).

```
⟨If it's an either-or property name, it must be being used adjectivally 3⟩ ≡
    if (spec_is_CONSTANT_of_kova(spec, PROPERTY_TY)) {
        property_name *prn = PROPERTY_spec_to_property_name(spec);
        if (prn_is_either_or(prn)) {
            prop = prop_concatenate(prop, atom_unary_PREDICATE_from_aph(
                    prn_either_or_get_aph(prn), FALSE));
            ⟨Typecheck the propositional form, and return 8⟩;
        }
    }
```

This code is used in §1.

§**4.** For example, if the SP is the number 17, we return the proposition *is*$(x, 17)$.

```
⟨If it isn't a description at this point, it must be an ordinary noun 4⟩ ≡
    if ((species_is(spec, DESCRIPTION_SPC) == FALSE) &&
        (spec_is_CONSTANT_of_kova(spec, OBJECT_DESCRIPTION_TY) == FALSE) &&
        (spec_is_CONSTANT_of_kova(spec, VALUE_DESCRIPTION_TY) == FALSE)) {
        prop = prop_concatenate(prop, prop_x_is_constant(spec_copy(spec)));
        ⟨Typecheck the propositional form, and return 8⟩;
    }
```

This code is used in §1.

§**5.** A description need not have any heading noun – "open door" does ("door"), but "lockable" does not. If there is such a noun, it will either be a common noun – the name of a kind or KOV – or a proper noun – the name of a specific object. Common nouns translate directly into `KIND_ATOM`s, while proper nouns can be treated exactly as we would treat a noun like "54".

⟨Begin the proposition for a description-like SP with an atom for the head noun 5⟩ ≡

```
pcalc_prop *head = NULL;
if (spec_get_described_kind(spec))
    head = atom_KIND_object_new(spec_get_described_kind(spec), term_new_variable(0));
else if (spec_get_described_kov(spec))
    head = atom_KIND_value_new(spec_get_described_kov(spec), term_new_variable(0));
else if (spec_get_described_object(spec)) {
    specification *the_object = world_object_to_OBJECT_spec(spec_get_described_object(spec));
    head = prop_x_is_constant(the_object);
}
if (head) prop = prop_concatenate(prop, head);
```

This code is used in §1.

§**6.** So now we extract the linked list of adjectives attached to the SP (if any) and convert them into atoms:

⟨Concatenate atoms for any adjectives in the description 6⟩ ≡

```
adjective_list_entry *ale;
LOOP_THROUGH_ADJECTIVE_LIST(ale, spec) {
    adjectival_phrase *aph = get_adjective_from_list_entry(ale);
    int negated = FALSE;
    if (adjective_used_positively(ale) == FALSE) negated = TRUE;
    prop = prop_concatenate(prop, atom_unary_PREDICATE_from_aph(aph, negated));
}
```

This code is used in §1.

§**7.** This is something we don't always want:

⟨Bind with a quantifier if the SP marks for one 7⟩ ≡

```
if (spec_get_quantifier(spec)) {
    if (spec_get_quantifier(spec) != exists_quantifier)
        prop = prop_concatenate(atom_new(DOMAIN_OPEN_ATOM), prop);
    prop = prop_concatenate(atom_QUANTIFIER_new(spec_get_quantifier(spec), 0,
        spec_get_quantification_parameter(spec)), prop);
    if (spec_get_quantifier(spec) != exists_quantifier)
        prop = prop_concatenate(prop, atom_new(DOMAIN_CLOSE_ATOM));
}
```

This code is used in §1.

§**8.** In all cases, we finish by doing the following. In the one-atom noun cases it's a formality, but we want to enforce the rule that all propositions created in Inform go through type-checking, so:

⟨Typecheck the propositional form, and return 8⟩ ≡

```
prop_type_check(prop, tc_no_problem_reporting());
return prop;
```

This code is used in §1,2,3,4,1,2,3,4,1,2,3,4.

Tree Conversions 6/treec

Purpose

The second of the three sources of propositions to conjure with: those which arise from subtrees constructed by the A-parser.

§**1. Elementary propositions.** The S-parser attacks whole sentences, but the A-parser more cautiously takes on only fragments, and so it makes much shorter propositions – usually with a single free variable representing an object or value to which something must be done.

We start with some elementary propositions which create things, by asserting their existence.

```
pcalc_prop *prop_to_make_a_kind(void) {
    return atom_ISAKIND_new(term_new_variable(0));
}
pcalc_prop *prop_to_make_a_kov(void) {
    return atom_ISAKOV_new(term_new_variable(0));
}
pcalc_prop *prop_to_make_a_var(void) {
    return atom_ISAVAR_new(term_new_variable(0));
}
pcalc_prop *prop_to_create_something(kind_of_value *kov, int w1, int w2) {
    pcalc_prop *prop = atom_QUANTIFIER_new(exists_quantifier, 0, 0);
    if (kovko_get_kind(kov))
        prop = prop_concatenate(prop,
            atom_KIND_object_new(kovko_get_kind(kov), term_new_variable(0)));
    else if ((kov) && (is_kova(kov, OBJECT_TY) == FALSE))
        prop = prop_concatenate(prop,
            atom_KIND_value_new(kov, term_new_variable(0)));
    if (w1 >= 0)
        prop = prop_concatenate(prop,
            atom_CALLED_new(w1, w2, term_new_variable(0), kov));
    return prop;
}
```

The function prop_to_make_a_kind is called from 8/creat.

The function prop_to_make_a_kov is called from 8/creat and 9/prop.

The function prop_to_make_a_var is called from 8/creat.

The function prop_to_create_something is called from 8/creat, 9/prop, 9/pp and 10/tab.

§**2.** A proposition to assert that an object has a given kind:

```
pcalc_prop *prop_to_set_kind(world_object *wo, world_object *k) {
    return atom_KIND_value_new(kovko(k), term_new_variable(0));
}
```

The function prop_to_set_kind is called from 8/knowc.

§**3.** Now propositions to assert that relations hold:

```
pcalc_prop *prop_to_set_mapping_relation(binary_predicate *bp, world_object *wo) {
    specification *spec;
    if (wo) spec = world_object_to_OBJECT_spec(wo);
    else spec = new_nothing_object_constant();
    return atom_binary_PREDICATE_new(bp,
        term_new_variable(0), term_new_constant(spec));
}
pcalc_prop *prop_to_set_relation(binary_predicate *bp,
    world_object *wo0, specification *spec0, world_object *wo1, specification *spec1) {
    pcalc_term pt0, pt1;
    pcalc_prop *prop;
    if (wo0) pt0 = term_new_constant(world_object_to_OBJECT_spec(wo0));
    else pt0 = term_new_constant(spec0);
    if (wo1) pt1 = term_new_constant(world_object_to_OBJECT_spec(wo1));
    else pt1 = term_new_constant(spec1);
    prop = atom_binary_PREDICATE_new(bp, pt0, pt1);
    int dummy;
    prop = simp_make_kinds_of_value_explicit(prop, &dummy);
    return prop;
}
```

The function prop_to_set_mapping_relation is called from 8/relv.
The function prop_to_set_relation is called from 8/knowp and 8/relv.

§**4.** Property provision is itself a relation:

```
pcalc_prop *prop_to_provide_property(property_name *prn) {
    return atom_binary_PREDICATE_new(a_provides_b_predicate,
        term_new_variable(0), term_new_constant(property_name_to_PROPERTY_spec(prn)));
}
pcalc_prop *prop_to_set_property(property_name *prn, specification *val) {
    if (val == NULL) return NULL;
    return atom_binary_PREDICATE_new(prn_get_setting_bp(prn),
        term_new_variable(0), term_new_constant(val));
}
```

The function prop_to_provide_property is called from 5/rel, 9/pp and 10/tab.
The function prop_to_set_property is called from 8/knowp.

§**5.** "Everywhere" and "here":

```
pcalc_prop *prop_to_put_everywhere(void) {
    return atom_EVERYWHERE_new(term_new_variable(0));
}
pcalc_prop *prop_to_put_here(void) {
    return atom_HERE_new(term_new_variable(0));
}
```

The function prop_to_put_everywhere is called from 8/relv.
The function prop_to_put_here is called from 8/relv.

§**6. Property setting.** Sometimes the A-parser wants to assert that a given property has the value whose text can be found in a node `py`...

```
pcalc_prop *prop_from_property_subtree(property_name *prn, parse_node *py) {
    return prop_to_set_property(prn, property_value_from_property_subtree(prn, py));
}
```

The function prop_from_property_subtree is called from 8/knowp.

§**7.** ...and sometimes it wants to assert a more elaborate list, such as "carrying capacity 10 and weight 4kg" or "lockable unlocked". This is a syntax allowed by the A-parser but not the S-parser, and here is where we deal with it.

```
pcalc_prop *prop_from_property_list(parse_node *p, kind_of_value *kov) {
    pcalc_prop *prop = NULL;
    if (p) {
        switch(pn_get_node_type(p)) {
            case AND_NT:
                for (p = p->down; p; p = p->next)
                    prop = prop_conjoin(prop, prop_from_property_list(p, NULL));
                break;
            case PROPERTYLIST_NT:
                ⟨Conjoin atoms to assert from a property list 8⟩;
                break;
            case ADJECTIVE_NT:
                ⟨Conjoin atoms to assert from an adjective node 11⟩;
                break;
            default: internal_error_on_node_type(p);
        }
    }
    if ((prop) && (kov))
        prop = prop_conjoin(atom_KIND_value_new(kov, term_new_variable(0)), prop);
    return prop;
}
```

The function prop_from_property_list is called from 8/knowp.

§**8.** Recall that a PROPERTYLIST_NT node is unannotated, as yet, and we have to parse the text to find what which property is referred to.

⟨Conjoin atoms to assert from a property list 8⟩ ≡

```
property_name *prn = NULL;
int pw1 = -1, pw2 = 0, vw1 = -1, vw2 = 0;
⟨Divide the property list entry into property name and value text 9⟩;
if ((pw1 >= 0) && (pw1 <= pw2)) prn = parse_property_name(pw1, pw2);
if (prn == NULL) ⟨Issue a problem message for no-such-property 10⟩;
if ((vw1 >= 0) && (vw1 <= vw2)) {                                   a value is supplied...
    if (prn_is_either_or(prn)) {
        quote_source(1, current_sentence);
        quote_words(2, p->word_ref1, p->word_ref2);
        quote_property(3, prn);
        quote_words(4, vw1, vw2);
        handmade_problem(_P_(C6WithEitherOrValue));
        issue_problem_segment(
            "The sentence '%1' seems to be trying to create something which "
            "has '%2', where the %3 property is being set equal to %4. But "
            "this made no sense to me, because %3 is an either/or property "
            "and cannot have a value.");
        issue_problem_end();
        return NULL;
    }
    parse_node *pn = new_nounphrase_worldly(vw1, vw2, FALSE);
    resolve_references(pn);
    prop = prop_conjoin(prop, prop_from_property_subtree(prn, pn));
} else {                                                            no value is supplied...
    if (prn_is_either_or(prn) == FALSE) {
        quote_source(1, current_sentence);
        quote_words(2, p->word_ref1, p->word_ref2);
        quote_property(3, prn);
        quote_kov(4, prn_get_kind_of_value(prn));
        handmade_problem(_P_(C6WithValuelessValue));
        issue_problem_segment(
            "The sentence '%1' seems to be trying to create something which "
            "has '%2', where the %3 property is being set in some way. But "
            "this made no sense to me, because %3 is a value property (it "
            "needs to be %4) and no value for it was given here.");
        issue_problem_end();
        return NULL;
    }
    prop = prop_conjoin(prop, prop_from_property_subtree(prn, NULL));
}
```

This code is used in §7.

§**9.** The node has text in the form "property name property value", with no obvious division of punctuation between the two. What makes matters worse is that we do not yet know all the property names, nor do we have the ability to discern values. So we seek the division by

(i) trying to find the longest known property name at the start of the text; if there is no known name,
(ii) we see if the final word of the text is a literal, such as a number or a quoted text, and if so we assume this is the entire property value and that the rest is property name; and otherwise
(iii) we assume the property name is one word only.

⟨Divide the property list entry into property name and value text 9⟩ ≡

```
if ((p->word_ref1 < 0) || (p->word_ref2 < p->word_ref1)) {
    assertion_problem(_P_(BelievedImpossible),
        "this looked to me as if it might be trying to create something "
        "which has certain properties",
        "and that made no sense on investigation. This sometimes happens "
        "if a sentence uses 'to have' oddly?");
    return NULL;
}
int name_length = match_longest_pname(p->word_ref1, p->word_ref2);
if (name_length < 0) {
    name_length = 1;
    if (is_a_literal(p->word_ref2, p->word_ref2))
        name_length = p->word_ref2 - p->word_ref1;
}
pw1 = p->word_ref1; pw2 = p->word_ref1+name_length-1;
vw1 = pw2+1; vw2 = p->word_ref2;
```

This code is used in §8.

§**10.**

⟨Issue a problem message for no-such-property 10⟩ ≡

```
LOG("Failed property list: pname = <$W>; pval = <$W>\n", pw1, pw2, vw1, vw2);
assertion_problem(_P_(C6BadPropertyList),
    "this looked to me as if it might be trying to create something "
    "which has certain properties",
    "and that made no sense on investigation. This sometimes happens "
    "if a sentence uses 'with' a little too liberally, or to specify "
    "a never-declared property. For instance, 'An antique is a kind of "
    "thing with an age.' would not be the right way to declare the "
    "property 'age' (because it does not tell Inform what kind of "
    "value this would be). Instead, try 'An antique is a kind of "
    "thing. An antique has a number called age.' It would then be all "
    "right to say 'The Louis Quinze chair is an antique with age 241.'");
return NULL;
```

This code is used in §8.

§**11.** An `ADJECTIVE_NT` node, on the other hand, is annotated with a valid property name `property` already, and may also have a value ready to put into that property, stored in `evaluation`. Nodes like this have been created from descriptions like "open openable door in the kitchen", and it's important not to lose the location information ("in the kitchen"): so the full evaluation of the original phrase is preserved in the `full_phrase_evaluation` field.

⟨Conjoin atoms to assert from an adjective node 11⟩ ≡

```
int negate_me = FALSE;
if (pn_int_annotation(p, negated_boolean_ANNOT)) negate_me = TRUE;
if (pn_get_aph(p) == NULL)
    internal_error("Bogus adjective at assert_property_list");
if ((pn_get_full_phrase_evaluation(p) != NULL) &&
    (spec_get_proposition(pn_get_full_phrase_evaluation(p)))) {
    prop = prop_conjoin(prop, spec_get_proposition(pn_get_full_phrase_evaluation(p)));
    pn_set_full_phrase_evaluation(p, NULL);
}
if (negate_me) prop = prop_conjoin(prop, atom_new(NEGATION_OPEN_ATOM));
prop = prop_conjoin(prop, atom_unary_PREDICATE_from_aph(pn_get_aph(p), FALSE));
if (negate_me) prop = prop_conjoin(prop, atom_new(NEGATION_CLOSE_ATOM));
```

This code is used in §7.

Sentence Conversions 6/sconv

Purpose

The third of the three sources of propositions to conjure with: those which arise by the parsing of complex sentence trees in the S-grammar.

6/sconv.§1-15 The meaning of a sentence; §16 Simplification; §17-26 The meaning of a noun phrase

---

§**1. The meaning of a sentence.** This section provides a single, but crucial, function to the rest of Inform: it takes a sentence subtree output by the S-parser and turns it into a proposition.

The sentence subtree can be headed by either a `SV_PRODUCTION`, representing a whole sentence, which we turn into a proposition with no free variables; or by an `SN_PRODUCTION`, representing a description which includes a relative clause, such as "an animal which can see the player". In this section we will loosely refer to the text parsed by either sort of subtree as the "sentence".

The basic idea is simple. The sentence will have a verb phrase (VP), together with two noun phrases: a subject phrase (SP) and object phrase (OP). English is an SVO language, so phrases (usually) occur in the sequence SP-VP-OP. In "Katy examines the painting", "Katy" is the SP and "painting" is the OP. (Although the subject is sometimes the more active participant, that isn't always the case: in "the painting is examined by Katy", "the painting" is now the SP. The subject is what the sentence talks about.) At this point in the program, the S-parser has turned the sentence into a neat tree structure identifying the SP, VP and OP. We need to find meanings for the SP, VP and OP independently, and then combine these into a single proposition representing the meaning of the whole sentence.

```
int conv_log_depth = 0;                                   recursion depth: used only to clarify the debugging log
pcalc_prop *S_subtree_to_proposition(meaning_list *ml, pcalc_term *subject_of_sentence) {
    int w1, w2, SV_not_SN = FALSE;
    meaning_list *subject_phrase_subtree = NULL, *object_phrase_subtree = NULL;
    pcalc_prop *subject_phrase_prop, *object_phrase_prop;
    pcalc_term subject_phrase_term, object_phrase_term;
    binary_predicate *verb_phrase_relation = NULL;
    int verb_phrase_negated = FALSE;
    pcalc_prop *sentence_prop = NULL;
    ⟨Check the tree position makes sense, and tell the debugging log 2⟩;
    if (ml_production(ml_down(ml)) == THERE_PRODUCTION) {
        ⟨Handle a THERE subtree, used for "there is/are NP" 4⟩;
    } else {
        ⟨Find meaning of the VP as a relation and a parity 5⟩;
        ⟨Find meanings of the SP and OP as propositions and terms 10⟩;
        ⟨Bind up any free variable in the OP and sometimes the SP, too 11⟩;
        ⟨Combine the SP, VP and OP meanings into a single proposition for the sentence 15⟩;
    }
    ⟨Simplify the resultant proposition 16⟩;
    ⟨Tell the debugging log what the outcome of the sentence was 3⟩;
    if (subject_of_sentence) *subject_of_sentence = subject_phrase_term;
    return sentence_prop;
}
```

The function S_subtree_to_proposition is called from 5/mlc and 13/test.

§**2.** Like all good computer-science algorithms, this is essentially divide and conquer: we handle a multi-clause sentence by recursive use of two routines, `S_subtree_to_proposition` at each SV- or SN-node, and `NP_subtree_to_proposition` at each noun phrase. These are rather like coroutines: the recursion is always S calls NP calls S calls NP... and so on, the entry point always being S, and the bottom leaves of the recursion always being NPs. For example:

```
S_subtree_to_proposition "a man is in a room which is adjacent to the Garden"
    NP_subtree_to_proposition "a man"
    NP_subtree_to_proposition "a room which is adjacent to the Garden"
        S_subtree_to_proposition "a room which is adjacent to the Garden"
            NP_subtree_to_proposition "a room"
            NP_subtree_to_proposition "the Garden"
```

⟨Check the tree position makes sense, and tell the debugging log 2⟩ ≡

```
if (ml == NULL) internal_error("S_subtree_to_proposition on null S-subtree");
switch(ml_production(ml)) {
    case SN_PRODUCTION: SV_not_SN = FALSE; break;
    case SV_PRODUCTION: SV_not_SN = TRUE; break;
    default: internal_error("S_subtree_to_proposition on non-S-subtree");
}
s_subtree_error_set_position(ml);
if ((conv_log_depth > 0) && (SV_not_SN))
    internal_error("S_subtree_to_proposition on S-subtree with an SV- as lower node");
ml_get_text(ml, &w1, &w2);
if (conv_log_depth == 0) LOGIF(CALCULUS, "----------\n");
conv_log_depth++;
LOGIF(CALCULUS, "[%d] Starting S_subtree_to_proposition on: <$W>\n", conv_log_depth, w1, w2);
```

This code is used in §1.

§**3.** And similarly, on the way out:

⟨Tell the debugging log what the outcome of the sentence was 3⟩ ≡

```
LOGIF(CALCULUS, "[%d] S_subtree_to_proposition: $W --> $D\n",
    conv_log_depth, w1, w2, sentence_prop);
conv_log_depth--;
```

This code is used in §1.

§**4.** The English verb "to be" has the syntactic quirk that it likes to have both SP and OP, even when only when thing is being discussed. We say "it is raining" and "there are seven continents", inserting "it" and "there" even though they refer to nothing at all, because we don't like to say "raining is" or "seven continents are". (There are rare exceptions, but usually sportive ones. In Stoppard's play *Jumpers*, the theologian opens his lecture by asking: "Is God?", then wonders if it should be "Are God?" – but he is using the wonkiness of this grammar to make points.)

At any rate Inform parses a sentence in the form "There is X" or "There are Y" into a simpler form of tree with just one noun phrase, and no verb phrase at all. We convert the noun phrase to a proposition ϕ in which x is free, then bind it with $\exists x$ to form $\exists x : \phi(x)$, making an S-proposition as required.

⟨Handle a THERE subtree, used for "there is/are NP" 4⟩ ≡

```
if (SV_not_SN == FALSE) internal_error("THERE subtree misplaced");
specification *spec = DC_subtree_to_spec(
    ml_down(ml_down(ml_right(ml_down(ml_right(ml_down(ml)))))), FALSE);
sentence_prop = prop_from_spec(spec, TRUE);
sentence_prop = vars_bind_existential(sentence_prop);
```

This code is used in §1.

§**5.** Here we only locate the subject and object subtrees – their meanings we leave for later – but we do find the content of the verb phrase. Given the combination of verb and preposition usage (the latter optional), we extract a binary predicate B plus a parity flag indicating if it is meant positively or negatively.

Of course a VU also records the tense of the verb, but we ignore that here. It has no effect on the proposition, only on the moment in history to which it can be applied.

⟨Find meaning of the VP as a relation and a parity 5⟩ ≡

```
meaning_list *verb_phrase_subtree;
verb_usage *vu; preposition_usage *pu = NULL;
subject_phrase_subtree = ml_down(ml);
if (subject_phrase_subtree == NULL) s_subtree_error("SP subtree null");
verb_phrase_subtree = ml_right(subject_phrase_subtree);
if (verb_phrase_subtree == NULL) s_subtree_error("VP subtree null");
if (ml_down(verb_phrase_subtree) == NULL) s_subtree_error("VP subtree broken");
object_phrase_subtree = ml_right(ml_down(verb_phrase_subtree));
if (object_phrase_subtree == NULL) s_subtree_error("OP subtree null");
vu = RETRIEVE_POINTER_verb_usage(ml_get_attached_data(ml_down(verb_phrase_subtree)));
if (vu == NULL) s_subtree_error("verb null");
if ((SV_not_SN == FALSE) && (vu_get_tense_used(vu) != IS_TENSE))
    ⟨Disallow the past tenses in relative clauses 6⟩;
if (ml_down(ml_down(verb_phrase_subtree))) {
    if (ml_production(ml_down(ml_down(verb_phrase_subtree))) != PREP_PRODUCTION)
        s_subtree_error("child of VERB not a PREP");
    pu = RETRIEVE_POINTER_preposition_usage(
        ml_get_attached_data(ml_down(ml_down(verb_phrase_subtree))));
    if (pu == NULL) s_subtree_error("PREP null");
}
if (pu) verb_phrase_relation = pu_get_meaning(pu);
else verb_phrase_relation = vu_get_meaning(vu);
verb_phrase_negated = (vu_is_used_negatively(vu))?TRUE:FALSE;
if ((pu) && (pu_implicitly_negates(pu)))
    verb_phrase_negated = (verb_phrase_negated)?FALSE:TRUE;
```

This code is used in §1.

§**6.** A sad necessity:

⟨Disallow the past tenses in relative clauses 6⟩ ≡

```
sentence_problem(_P_(C6PastSubordinate),
    "subordinate clauses have to be in the present tense",
    "so 'the Black Door was open' is fine, but not 'if the Black Door is "
    "something locked which had been open'. Only the main verb can be in "
    "the past tense.");
```

This code is used in §5.

§**7. First Rule.** The "meaning" of a noun phrase is a pair (ϕ, t), where ϕ is a proposition and t is a term. We read this as "t such that ϕ is true". Exactly one of the following will always be true:

(a) If the NP talks about a single definite thing C, then $t = C$ and $\phi = T$, the empty proposition.

(b) If the NP talks about a single definite thing C but imposes conditions about its current situation, then $t = v$ for some variable v and $\phi = \exists v : is(v, C) \wedge \psi$ where ψ is a description of the conditions with no free variables and which does not use v.

(c) If the NP talks about a single but vague thing, identifying it only by its current situation, then $t = v$ for some variable v and ϕ is a proposition having v as its unique free variable.

(d) If the NP talks about a range, number or proportion of things, then $t = v$ for some variable v and $\phi = Qv : v \in \{v \mid \psi(v)\}$, where v is the unique free variable of ψ, and Q is a generalised quantifier which is not $\exists$.

§**8.** As examples of all four cases:

(a) "Reverend Green" returns $t =$ `Green`, $\phi = T$ – a single definite thing.

(b) "Colonel Mustard in the Library" returns $t = x$ such that $\phi = \exists x : is(x, \texttt{Mustard}) \wedge in(\texttt{Mustard}, \texttt{Library})$ – a single definite thing but subject to conditions.

(c) "A suspect carrying the lead piping" returns $t = x$ and $\phi = suspect(x) \wedge carries(x, \texttt{piping})$ – a single but vague thing.

(d) "All the weapons in the Billiard Room" returns $t = x$ and $\phi = \forall x : x \in \{x \mid weapon(x) \wedge in(x, \texttt{Billiard})\}$ – a range of things.

§**9.** Thus ϕ can contain at most 1 free variable, and then only in case (c). But why does it do so at all? Why do we return "an open door" as $open(x) \wedge door(x)$? It would be more consistent with the way we handle "two open doors" to return it as $\exists x : open(x) \wedge door(x)$. The answer is that if we were only parsing whole sentences (SV-trees) then it would make no difference, because x ends up bound by $\exists x$ anyway when the final sentence is being put together. But we also want to parse descriptions. Consider:

(1) let L be the list of open doors in the Dining Room;

(2) let L be the list of two open doors in the Dining Room;

Here (1) is legal in Inform, (2) is not, because it implies a requirement about the list which will probably not be satisfied. (Maybe there are three open doors there, maybe none.) In case (1), `NPstp` applied to "open doors" will return $open(x) \wedge door(x)$, whose free variable x can become any single object we might want to test for open-door-ness. But in case (2), `NPstp` applied to "two open doors" will return $V_{=2}x : open(x) \wedge door(x)$, and here x is bound, and can't be set equal to some object being tested.

Or to put this more informally: it's possible for a single item to be an "open door", but it's not possible for a single item to be (say) "more than three open doors". So ϕ contains a free variable if and only if the NP describes a single but vague thing.

§**10.** The First Rule is implemented by `NP_subtree_to_proposition` below, and we apply it independently to the SP and OP:

⟨Find meanings of the SP and OP as propositions and terms 10⟩ ≡

```
subject_phrase_prop =
    NP_subtree_to_proposition(&subject_phrase_term, subject_phrase_subtree,
        bp_term_kind_of_value(verb_phrase_relation, 0));
object_phrase_prop =
    NP_subtree_to_proposition(&object_phrase_term, object_phrase_subtree,
        bp_term_kind_of_value(verb_phrase_relation, 1));
LOGIF(CALCULUS, "[%d] subject NP: $0 such that: $D\n",
    conv_log_depth, &subject_phrase_term, subject_phrase_prop);
LOGIF(CALCULUS, "[%d] object NP: $0 such that: $D\n",
    conv_log_depth, &object_phrase_term, object_phrase_prop);
```

This code is used in §1.

§**11.** The First Rule tells us that SP and OP are now each represented by propositions with either no free variables, or just one, and then only if the phrase refers to a single but vague thing.

So far we have treated the subject and object exactly alike, running the same computation on meaning lists generated by the same method. This is the first point at which the placement as subject rather than object will start to make a difference:

(i) we always bind a free variable in the object, but
(ii) we only bind a free variable in the subject if we are looking at the topmost verb in a whole sentence (i.e., for an SV rather than SN subtree).

The SP is called the "subject phrase" because it contributes the subject of a sentence: what it is a sentence about. For instance, for an SV-subtree for "a woman is carrying an animal", we produce $\phi_S = \exists x : \mathit{woman}(x)$ and $\phi_O = \exists x : \mathit{animal}(x)$. But for an SN-subtree for "a woman carrying an animal" – which vaguely describes something, in a way that can be tested for any given candidate x – we produce $\phi_S = \mathit{woman}(x)$ with x remaining free.

⟨Bind up any free variable in the OP and sometimes the SP, too 11⟩ ≡

```
if (SV_not_SN) subject_phrase_prop = vars_bind_existential(subject_phrase_prop);
object_phrase_prop = vars_bind_existential(object_phrase_prop);
```

This code is used in §1.

§**12.** Of all the thousands of paragraphs of code in Inform, this is the one which most sums up "how it works". We started with a sentence in the source text, and have now extracted the following components of its meaning: the subject phrase (SP) has become the term t_S subject to the proposition ϕ_S being true; the object phrase (OP) is similarly now a pair t_O such that ϕ_O. From the verb phrase (VP), we have found a binary relation B, meant either in a positive sense (B does hold) or a negative one (it doesn't). And now:

Second Rule. The combined "meaning" Σ is as follows:

(1) if we are parsing a whole sentence (i.e., an SV-subtree), or ϕ_S is not in the form $Qx \in \{x \mid \theta(x)\}$, then:

$$\Sigma = \begin{cases} \phi_S \wedge \phi'_O \wedge B(t_S, t'_O) & \text{if sense positive} \\ \phi_S \wedge \neg(\phi'_O \wedge B(t_S, t'_O)) & \text{if sense negative} \end{cases}$$

(2) if we are parsing a relative clause (i.e., an SN-subtree), and ϕ_S is of the form $Qx \in \{x \mid \theta(x)\}$, then:

$$\Sigma = \begin{cases} Qx \in \{x \mid \theta(x) \wedge \phi'_O \wedge B(t_S, t'_O)\} & \text{if sense positive} \\ Qx \in \{x \mid \theta(x) \wedge \neg(\phi'_O \wedge B(t_S, t'_O))\} & \text{if sense negative} \end{cases}$$

Here ϕ'_O and t'_O are ϕ_O and t_O modified to relabel its variables so that there are no accidental clashes with variables named in ϕ_S.

§**13.** That simple rule took the author a long, long time to work out, so it may be worth a little discussion:

(a) The Second Rule is a generalisation of the way comparison operators like `==` or `>=` work in conventional programming languages. For if t_S and t_O are both constants, and ϕ_S and ϕ_O both empty, we obtain just $B(t_S, t_O)$ and $\neg(B(t_S, t_O))$. For instance, "score is 10" becomes just $is(\texttt{score}, 10)$, which compiles just to `(score == 10)`.

(b) In general, though, the meaning of an English sentence is not just that the verb is true, but also that the subject and object make sense. For "a woman is carrying an animal" to be true, there has to be such a woman, and such an animal. This is the content of ϕ_S and ϕ_O. So the formula above can be read as "the subject makes sense, and the object makes sense, and they relate to each other in the way that the verb claims".

(c) In the case of negation, it's important that we produce $\phi_S \wedge \neg(\phi'_O \wedge B(t_S, t_O))$ rather than $\phi_S \wedge \phi'_O \wedge \neg(B(t_S, t_O))$. To see the difference, consider the sentence "The box does not contain three coins". The first formula, which is correct, means roughly "it's not true that there are three coins x such that x is in the box", whereas the second, wrong, means "three coins x exist such that x is not in the box".

(d) The difference between cases (1) and (2) is actually very slight. Case (2) arises only when a relative clause is qualifying the range of a collection of things: for instance, in "every man who is in the Garden", we have $\phi_S = \forall x \in \{x \mid man(x)\}$ and then need to apply the relation $in(x, \texttt{Garden})$. If we used formula (1) we would then have

$$\Sigma = \forall x \in \{x \mid man(x)\} : in(x, \texttt{Garden})$$

which means "every man is in the Garden" – making a statement about everything covered by ϕ_S, not restricting the coverage of ϕ_S, as a relative clause should. Using formula (2), however, we get:

$$\Sigma = \forall x \in \{x \mid man(x) \wedge in(x, \texttt{Garden})\}$$

Note that these formulae are identical except for what we might call punctuation.

(e) The modification needed to make ϕ'_O out of ϕ_O is pretty well inconsequential. It makes no difference to the meaning of ϕ_O. Consider the example "a woman is carrying an animal" once again. $t_S = x$ and $\phi_S = woman(x)$, which use x; and on the other hand $t_O = x$ and $\phi_O = animal(x)$, which also use x. Clearly we don't mean the same x on both sides, so we relabel the OP to get y such that $animal(y)$. There is not really any asymmetry between the SP and OP here, because it would have been just as good to relabel the SP.

§**14.** **Lemma.** The result Σ of the Second Rule is a proposition containing either 0 or 1 free variables; Σ has 1 free variable if and only if we are converting an SN-subtree, and the subject phrase of the sentence describes a single thing vaguely.

Proof. ϕ_O contains no free variables, since we bound it up above, and the same must be true of its relabelled version ϕ'_O. If we have an SV-subtree then ϕ_S similarly contains no free variables; we only leave it unbound for an SN-subtree. In that case, the First Rule tells us that it has a free variable if and only if the SP describes a single thing vaguely. The only other content of Σ is the predicate $B(t_S, t'_O)$, so extra free variables can only appear if either t_S or t'_O contains a variable not already seen in ϕ_S and ϕ'_O. But cases (b), (c) and (d) of the First Rule make clear that in any pair (t, ϕ) arising from a noun phrase, either t is a constant or else it is a variable appearing in ϕ. So the terms of the final B predicate in Σ cannot add new free variables, and the lemma is proved.

By similar argument, if ϕ_S and ϕ_O are well-formed propositions (syntactically valid and using variables either freely or within the scope of quantification) then so is Σ.

§**15.** Now to implement the Second Rule:

⟨Combine the SP, VP and OP meanings into a single proposition for the sentence 15⟩ ≡

```
int use_case_2 = FALSE;
if (SV_not_SN == FALSE)
    subject_phrase_prop = prop_remove_final_close_domain(subject_phrase_prop, &use_case_2);
object_phrase_term.variable =
    vars_renumber_bound(object_phrase_prop, subject_phrase_prop, object_phrase_term.variable);
sentence_prop = subject_phrase_prop;
if (verb_phrase_negated)
    sentence_prop = prop_concatenate(sentence_prop, atom_new(NEGATION_OPEN_ATOM));
sentence_prop = prop_concatenate(sentence_prop, object_phrase_prop);
sentence_prop = prop_concatenate(sentence_prop,
    atom_binary_PREDICATE_new(verb_phrase_relation, subject_phrase_term, object_phrase_term));
if (verb_phrase_negated)
    sentence_prop = prop_concatenate(sentence_prop, atom_new(NEGATION_CLOSE_ATOM));
if (use_case_2)
    sentence_prop = prop_concatenate(sentence_prop, atom_new(DOMAIN_CLOSE_ATOM));
LOGIF(CALCULUS, "[%d] Initial meaning: $D\n", conv_log_depth, sentence_prop);
```

This code is used in §1.

§**16. Simplification.** Every proposition generated by `S_subtree_to_proposition`, whether it arises as "there is/are" plus a noun phrase or by the Second Rule, is simplified before being returned. Because of the way the recursion is set up, this means that intermediate propositions for relative clauses within a sentence are always simplified before being used to build the whole sentence.

What happens here is that we try a sequence of tactical moves to change the proposition for the better – which usually means eliminating bound variables, where we can: they are a bad thing because they compile to loops which may be slow and awkward to construct.

Simplifications are allowed to change Σ – indeed that's the whole idea – but not t_S, the term representing what the sentence talks about. (Indeed, they aren't even shown what it is.) Moreover, a simplification can only turn Σ to Σ' if:

(i) Σ' remains a syntactically correct proposition with well-formed quantifiers,
(ii) Σ' has the same number of free variables as Σ, and
(iii) in all situations and for all possible values of any free variables, Σ' is true if and only if Σ is.

Rules (i) and (ii) are checked as we go, with internal errors thrown if ever they should fail; the checking takes only a trivial amount of time, and I generally agree with Tony Hoare's maxim that removing checks like this in the program as shipped to users is like wearing a life-jacket while learning to sail on dry land, and then taking it off when going to sea. Still, rule (iii) can only be ensured by writing the routines carefully.

The simplification routines can all be found in "Simplifications".

```
define APPLY_SIMPLIFICATION(proposition, simp) {
    int changed = FALSE, NF = vars_number_free(proposition);
    if (proposition) proposition = simp(proposition, &changed);
    if (changed) LOGIF(CALCULUS, "[%d] %s: $D\n", conv_log_depth, #simp, proposition);
    if ((prop_is_well_formed(proposition) == FALSE) ||
        (NF != vars_number_free(proposition))) {
        LOG("Failed after applying %s: $D", #simp, proposition);
        internal_error(#simp " simplified proposition into one which is not well-formed");
    }
}
```

⟨Simplify the resultant proposition 16⟩ ≡

```
    if (prop_is_well_formed(sentence_prop) == FALSE) {
        LOG("Failed before simplification: $D", sentence_prop);
        internal_error("tried to simplify proposition which is not well-formed");
    }
    APPLY_SIMPLIFICATION(sentence_prop, simp_nothing_constant);
    APPLY_SIMPLIFICATION(sentence_prop, simp_use_listed_in);
    APPLY_SIMPLIFICATION(sentence_prop, simp_negated_determiners_nonex);
    APPLY_SIMPLIFICATION(sentence_prop, simp_negated_satisfiable);
    APPLY_SIMPLIFICATION(sentence_prop, simp_make_kinds_of_value_explicit);
    APPLY_SIMPLIFICATION(sentence_prop, simp_redundant_kinds);
    APPLY_SIMPLIFICATION(sentence_prop, simp_turn_right_way_round);
    APPLY_SIMPLIFICATION(sentence_prop, simp_region_containment);
    APPLY_SIMPLIFICATION(sentence_prop, simp_reduce_predicates);
    APPLY_SIMPLIFICATION(sentence_prop, simp_eliminate_redundant_variables);
    APPLY_SIMPLIFICATION(sentence_prop, simp_not_related_to_something);
    APPLY_SIMPLIFICATION(sentence_prop, simp_convert_gerunds);
    APPLY_SIMPLIFICATION(sentence_prop, simp_eliminate_to_have);
    APPLY_SIMPLIFICATION(sentence_prop, simp_is_all_rooms);
    APPLY_SIMPLIFICATION(sentence_prop, simp_redundant_kinds);
    vars_renumber(sentence_prop);                    just for the sake of tidiness
```

This code is used in §1.

§**17. The meaning of a noun phrase.** The First Rule tells us to translate a noun phrase (NP) into a pair of a term t and a proposition ϕ. We read this as "t such that ϕ is true".

For reasons explained below, a small amount of context is supplied: if the term will need to have a particular kind of value, then that KOV is given to us. (But if it only needs to be an object, or if we don't know anything about its kind, the `kov` argument will be `NULL`.)

As can be seen, an NP subtree consists *either* of an SN subtree representing two further NPs joined by a verb to make a relative clause, *or* one of three basic noun phrases: a value, a description, or a marker for an implied but missing noun.

```
pcalc_prop *NP_subtree_to_proposition(pcalc_term *subject_of_NP, meaning_list *ml,
    kind_of_value *kov) {
    pcalc_prop *NP_prop = NULL; int w1, w2;
    ⟨Tell the debugging log about the NP-subtree 18⟩;
    ⟨Clamber up to the interesting part of the NP subtree 20⟩;
    switch(ml_production(ml)) {
        case SN_PRODUCTION: NP_prop = S_subtree_to_proposition(ml, subject_of_NP); break;
        case VAL_PRODUCTION: ⟨This NP was parsed as a value 21⟩; break;
        case DC_PRODUCTION: ⟨This NP was parsed as a description 22⟩; break;
        case ABSENT_SUBJECT_PRODUCTION: ⟨This NP is only a ghostly presence 23⟩; break;
        default: LOG("Under NP subtree:\n$m", ml); internal_error("Malformed NP subtree");
    }
    ⟨If we have a single adjective which could also be a noun, and a value is required, convert it to a noun 24⟩;
    ⟨If we have a constant qualified by a substantive proposition, rewrite in terms of variable 25⟩;
    ⟨Close any open domain group 26⟩;
    ⟨Verify that the output satisfies the First Rule, throwing internal errors if not 19⟩;
    return NP_prop;
}
```

§**18.** Just as for SV-subtrees, we tell the debugging log at the start...

⟨Tell the debugging log about the NP-subtree 18⟩ ≡

```
    ml_get_text(ml, &w1, &w2);
    conv_log_depth++;
    LOGIF(CALCULUS, "[%d] Starting NP_subtree_to_proposition on: <$W>\n",
        conv_log_depth, w1, w2);
```

This code is used in §17.

§**19.** ...and also at the end.

⟨Verify that the output satisfies the First Rule, throwing internal errors if not 19⟩ ≡

```
if (prop_is_well_formed(NP_prop) == FALSE) internal_error("malformed NP proposition");
int NF = vars_number_free(NP_prop);
if (NF >= 2) internal_error("two or more free variables from NP");
if (subject_of_NP->constant) {
    if (NP_prop) internal_error("constant plus substantive prop from NP");
} else if (NF == 1) {
    int v = term_variable_underlying(subject_of_NP);
    if (status_of_var(NP_prop, v) != FREE_VST)
        internal_error("free variable from NP but not the preferred term");
}
LOGIF(CALCULUS, "[%d] NP_subtree_to_proposition: $W --> t = $0, phi = $D\n",
    conv_log_depth, w1, w2, subject_of_NP, NP_prop);
conv_log_depth--;
```

This code is used in §17.

§**20.** The recursive method of the S-parser means that it sometimes begins SV- and SN-subtrees with a tendril of not very meaningful nodes. They cause no trouble, though, and this is where we skip down them to where the action is.

⟨Clamber up to the interesting part of the NP subtree 20⟩ ≡

```
if (ml == NULL) internal_error("Null ML");
if (ml_production(ml) == NP_PRODUCTION) ml = ml_down(ml);
if ((ml_production(ml) == VAL_PRODUCTION) && (ml_down(ml)) &&
    (ml_production(ml_down(ml)) == DC_PRODUCTION)) ml = ml_down(ml);
if ((ml_production(ml) == DC_PRODUCTION) && (ml_down(ml)) &&
    (ml_production(ml_down(ml)) == SN_PRODUCTION)) ml = ml_down(ml);
```

This code is used in §17.

§**21.** Here we find a constant C and return $t = C$ with a null ϕ, except in one case: where C is the name of an either/or property, such as "closed". In the context of a value, this is a noun – it identifies which property we are talking about – and this is why `VAL_subtree_to_spec` returns it as a constant. But inside a sentence, it has to be considered an adjective, so rather than returning $t =$ `closed`, $\phi = T$, we return $t = x$ and $\phi = \mathit{closed}(x)$. If we didn't do this, text like "the trapdoor is closed" would translate to the proposition $\mathit{is}($`trapdoor`, `closed`$)$, which would then fail in type-checking.

(Note that this is a different sort of noun/adjective ambiguity than the one arising below, which is to do with enumerated value properties.)

⟨This NP was parsed as a value 21⟩ ≡

```
specification *spec = VAL_subtree_to_spec(ml);
*subject_of_NP = term_new_constant(spec);
if (spec_is_CONSTANT_of_kova(spec, PROPERTY_TY)) {
    property_name *prn = PROPERTY_spec_to_property_name(spec);
    if (prn_is_either_or(prn)) {
        *subject_of_NP = term_new_variable(0);
        NP_prop = atom_unary_PREDICATE_from_aph(prn_either_or_get_aph(prn), FALSE);
    } else if (prn_coincides_with_kind_of_value(prn)) {
        *subject_of_NP = term_new_variable(0);
        kind_of_value *kov = prn_get_kind_of_value(prn);
        NP_prop = atom_KIND_value_new(kov, term_new_variable(0));
    }
}
```

This code is used in §17.

§**22.** If `prop_from_spec` is given a constant value C then it returns the proposition $is(x, C)$: we look out for this and translate it to $t = C, \phi = T$. Otherwise, ϕ can be exactly the proposition returned, and the first term occurring in it will be chosen as the subject t. (In particular, if ϕ opens with a quantifier then t will be the variable it binds.)

⟨This NP was parsed as a description 22⟩ ≡

```
specification *spec = DC_subtree_to_spec(ml, FALSE);
NP_prop = prop_from_spec(spec, TRUE);
if (prop_match(NP_prop, 2, PREDICATE_ATOM, NULL, END_PROP_HERE, NULL)) {
    pcalc_term *pt = atom_is_x_equals(NP_prop);
    if (pt) { *subject_of_NP = *pt; NP_prop = NULL; }
}
if (NP_prop) *subject_of_NP = prop_get_first_cited_term(NP_prop);
```

This code is used in §17.

§**23.** When Inform reads a condition so abbreviated that both the subject and the verb have been left out, it assumes the verb is "to be" and that the subject will be whatever is being worked on. For instance,

if an unlocked container, ...

is read as the verb phrase "is" with `ABSENT_SUBJECT_PRODUCTION` as SP and "an unlocked container" as OP.

`ABSENT_SUBJECT_PRODUCTION` nodes are easy to deal with since they translate to the I6 variable `self` in the final compiled code; the `new_self_object_constant` routine returns a specification which refers to this. From a predicate calculus point of view, this is just another constant.

⟨This NP is only a ghostly presence 23⟩ ≡

```
*subject_of_NP = term_new_constant(new_self_object_constant());
```

This code is used in §17.

§**24.** Suppose we have a situation like this:

Texture is a kind of value. Rough, smooth and jagged are textures. A thing has a texture.

Feeling relates various rooms to one texture. The verb to feel (he feels) implies the feeling relation.

and consider the sentences:

[1] the broken bottle is jagged [2] the Spiky Cavern feels jagged

Now suppose we are working on the NP "jagged". In (1), it's an adjective: we are talking about a quality of the bottle. But in (2), it's a noun: we are establishing a relation between two values, the Cavern and the jagged texture.

Up to this point, "jagged" will have produced $t = x$, $\phi = jagged(x)$ in both cases – the adjectival reading of the word. The way we can tell if we are in case (2) is if a value of a specific kind (and not an object) is expected as the outcome. In the case of the equality relation used in (1), "is", the terms can be anything; but in the case of the feeling relation used in (2), the second term, corresponding to the noun phrase "jagged" in this sentence, has to have the kind of value "texture". So we convert it into noun form, and return $t =$ `texture`, $\phi = T$.

(Note that this is a different sort of noun/adjective ambiguity than the one arising above, which is to do with either/or properties.)

Another case which can occur is:

the bottle provides the property closed

where the presence of the words "the property" needs to alert us that "closed" is a noun referring to the property itself, not to a nameless object possessing that property.

⟨If we have a single adjective which could also be a noun, and a value is required, convert it to a noun 24⟩ ≡
```
if ((([[w1, w2 == property ...]] || [[w1, w2 == the property ...]]) || (kov)) {
    pcalc_term pct = convert_adj_to_noun(NP_prop);
    if (pct.constant) { *subject_of_NP = pct; NP_prop = NULL; }
}
```

This code is used in §17.

§25. If we have so far produced a constant term $t = C$ and a non-null proposition ϕ, then we convert t to a new free variable, say $t = y$, we then bind any free variable in the old ϕ and then change to $\exists y : is(y, C) \wedge \phi$. For instance, if we are working on the OP "the box in a room" from this:

> a thing in the box in a room

then the constant is $C =$ `box`, and Sstp returned $\phi = \exists x : room(x) \wedge is(x, \texttt{ContainerOf(box)})$.

⟨If we have a constant qualified by a substantive proposition, rewrite in terms of variable 25⟩ ≡
```
if ((subject_of_NP->constant) && (NP_prop)) {
    int y = vars_find_unused(NP_prop);
    NP_prop = prop_concatenate(
        atom_binary_PREDICATE_new(a_is_b_predicate, *subject_of_NP, term_new_variable(y)),
        NP_prop);
    NP_prop = vars_bind_existential(NP_prop);
    *subject_of_NP = term_new_variable(y);
}
```

This code is used in §17.

§26. If the NP was something like "at least four open doors", we will so far have built `QUANTIFIER --> DOMAIN_OPEN --> KIND --> PREDICATE`, and now that we have reached the end of the noun phrase we need to add a `DOMAIN_CLOSE` atom. The following is written in a way that guarantees all such open groups are closed, but in fact there should only ever be one open, so `nq` should always evaluate to 0 or 1.

⟨Close any open domain group 26⟩ ≡
```
int i, nq = 0;
TRAVERSE_VARIABLE(p);
TRAVERSE_PROPOSITION(p, NP_prop)
    switch (p->element) {
        case DOMAIN_OPEN_ATOM: nq++; break;
        case DOMAIN_CLOSE_ATOM: nq--; break;
    }
if (nq < 0) internal_error("malformed proposition with too many domain ends");
for (i=1; i<=nq; i++)
    NP_prop = prop_concatenate(NP_prop, atom_new(DOMAIN_CLOSE_ATOM));
```

This code is used in §17.

Simplifications 6/simp

Purpose

A set of operations each of which takes a proposition and either leaves it unchanged or replaces it with a simpler one logically equivalent to the original.

6/simp.§1-3 Simplify the nothing constant (fudge); §4 Use listed-in predicates (deduction); §5-6 Simplify negated determiners (deduction); §7 Simplify negated satisfiability (deduction); §8 Make kind requirements explicit (deduction); §9-16 Remove redundant kind predicates (deduction); §17 Turn binary predicates the right way round (deduction); §18 Simplify region containment (fudge); §19 Reduce binary predicates (deduction); §20-22 Eliminating determined variables (deduction); §23 Simplify non-relation (deduction); §24 Convert gerunds to nouns (deduction); §25-27 Eliminate to have meaning property ownership (fudge); §28 Turn all rooms to everywhere (fudge)

Definitions

¶1. Recall the three rules for simplification routines: they take a proposition Σ (which they are allowed to destroy or modify) and return Σ', but such that:

(i) Σ' remains a syntactically correct proposition with well-formed quantifiers,
(ii) Σ' has the same number of free variables as Σ, and
(iii) in all situations and for all possible values of any free variables, Σ' is true if and only if Σ is.

Rules (i) and (ii) are always strictly obeyed. A simplification which obeys (iii) in its purely logical sense is called a "deduction"; one which bends (iii) to change the proposition from what the user wrote, to what he meant to write, is called a "fudge". Fudges are needed because English is quirky, and does not correspond perfectly to predicate logic.

What we mean by simpler is not shorter, or with less exotic contents: often the simplified form of a proposition is longer and uses relations or determiners less obviously derived from the original text. Instead, simpler means simpler to test and assert. Our ideal is a conjunction of a sequence of predicates, using the smallest possible number of variables (and hence quantifiers).

---

§**1. Simplify the nothing constant (fudge).** The word "nothing" is sometimes a noun ("the holder of the oak tree is nothing"), sometimes a determiner ("nothing is in the box"). This doesn't arise with the other no- words, nowhere and nobody, since those are not allowed as nouns in Inform.

Here we look for the noun form as one term in a binary predicate, and convert it to the determiner form unless the predicate is equality. Thus "X is nothing" is allowed to use the noun form, "X contains nothing" has to use the determiner form. (In particular "nothing is nothing" compares two identical nouns and is always true. I thought this was a sentence nobody would write, but Google finds 223,000 hits for it.)

```
pcalc_prop *simp_nothing_constant(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop)
        if ((atom_is_binary_predicate(pl)) && (atom_is_equality_predicate(pl) == FALSE)) {
            binary_predicate *bp = RETRIEVE_POINTER_binary_predicate(pl->predicate);
            int i;
            for (i=0; i<2; i++) {
                if (spec_is_nothing_object_constant(term_constant_underlying(&(pl->terms[i])))) {
                    ⟨Substitute for the term and quantify with does-not-exist 3⟩;
                    PROPOSITION_EDITED(pl, prop);
                    break;
                }
            }
        }
    return prop;
}
```

The function simp_nothing_constant is called from 6/sconv.

§**2.** Formally, if B is a predicate other than equality,

$$\Sigma = \cdots B(t, f_X(f_Y(\cdots(\texttt{nothing})))) \cdots \quad \longrightarrow \quad \Sigma' = \cdots \nexists v \in \{v \mid K_1(v)\} : B(t, f_X(f_Y(\cdots(v)))) \cdots$$

where v is unused in Σ, and – note the difference in placing –

$$\Sigma = \cdots B(f_X(f_Y(\cdots(\texttt{nothing}))), t) \cdots \quad \longrightarrow \quad \Sigma' = \nexists v \in \{v \mid K_2(v)\} : \cdots B(f_X(f_Y(\cdots(v))), t) \cdots$$

where K_1 and K_2 are the kinds of terms 1 and 2 in the predicate B.

The difference in where we place the quantifier is important in double-negative sentences. Consider these:

[1] the box does not contain nothing

which produces $\Sigma = \neg(\mathit{contains}(\texttt{box}, \texttt{nothing}))$. Here, `nothing` is part of the object phrase, not the subject phrase, and we need to quantify it within the OP – which means, within the negation, because our recipe for negated sentences was (roughly) SP $\wedge\neg($ OP $\wedge$ VP). We thus make $\Sigma' = \neg(\nexists x : \mathit{contains}(\texttt{box}, x))$, although later simplification converts that to $\exists x : \mathit{contains}(\texttt{box}, x)$, just as if the original sentence had been "the box contains something". On the other hand,

[2] nothing does not annoy Peter

produces $\Sigma = \neg(\mathit{annoys}(\texttt{nothing}, \texttt{Peter}))$, and now we have to quantify as $\Sigma' = \nexists x : \neg(\mathit{annoys}(x, \texttt{Peter}))$.

Double-negatives are a little odd. If natural language were really the same as predicate logic with some grunting sounds for decoration, then a double negative would always be a positive. But in 18th-century English, that wasn't true: it was a way of emphasising the negation, just as characters in Aaron Sorkin's *The West Wing* scripts are always saying "not for nothing, but..." when their meaning is equivalent to "this is nothing, but...". Still, Inform takes the view that a double negative is a positive.

§**3.** The code is simpler than the explanation:

⟨Substitute for the term and quantify with does-not-exist 3⟩ ≡

```
int nv = vars_find_unused(prop);
pcalc_term new_var = term_new_variable(nv);
substitute_nothing_in_term(&(pl->terms[i]), &new_var);
pcalc_prop *position = NULL;                                   at the front if nothing is the SP...
if (i == 1) position = pl_prev;                                ...but up close to the predicate if it's the OP
insert four atoms, in reverse order, at this position:
prop = prop_insert_atom(prop, position, atom_new(DOMAIN_CLOSE_ATOM));
if (bp_term_kind(bp, i))
    prop = prop_insert_atom(prop, position,
        atom_KIND_object_new(bp_term_kind(bp, i), new_var));
else if (bp_term_kind_of_value(bp, i))
    prop = prop_insert_atom(prop, position,
        atom_KIND_value_new(bp_term_kind_of_value(bp, i), new_var));
prop = prop_insert_atom(prop, position, atom_new(DOMAIN_OPEN_ATOM));
prop = prop_insert_atom(prop, position, atom_QUANTIFIER_new(not_exists_quantifier, nv, 0));
```

This code is used in §1.

§4. Use listed-in predicates (deduction). Specifications for entries in tables have a variety of forms (well, four of them), and one is by implication a condition: this is the 2-reference form of `TABLE_ENTRY_SPC` specification. Suppose the source text reads

> if X is a density listed in the Table of Solid Stuff, ...

Inform parses "a density listed in the Table of Solid Stuff" as a single specification, with references to the density column and the Solid Stuff table. In logical terms, this is just another constant, which we'll call L. At this point the sentence looks like:

$$is(X, L)$$

The trouble is that L is really a predicate, acting on some free variable v, because it stands for any value v found in the density column. We could try to interpret *is* so as to accommodate this, but it is much better to use Inform's regular predicate apparatus.

So we must make its nature explicit. Every table column has an associated binary predicate, and we rewrite:

$$\exists v : number(v) \wedge listed\text{-}in\text{-}density\text{-}column(v, T) \wedge is(v, X)$$

This looks extravagant, but later simplification will reduce it to

$$listed\text{-}in\text{-}density\text{-}column(X, T).$$

More formally suppose we write $L(C, T)$ for the constant representing "a C listed in T", and suppose we use the notation $P(\dots t \dots)$ for any predicate containing a term underlying which is t. Let v be a variable unused in Σ, and let K be the kind of value of entries in the C column. Then:

$$\Sigma = \cdots P(\dots L(C, T) \dots) \cdots \quad \longrightarrow \quad \Sigma' = \cdots \exists v : K(v) \wedge listed\text{-}in\text{-}C\text{-}column(v, T) \wedge P(\dots v \dots) \cdots$$

where the variable v has replaced the constant $L(C, T)$ underlying one of the terms of P.

Note that this can act twice on the same predicate, if such terms occur twice. For example,

> if a crispiness listed in the Table of Salad Stuff is a density listed in the Table of Solid Stuff, ...

generates $is(L(C_1, T_1), L(C_2, T_2))$. As it happens, Inform can't compile this efficiently and will produce a problem message to say so, but it's important that our code here should generate the correct proposition,

$$\exists x : number(x) \wedge listed\text{-}in\text{-}C1\text{-}column(x, T_1) \wedge listed\text{-}in\text{-}C2\text{-}column(x, T_2).$$

```
pcalc_prop *simp_use_listed_in(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        int j;
        for (j=0; j<pl->arity; j++) {
            specification *spec = term_constant_underlying(&(pl->terms[j]));
            if ((spec) && (spec_get_storage_form(spec) == TABLE_ENTRY_SPC) &&
                (spec_get_argc(spec) == 2)) {
                specification *col = spec_get_argument(spec, 0);
                specification *tab = spec_get_argument(spec, 1);
                table_column *tc = TABLE_COLUMN_spec_to_table_column(col);
                kind_of_value *kov = get_data_type_stored(tc);
                if (is_kova(kov, UNDERSTANDING_TY)) kov = kova(SNIPPET_TY);
                int nv = vars_find_unused(prop);
                pcalc_term nv_term = term_new_variable(nv);

```

```
                    atom_binary_PREDICATE_new(tc_get_listed_in_predicate(tc),
                        nv_term, term_new_constant(tab)));
                pcalc_prop *new_KIND = atom_KIND_value_new(kov, nv_term);
                new_KIND->predicate =
                    STORE_POINTER_binary_predicate(tc_get_listed_in_predicate(tc));
                prop = prop_insert_atom(prop, pl_prev, new_KIND);
                prop = prop_insert_atom(prop, pl_prev,
                    atom_QUANTIFIER_new(exists_quantifier, nv, 0));
                substitute_term_in_term(&(pl->terms[j]), &nv_term);
                we_need_ct_locals();
                PROPOSITION_EDITED(pl, prop);
            }
        }
    }
    return prop;
}
```

The function simp_use_listed_in is called from 6/sconv.

§**5. Simplify negated determiners (deduction).** The negation atom is worth removing wherever possible, since we want to keep propositions in a flat conjunction form if we can, and the negation of a string of atoms is therefore a bad thing. We therefore change thus:

$$\Sigma = \cdots \neg(Qv \in \{v \mid \phi(v)\} : \psi) \cdots \quad \longrightarrow \quad \Sigma' = \cdots \overline{Q}v \in \{v \mid \phi(v)\} : \psi \cdots$$

where $\overline{Q}$ is the negation of the generalised quantifier Q: for instance, $V_{<5}y$ becomes $V_{\geq 5}y$.

A curiosity here is that when simplifying during sentence conversion, we choose not to apply this deduction in the case of $Q = \exists$. This saves us having to make difficult decisions about the domain set of Q (see below), and also preserves $\exists v$ atoms in Σ, which are useful since they make some of our later simplifications more applicable.

```
pcalc_prop *simp_negated_determiners_nonex(pcalc_prop *prop, int *changed) {
    return simp_negated_determiners(prop, changed, FALSE);
}
pcalc_prop *simp_negated_determiners(pcalc_prop *prop, int *changed,
    int negate_existence_too) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        pcalc_prop *quant_atom;
        if (prop_match(pl, 2,
            NEGATION_OPEN_ATOM, NULL, QUANTIFIER_ATOM, &quant_atom)) {
            if ((negate_existence_too) ||
                ((atom_is_existence_quantifier(quant_atom) == FALSE))) {
                prop = prop_ungroup_and_negate_determiner(prop, pl_prev, TRUE);
                PROPOSITION_EDITED(pl, prop);
            }
        }
    }
    return prop;
}
```

The function simp_negated_determiners_nonex is called from 6/sconv.
The function simp_negated_determiners is called from 6/cdefp.

§**6.** And the following useful routine actually performs the change. The only tricky point here is that we store $\exists v$ without domain brackets; so if Q happens to be $\exists v$ then we have to turn $\neg(\exists v : \cdots)$ into $\nexists v \in \{v \mid \cdots\} \cdots$, and it's not obvious where to place the }. While there's no logical difference – the proposition means the same wherever we put it – the assert-propositions code is better at handling $\exists v \in X : \phi(v)$ than $\exists v \in Y$. So we want the braces to enclose fixed, unassertable matter – v being a container, say – and the ϕ outside the braces should then contain predicates which can be asserted.

In practice that's way too hard for this routine to handle. If `add_domain_brackets` is set, then it converts

$$\neg(\exists v : \cdots) \quad \longrightarrow \quad \nexists v \in \{v \mid \cdots\}$$

– that is, it will make the entire negated subproposition the domain of the quantifier. If `add_domain_brackets` is clear, the routine will return a syntactically incorrect proposition lacking the domain brackets, and it's the caller's responsibility to put that right.

```
pcalc_prop *prop_ungroup_and_negate_determiner(pcalc_prop *prop, pcalc_prop *after,
    int add_domain_brackets) {
    pcalc_prop *quant_atom, *last;
    int fnd;
    if (after == NULL)
        fnd = prop_match(prop, 2,
            NEGATION_OPEN_ATOM, NULL, QUANTIFIER_ATOM, &quant_atom);
    else
        fnd = prop_match(after, 3, ANY_ATOM_HERE, NULL,
            NEGATION_OPEN_ATOM, NULL, QUANTIFIER_ATOM, &quant_atom);
    if (fnd) {
        quantifier *quant = RETRIEVE_POINTER_quantifier(quant_atom->predicate);
        quantifier *antiquant = quant_get_negation(quant);
        quant_atom->predicate = STORE_POINTER_quantifier(antiquant);
        prop = prop_ungroup_after(prop, after, &last);                    remove negation group brackets
        if ((quant == exists_quantifier) && (add_domain_brackets)) {
            prop = prop_insert_atom(prop, quant_atom, atom_new(DOMAIN_OPEN_ATOM));
            prop = prop_insert_atom(prop, last, atom_new(DOMAIN_CLOSE_ATOM));
        }
        if (antiquant == exists_quantifier) {
            prop = prop_ungroup_after(prop, quant_atom, NULL);            remove domain group brackets
        }
        LOGIF(WORKINGS, "prop_ungroup_and_negate_determiner: $D\n", prop);
    } else internal_error("not a negate-group-determiner");
    return prop;
}
```

§**7. Simplify negated satisfiability (deduction).** When simplifying converted sentences, we chose not to use the `simp_negated_determiners` tactic on existence quantifiers $\exists v$, partly because it's tricky to establish their domain in a way helpful to the rest of Inform.

Here we handle a simple case which occurs frequently and where we can indeed identify the domain well:

$$\Sigma = \neg(\exists v : K(v) \wedge P) \quad \longrightarrow \quad \Sigma' = \nexists v \in \{v \mid K(v)\} : P$$

where K is a kind, and P is any single predicate other than equality. (In the case of equality, we'd rather leave matters as they stand, because substitution will later eliminate all of this anyway.)

```
pcalc_prop *simp_negated_satisfiable(pcalc_prop *prop, int *changed) {
    pcalc_prop *quant_atom, *predicate_atom, *kind_atom;
    *changed = FALSE;
    if ((prop_match(prop, 6,
        NEGATION_OPEN_ATOM, NULL,
        QUANTIFIER_ATOM, &quant_atom,
        KIND_ATOM, &kind_atom,
        PREDICATE_ATOM, &predicate_atom,
        NEGATION_CLOSE_ATOM, NULL,
        END_PROP_HERE, NULL)) &&
        (atom_is_existence_quantifier(quant_atom)) &&
        (atom_is_equality_predicate(predicate_atom) == FALSE) &&
        (kind_atom->terms[0].variable == quant_atom->terms[0].variable)) {
        prop = prop_ungroup_and_negate_determiner(prop, NULL, FALSE);
        prop = prop_insert_atom(prop, quant_atom, atom_new(DOMAIN_OPEN_ATOM));
        prop = prop_insert_atom(prop, kind_atom, atom_new(DOMAIN_CLOSE_ATOM));
        *changed = TRUE;
    }
    return prop;
}
```

The function simp_negated_satisfiable is called from 6/sconv.

§8. Make kind requirements explicit (deduction). Many predicates contain implicit requirements about the kinds of their terms. For instance, if R relates a door to a number, then $R(x, y)$ can only be true if x is a door and y is a number. We insert these requirements explicitly in order to defend the code testing R; it ensures we never have to test bogus values. We need do this only for variables, as with more constants and functions type-checking will certainly be able to test their kind in any event (whereas a free variable is anonymous enough that we can't necessarily know by other means).

Formally, let K_1 and K_2 be the kinds of value of terms 1 and 2 of the binary predicate R. Let v be a variable. Then:

$$\Sigma = \cdots R(v, t) \cdots \quad \longrightarrow \quad \Sigma' = \cdots K_1(v) \wedge R(v, t)$$
$$\Sigma = \cdots R(t, v) \cdots \quad \longrightarrow \quad \Sigma' = \cdots K_2(v) \wedge R(t, v)$$

and therefore, if both cases occur,

$$\Sigma = \cdots R(v, w) \cdots \quad \longrightarrow \quad \Sigma' = \cdots K_1(v) \wedge K_2(w) \wedge R(v, w)$$

Some of these new kind atoms are unnecessary, but `simp_redundant_kinds` will detect and remove those.

Why do we do this for binary predicates, but not unary predicates? The answer is that there's no need, and it's impracticable anyway, because adjectives are allowed to have multiple definitions for different kinds of value, and because the code testing them is written to cope properly with bogus values.

```
pcalc_prop *simp_make_kinds_of_value_explicit(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    TRAVERSE_PROPOSITION(pl, prop)
        if (atom_is_binary_predicate(pl)) {
            int i;
            binary_predicate *bp = RETRIEVE_POINTER_binary_predicate(pl->predicate);
            for (i=1; i>=0; i--) {
                int v = pl->terms[i].variable;
                if (v >= 0) {
                    kind_of_value *kov = bp_term_kind_of_value(bp, i);
                    if ((kov == NULL) && (bp_term_kind(bp, i)))
                        kov = kovko(bp_term_kind(bp, i));
                    if (kov) {
                        pcalc_prop *new_KIND = atom_KIND_value_new(kov, term_new_variable(v));
                        new_KIND->predicate = STORE_POINTER_binary_predicate(bp);
                        prop = prop_insert_atom(prop, pl_prev, new_KIND);
                    }
                    *changed = TRUE;
                }
            }
        }
    return prop;
}
```

The function simp_make_kinds_of_value_explicit is called from 6/treec and 6/sconv.

§**9. Remove redundant kind predicates (deduction).** Propositions often contain more `KIND` atoms than they need, not least as a result of `simp_make_kinds_of_value_explicit`. Here we remove (some of) those, and move the survivors to what we consider the best positions within the line. For reasons to be revealed below, we run this process twice over:

```
pcalc_prop *simp_redundant_kinds(pcalc_prop *prop, int *changed) {
    int c1 = FALSE, c2 = FALSE;
    prop = simp_redundant_kinds_dash(prop, prop, 1, &c1);
    prop = simp_redundant_kinds_dash(prop, prop, 1, &c2);
    if ((c1) || (c2)) *changed = TRUE; else *changed = FALSE;
    return prop;
}
```

The function simp_redundant_kinds is called from 6/sconv.

§**10.** This routine works recursively on subexpressions within the main proposition. These all begin and end with matched `*_OPEN_ATOM` and `*_CLOSED_ATOM` brackets, with one exception: the main proposition itself. `start_group` represents the first atom of the expression (the open bracket, in most cases) and `start_level` the level of bracket nesting at that point. This is 1 for the main proposition, but 0 for subexpressions, so that inside the brackets the main content will be at level 1.

This would all go wrong if the proposition were not well-formed, but we know that it is – an internal error would have been thrown if not.

```
pcalc_prop *simp_redundant_kinds_dash(pcalc_prop *prop, pcalc_prop *start_group,
    int start_level, int *changed) {
    pcalc_prop *optimal_kind_placings_domain[26], *optimal_kind_placings_statement[26];
    ⟨Recursively simplify all subexpressions first 11⟩;
    ⟨Find optimal positions for kind predicates 12⟩;
    ⟨Strike out redundant kind predicates applied to variables 13⟩;
    ⟨Strike out tautological kind predicates applied to constants 16⟩;
    return prop;
}
```

§**11.** For all of the atoms in the body of the group we're working on, the bracket level will be 1. When it raises to 2, then, we begin a subexpression, and we recurse into it. (We don't recurse at levels 3 and up because the level 2 call will already have taken care of those sub-sub-expressions.)

⟨Recursively simplify all subexpressions first 11⟩ ≡

```
    TRAVERSE_VARIABLE(pl);
    int blevel = start_level;
    TRAVERSE_PROPOSITION(pl, start_group) {
        if (element_get_group(pl->element) == OPEN_OPERATORS_GROUP) {
            blevel++;
            if (blevel == 2) prop = simp_redundant_kinds_dash(prop, pl, 0, changed);
        }
        if (element_get_group(pl->element) == CLOSE_OPERATORS_GROUP) blevel--;
        if (blevel == 0) break;
    }
```

This code is used in §10.

§**12.** Suppose we have a kind predicate $K(v)$ applied to a variable. What would be the best place to put this? Generally speaking, we want it as early as possible, because tests of K are cheap and this will keep running time low in compiled code. On the other hand we must not move it outside the current subexpression. The doctrine is:

(i) if v is unbound *within the subexpression* then $K(v)$ should move right to the front;
(ii) if v is bound by $\exists$, then $K(v)$ should move immediately after $\exists v$;
(iii) if v is bound by $Qv \in \{v \mid \phi(v)\}$ then any $K(v)$ occurring in the domain $\phi(v)$ should move to the front of v, whereas any later $K(v)$ should move after the domain closing, except
(iv) where v is bound by $\nexists v \in \{v \mid \phi(v)\}$, when $K(v)$ should move into the domain set, even if it occurs in the statement.

Rule (iv) there looks a little surprising. For instance, it causes

$$\Sigma = \nexists x \in \{x \mid \mathit{thing}(x) \wedge \mathit{contains}(\texttt{Ballroom}, x)\} : \mathit{container}(x) \wedge \mathit{open}(x) \quad \longrightarrow$$
$$\Sigma' = \nexists x \in \{x \mid \mathit{container}(x) \wedge \mathit{thing}(x) \wedge \mathit{contains}(\texttt{Ballroom}, x)\} : \mathit{open}(x).$$

These are logically equivalent because $\nexists$ behaves that way – they wouldn't be equivalent for other quantifiers. Rule (iii) would have said no movement was necessary; the reason we made the move is that it makes Σ' possible to assert with "now", as in the phrase "now nothing in the Ballroom is an open container".

The following calculates two arrays: `optimal_kind_placings_domain` marks the start of ϕ for each variable v, while `optimal_kind_placings_statement` marks the start of the statement following the quantifier.

⟨Find optimal positions for kind predicates 12⟩ ≡

```
TRAVERSE_VARIABLE(pl);
int bvsp = 0, bound_vars_stack[26];
int blevel = start_level, j;
for (j=0; j<26; j++) {
    optimal_kind_placings_domain[j] = (start_level == 1)?NULL:start_group;
    optimal_kind_placings_statement[j] = optimal_kind_placings_domain[j];
}
TRAVERSE_PROPOSITION(pl, start_group) {
    if (element_get_group(pl->element) == OPEN_OPERATORS_GROUP) blevel++;
    if (element_get_group(pl->element) == CLOSE_OPERATORS_GROUP) blevel--;
    if (blevel == 0) break;
    pcalc_prop *dom;
    if (prop_match(pl, 2,
            QUANTIFIER_ATOM, NULL, DOMAIN_OPEN_ATOM, &dom)) {
        if ((atom_is_existence_quantifier(pl)) ||
            (atom_is_nonexistence_quantifier(pl)))
            bound_vars_stack[bvsp++] = -1;
        else
            bound_vars_stack[bvsp++] = pl->terms[0].variable;
        optimal_kind_placings_domain[pl->terms[0].variable] = dom;
        optimal_kind_placings_statement[pl->terms[0].variable] = dom;
    } else if (atom_is_existence_quantifier(pl)) {
        optimal_kind_placings_domain[pl->terms[0].variable] = pl;
        optimal_kind_placings_statement[pl->terms[0].variable] = pl;
    }
    if (pl->element == DOMAIN_CLOSE_ATOM) {
        int v = bound_vars_stack[--bvsp];
        if (v >= 0) optimal_kind_placings_statement[v] = pl;
    }
}
```

This code is used in §10.

§**13.** The following looks at the predicates $K(v)$ applied to variables which are in the subexpression at the top level. It then does two things:

Suppose K and L are kinds of value such that $L \subseteq K$, and let ψ be a well-formed proposition. Then

$$\Sigma = \psi \wedge L(v) \cdots K(v) \cdots \quad \longrightarrow \quad \Sigma' = \psi \wedge L(v) \cdots$$

(that is, $K(v)$ is eliminated). This is clearly valid since $L(v) \Rightarrow K(v)$ and $L(v)$ is valid throughout the subexpression after its appearance.

Secondly, and it's not worth finding a logical notation for this, the kind is moved back to its optimal position, as calculated above.

At first sight, this process only removes redundancies when the stronger kind appears before the weaker one. What if they occur the other way around? This is why the simplification is run twice, and why it's important that the process of moving predicates back to their optimal position reverses their order. Suppose we start with $person(x) \wedge vehicle(y) \wedge woman(x)$.

(1a) On pass 1, *person* occurs before *woman*, but it is weaker – every woman is a person, but not necessarily vice versa – so neither is deleted.
(1b) But pass 1 also moves the kinds back, and this produces $woman(x) \wedge vehicle(y) \wedge person(x)$.
(2a) On pass 2, the stronger *woman* now occurs before *person*, so we eliminate to get $woman(x) \wedge vehicle(y)$.
(2b) And pass 2 again moves kinds back, producing $vehicle(y) \wedge woman(x)$.

(Because the order is reversed twice, any surviving kind predicates continue to appear in the same order as they did in the original proposition. This doesn't matter, but it's tidy.)

⟨Strike out redundant kind predicates applied to variables 13⟩ ≡

```
TRAVERSE_VARIABLE(pl);
int domain_passed[26], j;
int blevel = start_level;
for (j=0; j<26; j++) domain_passed[j] = FALSE;
TRAVERSE_PROPOSITION(pl, start_group) {
    for (j=0; j<26; j++)
        if (pl == optimal_kind_placings_statement[j])
            domain_passed[j] = TRUE;
    if (element_get_group(pl->element) == OPEN_OPERATORS_GROUP) blevel++;
    if (element_get_group(pl->element) == CLOSE_OPERATORS_GROUP) blevel--;
    if (blevel == 1) {
        if (pl->element == KIND_ATOM) {
            kind_of_value *early_kov = pl->assert_kind_of_value;
            int v = pl->terms[0].variable;
            if ((v >= 0) && (early_kov)) {
                ⟨Strike out any subsequent but weaker kind predicate on the same variable 14⟩;
                ⟨Move this predicate backwards to its optimal position 15⟩;
            }
        }
    }
    if (blevel == 0) break;
}
```

This code is used in §10.

§**14.** The noteworthy thing here is that we continue through the subexpression, deleting any weaker form of $K(v)$ that we find, but also allow ourselves to continue *beyond* the subexpression in one case. Suppose we have

$$Qv \in \{v \mid K(v) \wedge ...\} : L(v)$$

and we are working on the $K(v)$ term. If we continue only to the end of the current subexpression, that runs out at the }, the end of the domain specification. So in that one case alone we allow ourselves to sidestep the `DOMAIN_CLOSE_ATOM` and continue looking for $L(v)$ in the outer subexpression – the one which is governed by the quantifier.

⟨Strike out any subsequent but weaker kind predicate on the same variable 14⟩ ≡

```
TRAVERSE_VARIABLE(gpl);
int glevel = 1;
TRAVERSE_PROPOSITION(gpl, pl) {
    if (element_get_group(gpl->element) == OPEN_OPERATORS_GROUP) glevel++;
    if (gpl->element == DOMAIN_CLOSE_ATOM) {
        if (glevel > 1) glevel--;
    } else if (element_get_group(gpl->element) == CLOSE_OPERATORS_GROUP) glevel--;
    if (glevel == 0) break;
    if ((gpl != pl) && (gpl->element == KIND_ATOM) && (v == gpl->terms[0].variable)) {
        i.e., gpl now points to a different kind atom on the same variable
        kind_of_value *later_kov = gpl->assert_kind_of_value;
        if ((later_kov) && (can_we_cast_kovs(early_kov, later_kov) == ALWAYS_MATCH)) {
            prop = prop_delete_atom(prop, gpl_prev);
            PROPOSITION_EDITED_REPEATING_CURRENT(gpl, prop);
        }
    }
}
```

This code is used in §13.

§**15.**

⟨Move this predicate backwards to its optimal position 15⟩ ≡

```
pcalc_prop *best_place = optimal_kind_placings_domain[v];
if (domain_passed[v]) best_place = optimal_kind_placings_statement[v];
if (pl_prev != best_place) {
    prop = prop_delete_atom(prop, pl_prev);                    that is, delete the current K(v)
    prop = prop_insert_atom(prop, best_place,
        atom_KIND_value_new(early_kov, term_new_variable(v)));          insert a new one
    PROPOSITION_EDITED_REPEATING_CURRENT(pl, prop);
}
```

This code is used in §13.

§**16.** Suppose we find a term $K(C)$, where C is a constant in the sense of predicate calculus – that is, a `specification`. There is no need to perform such a test at run-time because we can determine the kind of C and compare it against K right now. For instance, *number*(`score`) is necessarily true at all times.

Formally, suppose C is a constant which, when evaluated, has kind of value L. Suppose that $L \subseteq K$ and that K is not a kind of object. Then

$$\Sigma = \cdots K(C) \cdots \quad \longrightarrow \quad \Sigma' = \cdots\cdots$$

(That is, we eliminate the $K(C)$ term.)

We could clearly go further than this:

(a) Why don't we eliminate $K(C)$ when K is an object, too? Logically this would be fine, but we choose not to, for two reasons: people sometimes write phrases in I6 which claim to return a room, say, but sometimes return `nothing`. Technically this is a violation of type safety. If t is a term representing a call to this function, then *room*(t) ought to be redundant. But in practice it will protect against the `nothing` value. The other reason is to ensure that text like "Peter is a man" is not simplified all the way down to the null proposition (as it clearly can be, if Peter is indeed a man). That might seem harmless, but means that "now Peter is a man" doesn't produce the problem message saying that kinds can't be asserted – a common mistake made by beginners. It's better consistently to reject all such attempts than to be clever and allow the ones which are logically redundant.

(b) Why don't we reduce $K(C)$ to falsity when C is a constant clearly not of the kind K, such as *text*(4)? Again, it would make it harder to issue a good problem message later, in type-checking; and besides our calculus lacks a "falsity" atom, so there's no way to store the universally false proposition which would result if we eliminated every atom this way. (It also doesn't matter what the running time of compiled code will be if the proposition is going to fail type-checking anyway.)

⟨Strike out tautological kind predicates applied to constants 16⟩ ≡

```
TRAVERSE_VARIABLE(pl);
int blevel = start_level;
TRAVERSE_PROPOSITION(pl, start_group) {
    if (element_get_group(pl->element) == OPEN_OPERATORS_GROUP) blevel++;
    if (element_get_group(pl->element) == CLOSE_OPERATORS_GROUP) blevel--;
    if (blevel == 1) {
        if (pl->element == KIND_ATOM) {
            kind_of_value *early_kov = pl->assert_kind_of_value;
            specification *spec = pl->terms[0].constant;
            if (family_is(spec, VALUE_FMY)) {
                kind_of_value *kov = kov_when_VALUE_is_evaluated(spec);
                if ((kov) && (kovko_get_kind(early_kov) == NULL) &&
                    (can_we_cast_kovs(early_kov, kov) == ALWAYS_MATCH)) {
                    prop = prop_delete_atom(prop, pl_prev);
                    PROPOSITION_EDITED_REPEATING_CURRENT(pl, prop);
                }
            }
        }
    }
}
```

This code is used in §10.

§**17. Turn binary predicates the right way round (deduction).** Recall that BPs are manufactured in pairs, each being the reversal of the other, in the sense of transposing their terms. Of each pair, one is considered the canonical way to represent the relation, and is "the right way round". This routine turns all BPs in the proposition the right way round, if they aren't already.

Suppose B is a binary predicate which is marked as the wrong way round, and R is its reversal. Then we change:

$$\Sigma = \cdots B(t_1, t_2) \cdots \quad \longrightarrow \quad \Sigma' = \cdots R(t_2, t_1) \cdots$$

(Note that the equality predicate *is* only has one way round, and it's the right one – this is the only exception to the rule that BPs come in pairs – so equality predicates won't be turned around here, not that it would matter if they were.)

```
pcalc_prop *simp_turn_right_way_round(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        binary_predicate *bp = atom_is_binary_predicate(pl);
        if ((bp) && (bp_is_the_wrong_way_round(bp))) {
            pcalc_term pt = pl->terms[0];
            pl->terms[0] = pl->terms[1];
            pl->terms[1] = pt;
            pl->predicate = STORE_POINTER_binary_predicate(bp_get_reversal(bp));
            PROPOSITION_EDITED(pl, prop);
        }
    }
    return prop;
}
```

The function simp_turn_right_way_round is called from 6/sconv.

§18. Simplify region containment (fudge). Most of Inform's prepositions are unambiguous, but "in" can mean two quite different relations. Usually it means (direct) containment, but there is an alternative interpretation as regional containment. "The diamond is in the teddy bear" is direct containment, but "The diamond is in Northumberland" is regional containment. We need to separate out these ideas into two different binary predicates because direct containment has a function f_D allowing simplification of many common sentences, but regional containment allows no such simplification. Basically: you can be directly contained by only one thing at a time, but might be in many regions at once.

So far we assume every "in" means the `a_contains_b_predicate`. This is the point where we choose to divert some uses to `a_region_contains_b_predicate`. If R is a constant region name, and C_D, C_R are the predicates for direct and region containment, then

$$\Sigma = \cdots C_D(t, R) \cdots \quad \longrightarrow \quad \Sigma' = \cdots C_R(t, R) \cdots$$

$$\Sigma = \cdots C_D(R, t) \cdots \quad \longrightarrow \quad \Sigma' = \cdots C_R(R, t) \cdots$$

(Note that a region cannot directly contain any object.)

```
pcalc_prop *simp_region_containment(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        binary_predicate *bp = atom_is_binary_predicate(pl);
        if (bp == a_contains_b_predicate) {
            int j;
            for (j=0; j<2; j++) {
                world_object *the_region =
                    spec_object_exactly_described_if_any(pl->terms[j].constant);
                if ((the_region) && (wo_of_kind(the_region, kind_region))) {
                    pl->predicate = STORE_POINTER_binary_predicate(a_region_contains_b_predicate);
                    PROPOSITION_EDITED(pl, prop);
                }
            }
        }
    }
    return prop;
}
```

The function simp_region_containment is called from 6/sconv.

§**19. Reduce binary predicates (deduction).** If we are able to reduce a binary to a unary predicate, we will probably gain considerably by being able to eliminate a variable altogether. For instance, suppose we have "Mme Cholet is in a burrow". This will initially come out as

$$\exists x : burrow(x) \wedge in(\texttt{Cholet}, x)$$

To test that proposition requires trying all possible burrows x. But exploiting the fact that Mme Cholet can only be in one place at a time, we can reduce the binary predicate to equality, thus:

$$\exists x : burrow(x) \wedge is(\texttt{ContainerOf}(\texttt{Cholet}), x)$$

A later simplification can then observe that this tells us what x must be, and eliminate both quantifier and variable.

Formally, suppose B is a predicate with a function f_B such that $B(x, y)$ is true if and only $y = f_B(x)$. Then:

$$\Sigma = \cdots B(t_1, t_2) \cdots \quad \longrightarrow \quad \Sigma' = \cdots is(f_B(t_1), t_2) \cdots$$

Similarly, if there is a function g_B such that $B(x, y)$ if and only if $x = g_B(y)$ then

$$\Sigma = \cdots B(t_1, t_2) \cdots \quad \longrightarrow \quad \Sigma' = \cdots is(t_1, g_B(t_2)) \cdots$$

See "Binary Predicates" in Chapter 5 for how such functions are constructed. Not all BPs have them: the reason for our fudge on regional containment (above) is that direct containment does, but region containment doesn't, and this is why it was necessary to separate the two out.

```
pcalc_prop *simp_reduce_predicates(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        binary_predicate *bp = atom_is_binary_predicate(pl);
        if (bp) {
            int j;
            for (j=0; j<2; j++)
                if ((bp_get_term_as_function_of_other(bp, j)) &&
                    (bp_allows_function_simplification(bp))) {
                    pl->terms[1-j] = term_new_function(bp, pl->terms[1-j], 1-j);
                    pl->predicate = STORE_POINTER_binary_predicate(a_is_b_predicate);
                    PROPOSITION_EDITED(pl, prop);
                }
        }
    }
    return prop;
}
```

The function simp_reduce_predicates is called from 6/sconv.

§20. Eliminating determined variables (deduction). The above operations will try to get as many variables as possible into a form which makes their values explicit with a predicate $is(v, t)$. We detect such equations and use them to eliminate the variable concerned, where this is safe.

```
define NOT_BOUND_AT_ALL 1
define BOUND_BY_EXISTS 2
define BOUND_BY_SOMETHING_ELSE 3

pcalc_prop *simp_eliminate_redundant_variables(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    int level, binding_status[26], binding_level[26], binding_sequence[26];
    pcalc_prop *position_of_binding[26];
    *changed = FALSE;
    ⟨Find out where and how variables are bound 21⟩;
    EliminateVariables:
    level = 0;
    TRAVERSE_PROPOSITION(pl, prop) {
        if (element_get_group(pl->element) == OPEN_OPERATORS_GROUP) level++;
        if (element_get_group(pl->element) == CLOSE_OPERATORS_GROUP) level--;
        if (atom_is_equality_predicate(pl)) {
            int j;
            for (j=1; j>=0; j--) {
                int var_to_sub = pl->terms[j].variable;
                int var_in_other_term = term_variable_underlying(&(pl->terms[1-j]));
                int var_is_redundant = FALSE, value_can_be_subbed = FALSE;
                ⟨Decide if the variable is redundant, and if its value can safely be subbed 22⟩;
                if ((var_is_redundant) && (value_can_be_subbed)) {
                    int permitted;
                    vars_substitute_term(prop, var_to_sub, pl->terms[1-j],
                        TRUE, &permitted, changed);
                    if (permitted) {
                        LOGIF(WORKINGS, "Substituting %c <-- $0\n",
                            pcalc_vars[var_to_sub], &(pl->terms[1-j]));
                        first delete the is(v,t) predicate
                        prop = prop_delete_atom(prop, pl_prev);
                        then unbind the variable, by deleting its ∃v quantifier
                        prop = prop_delete_atom(prop, position_of_binding[var_to_sub]);
                        binding_status[var_to_sub] = NOT_BOUND_AT_ALL;
                        then substitute for all other occurrences of v
                        prop = vars_substitute_term(prop, var_to_sub, pl->terms[1-j],
                            FALSE, NULL, changed);
                        *changed = TRUE;
                        since the proposition is now shorter by 2 atoms, this loop terminates
                        goto EliminateVariables;
                    }
                }
            }
        }
    }
    vars_renumber(prop);                                   for the sake of tidiness
    return prop;
}
```

The function simp_eliminate_redundant_variables is called from 6/sconv.

§**21.** The information-gathering stage:

⟨Find out where and how variables are bound 21⟩ ≡

```
int j, c = 0, level = 0;
for (j=0; j<26; j++) {
    binding_status[j] = NOT_BOUND_AT_ALL;
    binding_level[j] = 0; binding_sequence[j] = 0; position_of_binding[j] = NULL;
}
TRAVERSE_PROPOSITION(pl, prop) {
    if (element_get_group(pl->element) == OPEN_OPERATORS_GROUP) level++;
    if (element_get_group(pl->element) == CLOSE_OPERATORS_GROUP) level--;
    if (atom_is_quantifier(pl)) {
        int v = pl->terms[0].variable;
        if (atom_is_existence_quantifier(pl)) binding_status[v] = BOUND_BY_EXISTS;
        else binding_status[v] = BOUND_BY_SOMETHING_ELSE;
        binding_level[v] = level;
        binding_sequence[v] = c;
        position_of_binding[v] = pl_prev;
    }
    c++;
}
```

This code is used in §20.

§**22.** At this point we have a predicate $is(t, f_A(f_B(\cdots s)))$. Should the term t be a variable v, which is bound by an $\exists v$ atom at the same level in its subexpression, then we can consider eliminating v by substituting $v = f_A(f_B(\cdots s))$.

But only if the term s underneath those functions does not make the equation $is(v, f_A(f_B(\cdots s)))$ implicit. Suppose s depends on a variable w which is bound and occurs *after* the binding of v. The value of such a variable w can depend on the value of v. Saying that $v = s$ may therefore not determine a unique value of v at all: it may be a subtle condition passed by a whole class of possible values, or none.

The simplest example of such circularity is $is(v, v)$, true for all v. More problematic is $is(v, f_C(v))$, "v is the container of v", which is never true. Still worse is

$$\exists v : V_{=2} w : is(v, w)$$

which literally says there is a value of v equal to two different things – certainly false. But if we were allowed to eliminate v, we would get just

$$V_{=2} w$$

which asserts "there are exactly two objects" – which is certainly not a valid deduction, and might even be true.

Here `var_to_sub` is v and `var_in_other_term` is w, or else they are -1 if no variables are present in their respective terms.

⟨Decide if the variable is redundant, and if its value can safely be subbed 22⟩ ≡

```
if ((var_to_sub >= 0)
    && (binding_status[var_to_sub] == BOUND_BY_EXISTS)
    && (binding_level[var_to_sub] == level))
        var_is_redundant = TRUE;
if ((var_in_other_term < 0)
    || (binding_status[var_in_other_term] == NOT_BOUND_AT_ALL)
    || (binding_sequence[var_in_other_term] < binding_sequence[var_to_sub]))
        value_can_be_subbed = TRUE;
```

This code is used in §20.

§23. Simplify non-relation (deduction). As a result of the previous simplifications, it fairly often happens that we find a term like

$$\neg(\mathit{thing}(t.\texttt{component\_parent}))$$

in the proposition. This comes out of text such as "... not part of something", asserting first that there is no y such that t is a part of y, and then simplifying to remove the y variable. A term like the one above is then left behind. But the negation is cumbersome, and makes the proposition harder to assert or test. Exploiting the fact that `component_parent` is a property which is either the part-parent or else `nothing`, we can simplify to:

$$\mathit{is}(t.\texttt{component\_parent}, \texttt{nothing})$$

And similar tricks can be pulled for other various-to-one-object predicates.

Formally, let B be a binary predicate supporting either a function f_B such that $B(x, y)$ iff $f_B(x) = y$, or else such that $B(x, y)$ iff $f_B(y) = x$; and such that the values of f_B are objects. Let K be a kind of object. Then:

$$\Sigma = \cdots \neg(K(f_B(t))) \cdots \quad \longrightarrow \quad \Sigma' = \cdots \mathit{is}(f_B(t), \texttt{nothing}) \cdots$$

A similar trick for kinds of value is not possible, because – unlike objects – they have no "not a valid case" value analogous to the non-object `nothing`.

```
pcalc_prop *simp_not_related_to_something(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        pcalc_prop *kind_atom;
        if (prop_match(pl, 3,
            NEGATION_OPEN_ATOM, NULL,
            KIND_ATOM, &kind_atom,
            NEGATION_CLOSE_ATOM, NULL)) {
            world_object *k = kovko_get_kind(kind_atom->assert_kind_of_value);
            if (k) {
                binary_predicate *bp = NULL;
                pcalc_term KIND_term = kind_atom->terms[0];
                if (KIND_term.function) bp = KIND_term.function->bp;
                if ((bp) && (bp_term_kind(bp, 1) == k)) {
                    specification *new_nothing =
                        new_QUANTITY_spec(i6_nothing_quantity);
                    prop = prop_ungroup_after(prop, pl_prev, NULL);          remove negation grouping
                    prop = prop_delete_atom(prop, pl_prev);                  remove KIND_ATOM
                    now insert equality predicate:
                    prop = prop_insert_atom(prop, pl_prev,
                        atom_binary_PREDICATE_new(a_is_b_predicate,
                            KIND_term, term_new_constant(new_nothing)));
                    PROPOSITION_EDITED(pl, prop);
                }
            }
        }
    }
    return prop;
}
```

The function simp_not_related_to_something is called from 6/sconv.

§24. Convert gerunds to nouns (deduction). Suppose we write:

The funky thing to do is a stored action that varies.

and subsequently:

the funky thing to do is waiting

Here "waiting" is a gerund, and although it describes an action it is a noun (thus a value) rather than a condition. We coerce its constant value accordingly.

```
pcalc_prop *simp_convert_gerunds(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        if (atom_is_equality_predicate(pl)) {
            int i;
            for (i=0; i<2; i++)
                if (species_is(pl->terms[i].constant, TEST_ACTION_SPC))
                    coerce_TEST_ACTION_to_DESCRIPTION_OF_ACTION(pl->terms[i].constant);
        }
    }
    return prop;
}
```

The function simp_convert_gerunds is called from 6/sconv.

§25. Eliminate to have meaning property ownership (fudge). The verb "to have" normally means ownership of a physical thing, but it can also arise from text such as

the balloon has weight at most 1

where it's the numerical "weight" property which is owned by the balloon. (The language of abstract "property" always echoes that of real physical things – consider how the iTunes Music Store invites you to "buy" what is at best a lease of temporary, partial and revocable rights to make use of something with no physical essence. This isn't a con trick, or not altogether so. We like the word "buy"; we immediately understand it.) At this stage of simplification, the above has produced

$$\mathit{at\text{-}most}(\texttt{weight}, 1) \wedge \mathit{is}(\texttt{balloon}, f_H(\texttt{weight}))$$

where H is the predicate `a_has_b_predicate`. As it stands, this proposition will fail type-checking, because it contains an implicit free variable – the object which owns the weight. We make this explicit by removing $\mathit{is}(\texttt{balloon}, f_H(\texttt{weight}))$ and replacing all other references to `weight` with "the weight of `balloon`".

This is a fudge because it assumes – possibly wrongly – that all references to the weight are to the weight of the same thing. In sufficiently contrived sentences, this wouldn't be true.

```
pcalc_prop *simp_eliminate_to_have(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        if (atom_is_equality_predicate(pl)) {
            int i;
            for (i=0; i<2; i++)
                if ((pl->terms[i].function) &&
                    (pl->terms[i].function->bp == a_has_b_predicate) &&
                    (pl->terms[i].function->fn_of.constant) && (pl->terms[1-i].constant)) {
                    specification *spec = pl->terms[i].function->fn_of.constant;
                    if (spec_is_actual_CONSTANT_of_kova(spec, PROPERTY_TY))
                        ⟨Found an indication of who owns a property 26⟩;
                }
        }
    }
    return prop;
}
```

The function simp_eliminate_to_have is called from 6/sconv.

§26. So the current atom is $\mathit{is}(f_H(P), C)$ or $\mathit{is}(C, f_H(P))$ (according to whether i is 0 or 1), for a property P and a constant term C.

⟨Found an indication of who owns a property 26⟩ ≡

```
    property_name *prn = PROPERTY_spec_to_property_name(spec);
    specification *po_spec =
        new_PROPERTY_VALUE_spec(spec, pl->terms[1-i].constant);
    po_spec->word_ref1 = prn->word_ref1; po_spec->word_ref2 = prn->word_ref2;
    int no_substitutions_made;
    prop = prop_substitute_prop_cons(prop, prn, po_spec, &no_substitutions_made, pl);
    if (no_substitutions_made > 0) {
        prop = prop_delete_atom(prop, pl_prev);
        PROPOSITION_EDITED_REPEATING_CURRENT(pl, prop);
    }
```

This code is used in §25.

§**27.** Here we make the necessary substitution of "P" with "the P of C", where P is a property and C the constant value of its owner. We make this to every occurrence throughout the proposition, except for the one in the original $is(f_H(P), C)$ atom, and we count the number of changes made.

```
pcalc_prop *prop_substitute_prop_cons(pcalc_prop *prop, property_name *prn,
    specification *po_spec, int *count, pcalc_prop *not_this) {
    TRAVERSE_VARIABLE(pl);
    int j, c = 0;
    TRAVERSE_PROPOSITION(pl, prop)
        if (pl != not_this)
            for (j=0; j<pl->arity; j++) {
                pcalc_term *pt = &(pl->terms[j]);
                while (pt->function) pt = &(pt->function->fn_of);
                if (pt->constant == NULL) continue;
                if (spec_is_actual_CONSTANT_of_kova(pt->constant, PROPERTY_TY)) {
                    property_name *tprn;
                    tprn = PROPERTY_spec_to_property_name(pt->constant);
                    if (tprn == prn) {
                        pt->constant = po_spec;
                        c++;
                    }
                }
            }
    *count = c;
    return prop;
}
```

§28. Turn all rooms to everywhere (fudge). This rather special rule handles the consequences of the English word "everywhere". Inform reads that as "all rooms", literally "every where", which is logical but loses the connotation of place – by "everywhere", we usually mean "in all rooms", so that the sentence

The sky is everywhere.

means the sky is in every room, not that the sky is equal to every room. Since the literal reading would make no useful sense, Inform fudges the proposition to change it to the idiomatic one.

$$\Sigma = \cdots \forall v \in \{v \mid room(v)\} : is(v, t) \quad \longrightarrow \quad \Sigma' = \cdots everywhere(t)$$
$$\Sigma = \cdots \forall v \in \{v \mid room(v)\} : is(t, v) \quad \longrightarrow \quad \Sigma' = \cdots everywhere(t)$$
$$\Sigma = \cdots \not\forall v \in \{v \mid room(v)\} : is(v, t) \quad \longrightarrow \quad \Sigma' = \cdots \neg(everywhere(t))$$
$$\Sigma = \cdots \not\forall v \in \{v \mid room(v)\} : is(t, v) \quad \longrightarrow \quad \Sigma' = \cdots \neg(everywhere(t))$$

Note that we match this only at the end of a proposition, where v can have no other consequence.

```
pcalc_prop *simp_is_all_rooms(pcalc_prop *prop, int *changed) {
    TRAVERSE_VARIABLE(pl);
    *changed = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        pcalc_prop *q_atom, *k_atom, *bp_atom;
        if ((prop_match(pl, 6,
            QUANTIFIER_ATOM, &q_atom,
            DOMAIN_OPEN_ATOM, NULL,
            KIND_ATOM, &k_atom,
            DOMAIN_CLOSE_ATOM, NULL,
            PREDICATE_ATOM, &bp_atom,
            END_PROP_HERE, NULL)) &&
            ((atom_is_forall_quantifier(q_atom)) || (atom_is_notall_quantifier(q_atom))) &&
            (kovko_get_kind(k_atom->assert_kind_of_value) == kind_room) &&
            (bp_atom->arity == 2) &&
            (RETRIEVE_POINTER_binary_predicate(bp_atom->predicate) == a_is_b_predicate)) {
            int j, v = k_atom->terms[0].variable;
            for (j=0; j<2; j++) {
                if ((bp_atom->terms[1-j].variable == v) && (v >= 0)) {
                    prop = prop_delete_atom(prop, pl_prev);                  remove QUANTIFIER_ATOM
                    prop = prop_delete_atom(prop, pl_prev);                  remove DOMAIN_OPEN_ATOM
                    prop = prop_delete_atom(prop, pl_prev);                  remove KIND_ATOM
                    prop = prop_delete_atom(prop, pl_prev);                  remove DOMAIN_CLOSE_ATOM
                    prop = prop_delete_atom(prop, pl_prev);                  remove PREDICATE_ATOM
                    if (atom_is_notall_quantifier(q_atom))
                        prop = prop_insert_atom(prop, pl_prev, atom_new(NEGATION_CLOSE_ATOM));
                    prop = prop_insert_atom(prop, pl_prev,
                        atom_EVERYWHERE_new(bp_atom->terms[j]));
                    if (atom_is_notall_quantifier(q_atom))
                        prop = prop_insert_atom(prop, pl_prev, atom_new(NEGATION_OPEN_ATOM));
                    PROPOSITION_EDITED(pl, prop);
                    break;
                }
            }
        }
    }
    return prop;
}
```

The function simp_is_all_rooms is called from 6/sconv.

Type Check Propositions 6/tcpr

Purpose

Predicate calculus is a largely symbolic exercise, and its rules of working tend to assume that all predicates are meaningful for all terms: this means, for instance, that "if blue is 14" is likely to make a well-formed sentence in predicate calculus. In this section we reject such propositions on the grounds that they violate type-checking requirements on relations – in this example, the equality relation.

Definitions

¶1. We can unambiguously find the kind of value of any constant C, so if a proposition's terms are all constant then type-checking is easy. $is(4, \texttt{score})$ good, $is(4, \texttt{"fish"})$ bad. The subtlety comes in interpreting $is(4, x)$, where x is a variable. Our calculus allows variables to range over many domains – numbers, texts, scenes, objects, and so on. So it turns out to be convenient to have a structure holding a choice of kinds of value for the contents of the variables; such structures exist temporarily on the stack while we work.

```
typedef struct variable_type_assignment {
    struct kind_of_value *assigned_KOVs[26];                    one for each of the 26 variables
} variable_type_assignment;
```

The structure variable_type_assignment is private to this section.

¶2. Another convenience is a sort of kit for preparing problem messages:

```
typedef struct tc_problem_kit {
    int issue_error;
    int ew1, ew2;
    char *intention;
    int log_to_I6_text;
    int flag_problem;
} tc_problem_kit;
```

The structure tc_problem_kit is shared with 2/prob3, 6/equal, 9/cmpbp and 10/qnbp.

---

§**1. Problem reporting kit.** The caller to `prop_type_check` has to fill this form out first. Paperwork, what can you do, eh?

```
tc_problem_kit tc_no_problem_reporting(void) {
    tc_problem_kit tck;
    tck.issue_error = FALSE; tck.ew1 = -1; tck.ew2 = -1; tck.intention = "be silent checking";
    tck.log_to_I6_text = FALSE; tck.flag_problem = FALSE; return tck;
}
tc_problem_kit tc_problem_reporting(int w1, int w2, char *intent) {
    tc_problem_kit tck = tc_no_problem_reporting();
    tck.issue_error = TRUE; tck.ew1 = w1; tck.ew2 = w2; tck.intention = intent;
    return tck;
}
```

The function tc_no_problem_reporting is called from 6/pform, 7/tc, 11/ap, 13/nft and 13/test.
The function tc_problem_reporting is called from 6/asp, 6/defer and 7/tc.

§**2.** A version used only for the internal testing mode, when we print the outcome into the debugging log, but diverted to an I6 string in the compiled code.

```
tc_problem_kit tc_problem_logging(void) {
    tc_problem_kit tck = tc_no_problem_reporting();
    tck.intention = "be internal testing"; tck.log_to_I6_text = TRUE; return tck;
}
```

The function tc_problem_logging is called from 13/test.

§3. Type-checking whole propositions. This section provides a single routine to the rest of Inform: `prop_type_check`. We determine the KOVs for all variables, then work through the proposition, ensuring that every predicate-like atom has terms which match at least one possible reading of the meaning of the atom.

As usual in Inform, type-checking is not a passive process. If it can make sense of the proposition by changing it, it will do so.

```
int prop_type_check(pcalc_prop *prop, tc_problem_kit tck_s) {
    TRAVERSE_VARIABLE(pl);
    variable_type_assignment vta;
    tc_problem_kit *tck = &tck_s;
    int j;
    if (prop == NULL) return ALWAYS_MATCH;
    if (prop_is_well_formed(prop) == FALSE) internal_error("type-checking malformed proposition");
    ⟨First make sure any constants in the proposition have themselves been typechecked 4⟩;
    for (j=0; j<26; j++) vta.assigned_KOVs[j] = NULL;
    ⟨Look at KIND atoms to see what kinds of value are asserted for the variables 5⟩;
    ⟨Assume any still-unfathomable variables represent objects 6⟩;
    TRAVERSE_PROPOSITION(pl, prop) {
        for (j=0; j<pl->arity; j++) kov_of_term(&(pl->terms[j]), &vta, tck);
        if (tck->flag_problem) return NEVER_MATCH;
        if (pl->element == KIND_ATOM)
            ⟨A KIND atom is not allowed if it can be proved to be false 8⟩;
        if ((pl->element == PREDICATE_ATOM) && (pl->arity == 2))
            ⟨A binary predicate is required to apply to terms of the right kinds 10⟩;
        if ((pl->element == PREDICATE_ATOM) && (pl->arity == 1))
            ⟨A unary predicate is required to have an interpretation matching the kind of its term 9⟩;
        if (pl->element == EVERYWHERE_ATOM)
            ⟨An EVERYWHERE atom needs its term to be an object 13⟩;
        if (pl->element == ISAKIND_ATOM)
            ⟨An ISAKIND atom needs its term to be an object 12⟩;
        if (pl->element == HERE_ATOM)
            ⟨A HERE atom needs its term to be an object 14⟩;
    }
    if (tck->log_to_I6_text) ⟨Show the variable assignment in the debugging log 15⟩;
    return ALWAYS_MATCH;
}
```

The function prop_type_check is called from 6/pform, 6/asp, 6/defer, 7/tc, 11/ap, 13/nft and 13/test.

§**4. Finding KOVs for variables.** Every specification compiled by Inform has to pass through type-checking. That includes the ones which occur as constants inside propositions, and this is where.

The presence of an `UNKNOWN` constant indicates something which failed to be recognised by the S-parser. That shouldn't happen, but we allow for it so that we can recover from an already reported problem.

After this point, we can be sure that every constant is an actual rather than generic value, which makes sense within itself. For instance, if it is a phrase to decide a value, that its parameters themselves satisfy type-checking: "the location of 134" would be rejected.

⟨First make sure any constants in the proposition have themselves been typechecked 4⟩ ≡

```
TRAVERSE_PROPOSITION(pl, prop) {
    int j;
    for (j=0; j<pl->arity; j++) {
        specification *spec = term_constant_underlying(&(pl->terms[j]));
        if (spec) {
            if ((spec_is_UNKNOWN(spec)) ||
                (spec_is_generic(spec)) ||
                (typecheck_without_expectations(spec) == NEVER_MATCH))
                ⟨Recover from problem in S-parser by not issuing problem 7⟩;
        }
    }
}
```

This code is used in §3.

§**5.** If the proposition contains contradictory `KIND` atoms, it automatically fails type-checking, even if there is no implication that both apply at once. This throws out, for instance:

```
1. a scene which is not a number
[ scene(x) & NOT[ number(x) NOT] ]
Failed: proposition would not type-check
x is both scene and number
```

It could be argued that all scenes ought to pass this proposition, but we will treat it as a piece of nonsense, like "if Wednesday is not custard".

⟨Look at KIND atoms to see what kinds of value are asserted for the variables 5⟩ ≡

```
TRAVERSE_PROPOSITION(pl, prop)
    if (pl->element == KIND_ATOM) {
        int v = pl->terms[0].variable;
        if (v >= 0) {
            kind_of_value *new_kov = pl->assert_kind_of_value;
            if (is_kova(new_kov, OBJECT_TY)) new_kov = kova(OBJECT_TY);
            kind_of_value *old_kov = vta.assigned_KOVs[v];
            if (old_kov) {
                if (can_we_cast_kovs(old_kov, new_kov) == NEVER_MATCH) {
                    if (tck->log_to_I6_text)
                        LOG("%c is both $u and $u\n", pcalc_vars[v], old_kov, new_kov);
                    issue_kind_typecheck_error(old_kov, new_kov, tck, pl);
                    return NEVER_MATCH;
                }
            }
            vta.assigned_KOVs[v] = new_kov;
        }
    }
```

This code is used in §3.

§**6.** It's possible for a proposition to specify nothing about the kind of a variable (usually a free one). If so, it's assumed to be an object. For instance, if we define

Definition: a container is empty if the number of things in it is 0.

then we find that, say:

```
1. empty which is empty
[ 'empty'(x) & 'empty'(x) ]
x (free) - object.
```

though in fact it would also have been viable for x to be a rulebook, a list, or various other kinds of value.

⟨Assume any still-unfathomable variables represent objects 6⟩ ≡

```
int j;
for (j=0; j<26; j++)
    if (vta.assigned_KOVs[j] == NULL)
        vta.assigned_KOVs[j] = kova(OBJECT_TY);
```

This code is used in §3.

§**7.** The following is really rather paranoid; it ought to be certain that a problem message has already been issued, but just in case not...

⟨Recover from problem in S-parser by not issuing problem 7⟩ ≡

```
if (problem_count == 0) {
    if (tck->log_to_I6_text) LOG("Atom $o contains failed constant\n", pl);
    if (tck->issue_error == FALSE) return NEVER_MATCH;
    sentence_problem(_P_(BelievedImpossible),                    well, except via internal tests
        "this sentence seems to contain a value which makes no sense",
        "and I'm unfortunately not able to say why not. I can only "
        "suggest staring at it for a while.");
    LOG("Stare at this, then: $S\n", spec);
}
return NEVER_MATCH;
```

This code is used in §4.

§**8. Type-checking enforced on predicate-like atoms.** As with contradictory `KIND` atoms applied to variables, we will reject any `KIND` atom applied to a constant if it necessarily fails – even when the sense of the proposition is arguably correct. For example:

```
1. 100 is not a text
[ NOT[ text('100') NOT] ]
Failed: proposition would not type-check
Term '100' is number not text
```

"100 is not a number" would pass, on the other hand. It is obviously false, but not meaningless.

⟨A KIND atom is not allowed if it can be proved to be false 8⟩ ≡

```
kind_of_value *need_to_find = pl->assert_kind_of_value;
if (is_kova(need_to_find, OBJECT_TY)) need_to_find = kova(OBJECT_TY);
kind_of_value *actually_find = kov_of_term(&(pl->terms[0]), &vta, tck);
if (can_we_cast_kovs(actually_find, need_to_find) == NEVER_MATCH) {
    if (tck->log_to_I6_text)
        LOG("Term $0 is $u not $u\n", &(pl->terms[0]), actually_find, need_to_find);
    issue_kind_typecheck_error(actually_find, need_to_find, tck, pl);
    return NEVER_MATCH;
}
```

This code is used in §3.

§**9.** See below, of course.

⟨A unary predicate is required to have an interpretation matching the kind of its term 9⟩ ≡
```
if (type_check_unary_predicate(pl, &vta, tck) == NEVER_MATCH) {
    if (tck->log_to_I6_text) LOG("Adjective $o cannot be applied\n", pl);
    return NEVER_MATCH;
}
```
This code is used in §3.

§**10.** The BP case is interesting because it forgives a failure in one case: of $is(t, C)$, where C is a constant representing a value of an enumerated KOV. Sentence conversion is actually quite good at distinguishing these cases and can see the difference between "the bus is red" and "the fashionable hue is red", but it is defeated by cases where adjectives representing values are used about other values – "the Communist Rally is red", where "Communist Rally" is a scene rather than an object, for instance. We first try requiring `Rally` to be a colour: when that fails, we see if the atom *red*(`Rally`) would work instead. If it would, we make the change within the proposition.

⟨A binary predicate is required to apply to terms of the right kinds 10⟩ ≡
```
binary_predicate *bp = RETRIEVE_POINTER_binary_predicate(pl->predicate);
if (bp_is_the_wrong_way_round(bp)) internal_error("BP wrong way round");
if (type_check_binary_predicate(pl, &vta, tck) == NEVER_MATCH) {
    if (bp == a_is_b_predicate) {
        adjective_list_entry *alt = prop_noun_to_adj_conversion(pl->terms[1]);
        if (alt) {
            pcalc_prop test_unary = *pl;
            test_unary.arity = 1;
            test_unary.predicate = STORE_POINTER_adjective_list_entry(alt);
            if (type_check_unary_predicate(&test_unary, &vta, tck) == NEVER_MATCH)
                ⟨The BP fails type-checking 11⟩;
            pl->arity = 1;
            pl->predicate = STORE_POINTER_adjective_list_entry(alt);
        } else ⟨The BP fails type-checking 11⟩;
    } else ⟨The BP fails type-checking 11⟩;
}
```
This code is used in §3.

§**11.**

⟨The BP fails type-checking 11⟩ ≡
```
if (tck->log_to_I6_text) LOG("BP $o cannot be applied\n", pl);
return NEVER_MATCH;
```
This code is used in §10.

§**12.**

⟨An ISAKIND atom needs its term to be an object 12⟩ ≡
```
kind_of_value *actually_find = kov_of_term(&(pl->terms[0]), &vta, tck);
if (can_we_cast_kovs(actually_find, kova(OBJECT_TY)) == NEVER_MATCH)
    internal_error("ISAKIND atom misapplied");
```
This code is used in §3.

§**13.**

⟨An EVERYWHERE atom needs its term to be an object 13⟩ ≡

```
kind_of_value *actually_find = kov_of_term(&(pl->terms[0]), &vta, tck);
if (can_we_cast_kovs(actually_find, kova(OBJECT_TY)) == NEVER_MATCH) {
    if (tck->log_to_I6_text)
        LOG("Term $0 is $u not an object\n", &(pl->terms[0]), actually_find);
    quote_kov(4, actually_find);
    tcp_problem(_P_(C6EverywhereMisapplied), tck,
        "that seems to say that a value - specifically, %4 - is everywhere. "
        "To Inform, everywhere means 'in every room', and only objects "
        "can be everywhere - in fact not even all of those, as it's a "
        "privilege reserved for backdrops. (For instance, 'The sky is a "
        "backdrop. The sky is everywhere.' is allowed.)");
    return NEVER_MATCH;
}
```

This code is used in §3.

§**14.** It seems to be true that the A-parser never generates propositions which apply `HERE` incorrectly, but just in case:

⟨A HERE atom needs its term to be an object 14⟩ ≡

```
kind_of_value *actually_find = kov_of_term(&(pl->terms[0]), &vta, tck);
if (can_we_cast_kovs(actually_find, kova(OBJECT_TY)) == NEVER_MATCH) {
    if (tck->log_to_I6_text)
        LOG("Term $0 is $u not an object\n", &(pl->terms[0]), actually_find);
    quote_kov(4, actually_find);
    tcp_problem(_P_(BelievedImpossible), tck,
        "that seems to say that a value - specifically, %4 - is here. "
        "To Inform, here means 'in the room we're talking about', so only "
        "objects can be 'here'.");
    return NEVER_MATCH;
}
```

This code is used in §3.

§**15.** Not so much for the debugging log as for the internal test, in fact, which prints the log to an I6 string. This is the type-checking report in the case of success.

⟨Show the variable assignment in the debugging log 15⟩ ≡

```
int j, var_states[26], c=0;
vars_determine_status(prop, var_states, NULL);
for (j=0; j<26; j++)
    if (var_states[j] != UNUSED_VST) {
        LOG("%c%s - $u. ", pcalc_vars[j],
            (var_states[j] == FREE_VST)?" (free)":"",
            vta.assigned_KOVs[j]); c++;
    }
if (c>0) LOG("\n");
```

This code is used in §3.

§**16. The KOV of a term.** The following routine works out the kind of value stored in a term, something which requires contextual information: unless we know the kind of value stored in each variable, we cannot know the kind of value a general term represents, which is why the routine is here and not in the Terms section.

```
kind_of_value *kov_of_term(pcalc_term *pt, variable_type_assignment *vta,
    tc_problem_kit *tck) {
    kind_of_value *kov = kov_of_term_inner(pt, vta, tck);
    pt->term_checked_as_kov = kov;
    if (kov == NULL) tck->flag_problem = TRUE;
    return kov;
}
```

§**17.** The case needing attention is a term in the form $t = f_B(s)$. By recursion we can know the KOV of s, but we must check that f_B can validly be applied to a value of that kind. If B is a binary predicate with domains R and S (i.e., a subset of $R \times S$) then we will either have $f_B : R \to S$ or vice versa; so we have to check that s lies in R (or S, respectively).

```
kind_of_value *kov_of_term_inner(pcalc_term *pt, variable_type_assignment *vta,
    tc_problem_kit *tck) {
    if (pt->constant) return spec_evaluates_to(pt->constant);
    if (pt->variable >= 0) return vta->assigned_KOVs[pt->variable];
    if (pt->function) {
        binary_predicate *bp = pt->function->bp;
        kind_of_value *kov_found = kov_of_term(&(pt->function->fn_of), vta, tck);
        kind_of_value *kov_from = approximate_argument_kov(bp, pt->function->from_term);
        kind_of_value *kov_to = approximate_argument_kov(bp, 1 - pt->function->from_term);
        if ((kov_from) && (can_we_cast_kovs(kov_found, kov_from) == NEVER_MATCH)) {
            if (tck->log_to_I6_text)
                LOG("Term $0 applies function to $u not $u\n", pt, kov_found, kov_from);
            issue_bp_typecheck_error(bp, kov_found, kov_to, tck);
            kov_found = kov_from;                                    the better to recover
        }
        if (kov_to) return kov_to;
        return kov_found;
    }
    return NULL;
}
```

§**18.** Some relations specify a KOV or kind of object for their terms, others do not. When they do specify a kind of object, we usually want to be forgiving about nuances of the kind of object – for our purposes here, any object will do. (Run-time type checking takes care of those nuances better.)

The following gives either the KOV or, for any kind of object at all, `OBJECT_TY`, for a given term. It should be used only where the BP is one constraining its terms, such as when it provides a f_B function.

```
kind_of_value *approximate_argument_kov(binary_predicate *bp, int i) {
    kind_of_value *kov = bp_term_kind_of_value(bp, i);
    if (kov) return kov;
    return kova(OBJECT_TY);
}
```

§**19. Type-checking predicates.** We take unary predicates first, then binary. Unary predicates are just adjectives, and all of the work for that has already been done in Chapter 5, so we need only produce a problem message when the worst happens.

```
int type_check_unary_predicate(pcalc_prop *pl, variable_type_assignment *vta,
    tc_problem_kit *tck) {
    adjective_list_entry *tr = RETRIEVE_POINTER_adjective_list_entry(pl->predicate);
    adjectival_phrase *aph = get_adjective_from_list_entry(tr);
    kind_of_value *kov = kov_of_term(&(pl->terms[0]), vta, tck);
    if (aph_applicable_to(aph, kov) == FALSE) {
        if (tck->log_to_I6_text)
            LOG("Adjective '$W' undefined on $u\n", aph->word_ref1, aph->word_ref2, kov);
        quote_words(4, aph->word_ref1, aph->word_ref2);
        quote_kov(5, kov);
        tcp_problem(_P_(C6AdjectiveMisapplied), tck,
            "that seems to involve applying the adjective '%4' to %5 - and I "
            "have no definition of it which would apply in that situation. "
            "(Try looking it up in the Lexicon part of the Phrasebook index "
            "to see what definition(s) '%4' has.)");
        return NEVER_MATCH;
    }
    return ALWAYS_MATCH;
}
```

§**20.** Binary predicates (BPs) are both easier and harder. Easier because they have only one definition at a time (unlike, say, the adjective "empty"), harder because the work hasn't already been done and because some BPs – like "is" – are polymorphic. Here goes:

```
int type_check_binary_predicate(pcalc_prop *pl, variable_type_assignment *vta,
    tc_problem_kit *tck) {
    binary_predicate *bp = RETRIEVE_POINTER_binary_predicate(pl->predicate);
    kind_of_value *kovs_of_terms[2], *kovs_required[2];
    ⟨Work out what KOVs we find, and what we should have found 21⟩;
    int result = bp_typecheck(bp, kovs_of_terms, kovs_required, tck);
    if (result != DECLINE_TO_MATCH) {
        if (result == NEVER_MATCH_SAYING_WHY_NOT) {
            if (tck->issue_error == FALSE) return NEVER_MATCH;
            if (pl->terms[0].function)
                issue_bp_typecheck_error(pl->terms[0].function->bp,
                    kov_of_term(&(pl->terms[0].function->fn_of), vta, tck),
                    kovs_of_terms[1], tck);
            else if (pl->terms[1].function)
                issue_bp_typecheck_error(pl->terms[1].function->bp,
                    kovs_of_terms[0],
                    kov_of_term(&(pl->terms[1].function->fn_of), vta, tck),
                    tck);
            else {
                LOG("($u, $u) failed in $2\n", kovs_of_terms[0], kovs_of_terms[1], bp);
                quote_kov(4, kovs_of_terms[0]);
                quote_kov(5, kovs_of_terms[1]);
                tcp_problem(_P_(C6ComparisonFailed), tck,
                    "that would mean comparing two kinds of value which cannot mix - "
```

```
                "%4 and %5 - so this must be incorrect.");
        }
        return NEVER_MATCH;
    }
    return result;
}
⟨Apply default rule applying to most binary predicates 22⟩;
return ALWAYS_MATCH;
}
```

§**21.** Once again we treat any kind of object as just `OBJECT_TY`, but we do take note that some BPs – like *is* – specify no kinds at all, and so produce a `kov_required` which is `NULL`.

⟨Work out what KOVs we find, and what we should have found 21⟩ ≡

```
int i;
for (i=0; i<2; i++) {
    if (bp_term_kind_of_value(bp, i)) kovs_required[i] = bp_term_kind_of_value(bp, i);
    else if (bp_term_kind(bp, i)) kovs_required[i] = kova(OBJECT_TY);
    else kovs_required[i] = NULL;
    kovs_of_terms[i] = kov_of_term(&(pl->terms[i]), vta, tck);
}
```

This code is used in §20.

§**22.** The default rule is straightforward: the KOVs found have to match the KOVs required.

⟨Apply default rule applying to most binary predicates 22⟩ ≡

```
int i;
for (i=0; i<2; i++)
    if (kovs_required[i])
        if (can_we_cast_kovs(kovs_of_terms[i], kovs_required[i]) == NEVER_MATCH) {
            if (tck->log_to_I6_text)
                LOG("Term %d is $u not $u\n",
                    i, kovs_of_terms[i], kovs_required[i]);
            issue_bp_typecheck_error(bp, kovs_of_terms[0], kovs_of_terms[1], tck);
            return NEVER_MATCH;
        }
```

This code is used in §20.

§23. Two problem messages needed more than once.

```
void issue_bp_typecheck_error(binary_predicate *bp,
    kind_of_value *t0, kind_of_value *t1, tc_problem_kit *tck) {
    quote_kov(4, t0);
    quote_kov(5, t1);
    quote_relation(6, bp);
    tcp_problem(_P_(C6TypeCheckBP2), tck,
        "that would mean applying %6 to kinds of value which do not "
        "fit - %4 and %5 - so this must be incorrect.");
}

void issue_kind_typecheck_error(kind_of_value *actually_find,
    kind_of_value *need_to_find, tc_problem_kit *tck, pcalc_prop *ka) {
    binary_predicate *bp = NULL;
    if ((ka) && (GENERAL_POINTER_IS_NULL(ka->predicate) == FALSE))
        bp = RETRIEVE_POINTER_binary_predicate(ka->predicate);
    quote_kov(4, actually_find);
    quote_kov(5, need_to_find);
    if (bp) {
        quote_relation(6, bp);
        tcp_problem(_P_(C6TypeCheckBP2a), tck,
            "that doesn't work because you use %6 with %4 instead of %5.");
    } else {
        tcp_problem(_P_(C6TypeCheckKind), tck,
            "%4 cannot be %5, so this must be incorrect.");
    }
}
```

The function issue_bp_typecheck_error is called from 9/mapbp and 9/cmpbp.

The Equality Relation 6/equal

Purpose

To define that prince among predicates, the equality relation.

Definitions

¶1. This predicate expresses the meaning of $a = b$, and plays a very special role in our calculus.

```
binary_predicate *a_is_b_predicate = NULL;
```

---

§**1. Initial stock.** This relation is hard-wired in, and it is made in a slightly special way since (alone among binary predicates) it has no distinct reversal.

```
void EQUALITY_KBP_create_initial_stock(void) {
    a_is_b_predicate = make_equality();
    register_reworded_meaning(MISCELLANEOUS_MC, RELATION_SMC,
        equality_V, relation_V, -1, -1, 0,
        STORE_POINTER_binary_predicate(a_is_b_predicate));
}
```

The function EQUALITY_KBP_create_initial_stock is called from 5/bp.

§**2. Second stock.** There is none, of course.

```
void EQUALITY_KBP_create_second_stock(void) {
}
```

The function EQUALITY_KBP_create_second_stock is called from 5/bp.

§**3. Typechecking.** This is a very polymorphic relation, in that it can accept terms of almost any kind.

```
int EQUALITY_KBP_typecheck(binary_predicate *bp,
        kind_of_value **kovs_of_terms, kind_of_value **kovs_required, tc_problem_kit *tck) {
    if ((is_kova(kovs_of_terms[0], OBJECT_TY)) &&
        (kov_name_can_coincide_with_property(kovs_of_terms[1])))
        ⟨Apply rule for "is" applied to an object and a value 4⟩
    else if ((is_kova(kovs_of_terms[0], STORED_ACTION_TY)) &&
        (is_kova(kovs_of_terms[1], DESCRIPTION_OF_ACTION_TY)))
        ⟨Apply rule for "is" applied to a stored action and a gerund 5⟩
    else
        ⟨Allow comparison only where left domain and right domain are not disjoint 6⟩;
    return ALWAYS_MATCH;
}
```

The function EQUALITY_KBP_typecheck is called from 5/bp.

§**4.** This case is only separated in order to provide a better problem message for a fairly common mistake:

⟨Apply rule for "is" applied to an object and a value 4⟩ ≡

```
property_name *prn = kov_get_coinciding_property(kovs_of_terms[1]);
if (prn == NULL) {
    if (tck->log_to_I6_text)
        LOG("Comparison of object with $u value\n", kovs_of_terms[1]);
    quote_kov(4, kovs_of_terms[1]);
    tcp_problem(_P_(C6NonPropertyCompared), tck,
        "taken literally that says that an object is the same as a "
        "value. Maybe you intended to say that the object "
        "has a property - but right now %4 is not yet a property; if you "
        "want to use it as one, you'll need to say so. (You can turn a "
        "kind of value - say, 'colour' - into a property by writing - "
        "say - 'A thing has a colour.')");
    return NEVER_MATCH;
}
```

This code is used in §3.

§**5.** This rule is the easiest of all – we always allow it. For instance,

if the current action is taking something...

⟨Apply rule for "is" applied to a stored action and a gerund 5⟩ ≡

```
;
```

This code is used in §3.

§**6.** With comparisons there is no restriction on the two KOVs except that they must match each other; $is(t, s)$ is allowed if $K(t) \subseteq K(s)$ or vice versa. So rules and rulebooks are comparable, for instance, but numbers and scenes are not.

⟨Allow comparison only where left domain and right domain are not disjoint 6⟩ ≡

```
if ((can_we_cast_kovs(kovs_of_terms[0], kovs_of_terms[1]) == NEVER_MATCH) &&
    (can_we_cast_kovs(kovs_of_terms[1], kovs_of_terms[0]) == NEVER_MATCH)) {
    if (tck->log_to_I6_text)
        LOG("Unable to compare $u with $u\n", kovs_of_terms[0], kovs_of_terms[1]);
    return NEVER_MATCH_SAYING_WHY_NOT;
}
```

This code is used in §3.

§**7. Assertion.** In general values differ, and cannot be equated by fiat. But an exception is setting a global variable.

```
int EQUALITY_KBP_assert(binary_predicate *bp,
        world_object *wo0, specification *spec0,
        world_object *wo1, specification *spec1) {
    if (spec_is_actual_NONLOCAL_VARIABLE(spec0)) {
        quantity *q = RETRIEVE_FROM_SPEC(spec0, quantity);
        inference_subject infs = inference_subject_q(q);
        inference *i;
        if (wo1) {
            i = create_global_inference(infs, world_object_to_OBJECT_spec(wo1));
            i->word_ref1 = wo1->word_ref1; i->word_ref2 = wo1->word_ref2;
        } else {
            i = create_global_inference(infs, spec1);
            i->word_ref1 = spec1->word_ref1; i->word_ref2 = spec1->word_ref2;
        }
        join_inference(i, infs);
        qty_now_has_initial_value_set(q);
        return TRUE;
    }
    return FALSE;
}
```

The function EQUALITY_KBP_assert is called from 5/bp.

§**8. Compilation.** Since we are compiling to I6, which is itself a C-level programming language, it looks at first as if we can compile *is* into `==` when testing equality and `=` when asserting it: thus

now the score is 10;

if the score is 10, ...

would compile to `score = 10;` and `if (score == 10) ...` respectively.

But there are three problems with this simplistic approach to "A is B".

(a) Sometimes "now A is B" must set a property of A, which does not change, rather than making A equal to B; and similarly for testing.
(b) Sometimes A is reference to a value stored in some data structure other than a local or global variable: for example, in "now entry 3 of the passenger list is 208", where A is "entry 3 of the passenger list". Access to this value is via I6 routines in the template, and the form of what we compile has to be different depending on whether we are reading or writing.
(c) Sometimes the values in question are block values, that is, they are stored as pointers to blocks of data on the heap at run-time. If we compile "now T is X", where T is an indexed text variable and X is some piece of text, we cannot simply copy the pointers: T needs to hold a fresh, independent copy of the text referred to by X.

Problem (a) is easily detected by looking at the kinds of value of A and B. To handle problems (b) and (c), we use a general framework in which the schema is a function of both the storage class of A and the kinds of value of both A and B.

```
int EQUALITY_KBP_compile(int task, binary_predicate *bp, annotated_i6_schema *asch) {
    kind_of_value *st[2];
    st[0] = cind_kind_of_value_of_term(asch->pt0);
    st[1] = cind_kind_of_value_of_term(asch->pt1);
    if ((is_kova(st[0], OBJECT_TY)) &&
        (kov_name_can_coincide_with_property(st[1])) && (kov_get_coinciding_property(st[1])))
        ⟨Handle the case of setting a property of A separately 9⟩;
    switch (task) {
        case TEST_ATOM_TASK:
            sch_write_to_existing(asch->schema, kov_interpret_test_equality(st[0], st[1]));
            return TRUE;
        case NOW_ATOM_FALSE_TASK:
            break;
        case NOW_ATOM_TRUE_TASK: {
            int storage_class = spec_get_storage_form(asch->pt0.constant);
            ⟨Forbid setting something to an action pattern 10⟩;
            if (storage_class != UNKNOWN) {
                ⟨Exceptional case of setting the "player" global variable 11⟩;
                sch_write_to_existing(asch->schema,
                    kov_interpret_store(storage_class, st[0], st[1]));
                return TRUE;
            }
            ⟨Issue problem message for being unable to set equal 12⟩;
            break;
        }
    }
    return FALSE;
}
```

The function EQUALITY_KBP_compile is called from 5/bp.

§**9.** So here is the exceptional case (a) mentioned above. Suppose we have:

if the lantern is bright, ...

where "bright" is one value of "luminance", which is both a kind of value and also a property. We then want to test if the luminance property of the lantern equals the constant value "bright"; and similarly for "now the lantern is bright".

⟨Handle the case of setting a property of A separately 9⟩ ≡

```
property_name *prn = kov_get_coinciding_property(st[1]);
switch (task) {
    case TEST_ATOM_TASK:
        sch_write_to_existing_1(asch->schema, "*1.%s == *2", prn_get_i6_identifier(prn));
        return TRUE;
    case NOW_ATOM_FALSE_TASK:
        break;
    case NOW_ATOM_TRUE_TASK:
        sch_write_to_existing_1(asch->schema, "*1.%s = *2", prn_get_i6_identifier(prn));
        return TRUE;
}
return FALSE;
```

This code is used in §8.

§**10.** Setting true exceptions. It could be argued that this ought to be a typechecking rule, but it applies only to setting true, so is here instead. The distinction is there because we can check whether an action is "taking a container" (say) but can't set a stored action equal to it, because it's too vague: what is the container to be taken?

⟨Forbid setting something to an action pattern 10⟩ ≡

```
if (is_kova(asch->pt1.term_checked_as_kov, DESCRIPTION_OF_ACTION_TY)) {
    sentence_problem(_P_(C6SetStoredAction),
        "that would use 'now' to set a value to an action",
        "and you've written this action as a condition: you need to use the "
        "form 'action of...' instead. For instance, 'now X is the action of "
        "taking the diamonds' is legal, but 'now X is taking the diamonds' "
        "is not.");
    asch->schema = NULL;
    return TRUE;
}
```

This code is used in §8.

§**11.** A little bit of support within Inform to help the template layer. It's very important that code compiled by Inform 7 not ever simply alter the value of `player`, as that if executed would break the invariants for the various I6 variables about the current situation. The correct thing is always to call the template routine `ChangePlayer`. But the user of I7 should not need to know that, so we take care of it here:

⟨Exceptional case of setting the "player" global variable 11⟩ ≡

```
if (spec_is_this_NONLOCAL_VARIABLE(asch->pt0.constant, player_quantity)) {
    sch_write_to_existing(asch->schema, "ChangePlayer(*2)");
    return TRUE;
}
```

This code is used in §8.

§**12.** Rather than just returning `FALSE` for a generic problem message, we issue one that's more helpfully specific and return `TRUE`.

⟨Issue problem message for being unable to set equal 12⟩ ≡

```
if (spec_get_constant_quantity_if_any(asch->pt0.constant))
    sentence_problem(_P_(C6CantChangeNamedConstant),
        "I can't change that",
        "because it is a name for a constant value. Some named values, "
        "like 'the score', can be changed, because they were defined "
        "as values that vary. But others are fixed. If we write 'The "
        "oak tree can be sturdy, lightning-struck or leaning.', for "
        "instance, then 'sturdy' is a name for a value which is fixed, "
        "just as the number '7' is fixed.");
else
    sentence_problem(_P_(C6CantEquateValues),
        "equality is not something I can change",
        "so either those are already the same or are different, and I "
        "can't alter matters.");
asch->schema = NULL;
return TRUE;
```

This code is used in §8.

§13. Problem message text.

```
int EQUALITY_KBP_describe_for_problems(binary_predicate *bp, char *problem_buffer) {
    return FALSE;
}
```

The function EQUALITY_KBP_describe_for_problems is called from 5/bp.

Assert Propositions 6/asp

Purpose

To declare that a given proposition is a true statement about the state of the world when play begins.

Definitions

¶1. Inside Inform, the term "the model" means the collection of the following:

(1) The objects, divided into:
  (1a) World objects, such as "Brazilian frog" or "Jungle Clearing"; each of which belongs to a kind;
  (1b) Kinds of (world) object, such as "animal" or "room"; each of which is a kind in turn of another kind, even if only "kind", which is its own kind;
  (1c) Named constant values, such as "red" or "Entire Game"; each of which belongs to a kind of value;
  (1d) Kinds of value whose values are all named, such as "colour" or "scene".

(2) The associated values, divided into:
  (2a) Properties, such as "open" or "carrying capacity", each of which is held by some subset of the objects – for instance, containers and people are permitted to have the "carrying capacity" property;
  (2b) Global variables, such as "time of day".

(3) Relations between the objects (or in some cases between objects and values outside the model), such as "containment".

Much else lies outside the model: values like `152` or `"alfalfa"`, rules, rulebooks, phrases, relations which can only be tested (such as "less than" or "visibility") and so on. Some of this is excluded because it is beyond the source text's power to decide facts about it (for instance, that 5 is less than 6); other matter is left out because it only relates to what happens to the world after its initial creation (for instances, actions and activities). The model is that which the source text can decide about the initial state of things.

¶2. The initial state of the world is built from the model. Properly speaking a few other things contribute, too – such as the entries initially found in table cells – but these don't need careful handling, since they are explicitly declared as literals in the source text: there is no need to analyse their meaning.

To build or change the model, we assert that propositions about it are true, using `prop_true_in_world_model` or `prop_true_in_world_model_about`. This is the *only* way to create kinds, world objects, kinds of value, global variables, and constant values, and also the *only* way to attach properties to objects, to set property values or the kind of a given object or the value of a global variable, or to declare that relationships hold.

However, creating new property names and new relations does not count as a change in the model world. (After all, we could create a new property called "scent" and a new relation called "admiring", but then choose not to attach scent to anything or to relate any objects by admiring. The model world would then not have changed at all.) So creating new properties and new relations is not done by asserting propositions.

¶3. `prop_true_in_world_model` asserts propositions in which all variables are bound (or which have no variables); `prop_true_in_world_model_about` asserts propositions in which x is free but all other variables are bound, and substitutes either an object O or a value V into x before asserting. These two procedures are the entire API, so to speak, for growing or changing the model. They are used by the detailed-look part of the A-parser, mostly found in Chapter 8, which takes assertion sentences in the source text and converts them into a series of propositions which it would like to make true.

Either way those requests come in, they all end up in the central `prop_true_in_model` procedure, one of the most important choke points within Inform. `prop_true_in_model` and its delegates – routines to assert the truth of various adjectives or relations – are allowed to call routines such as `set_kind` and `create_world_object` which are forbidden for use in the rest of Inform. These are guarded with the following macro, to ensure that we don't accidentally break this rule:

```
define PROTECTED_MODEL_PROCEDURE
    if (ptim_recursion_depth == 0)
        internal_error("protected model-affecting procedure used outside proposition assert");
```

```
int ptim_recursion_depth = 0;                                   depth of recursion of prop_true_in_model
```

---

§**1. Entrance.** This first entrance is a mere alias for the second.

```
void prop_true_in_world_model(pcalc_prop *prop) {
    prop_true_in_world_model_about(prop, NULL, NULL);
}
```

The function prop_true_in_world_model is called from 8/creat, 8/knowp, 8/relv, 9/prop, 9/pp and 10/tab.

§**2.** If we are working along a proposition and reach, say, $door(x)$, we can only assert that if we know what the value of x is. We therefore keep an array (or a pair of arrays) holding our current beliefs about the values of the variables – this is called the "identification slate".

```
world_object **current_interpretation_as_wo = NULL;             must point to a 26-element array
specification **current_interpretation_as_spec = NULL;          must point to a 26-element array
```

§**3.** The second entrance, then, keeps track of the recursion depth but also ensures that the identification slate is always correct, stacking them so that an inner `prop_true_in_model` has an independent slate from an outer one.

```
void prop_true_in_world_model_about(pcalc_prop *prop,
    world_object *ox, specification *ots) {
    world_object **saved_interpretation_as_wo = current_interpretation_as_wo;
    specification **saved_interpretation_as_spec = current_interpretation_as_spec;
    int saved_prevailing_mood = prevailing_mood;                which should not change, but just in case
    ⟨Establish a new identification slate for the variables in the proposition 4⟩;
    ptim_recursion_depth++;
    prop_true_in_model(prop);
    ptim_recursion_depth--;
    prevailing_mood = saved_prevailing_mood;
    current_interpretation_as_wo = saved_interpretation_as_wo;
    current_interpretation_as_spec = saved_interpretation_as_spec;
}
```

The function prop_true_in_world_model_about is called from 5/rel, 8/creat, 8/mass, 8/knowc, 8/knowp, 8/relv, 8/imp, 9/pp and 10/tab.

§**4.** The slate is initially blank unless substitutions for variable x have been supplied; x of course is variable number 0.

```
⟨Establish a new identification slate for the variables in the proposition 4⟩ ≡
    world_object *ciawo[26]; specification *ciats[26];
    int k;
    for (k=0; k<26; k++) { ciawo[k] = NULL; ciats[k] = NULL; }
    ciawo[0] = ox; ciats[0] = ots;
    if ((ox) && (ots)) internal_error("both ox and ots targets set");
    current_interpretation_as_wo = ciawo; current_interpretation_as_spec = ciats;
```

This code is used in §3.

§**5. Main procedure.** As can be seen, `prop_true_in_model` is a simple procedure. After a little fuss to check that everything is set up right, we simply run through the proposition one atom at a time.

This is a modest scheme. We are unable to assert any proposition other than $\exists$, so that we never see their attendant domain brackets. We are therefore left with a proposition in the form $P_1 \wedge P_2 \wedge ... \wedge P_n$ where each P_i is either a predicate-like atom, an $\exists v$ term for some variable v, or else $\neg(...)$ of a similar conjunction.

This is an ambiguous task if we have to assert $\neg(P \wedge Q)$, which is in effect a form of disjunction: $P \wedge Q$ fails if either is false, so which do we falsify? We choose both.

That means we can simply assert each atom in turn, with a parity depending on its nesting in negation brackets, which is nice and easy to write:

```
void prop_true_in_model(pcalc_prop *prop) {
    if (prop == NULL) return;
    ⟨Record the proposition in the debugging log 6⟩;
    if (prop_contains_nonexistence_quantifier(prop))
        ⟨Issue a problem message explaining that the proposition isn't exact enough 7⟩;
    ⟨Typecheck the proposition, in case this has not already been done 8⟩;
    ⟨Check the identification slate against variable usage in the proposition 9⟩;
    TRAVERSE_VARIABLE(pl);
    int now_negated = FALSE;
    TRAVERSE_PROPOSITION(pl, prop) {
        switch(pl->element) {
            case NEGATION_OPEN_ATOM: case NEGATION_CLOSE_ATOM:
                now_negated = (now_negated)?FALSE:TRUE; break;
            case QUANTIFIER_ATOM: ⟨Assert the truth or falsity of a QUANTIFIER atom 10⟩; break;
            case KIND_ATOM: ⟨Assert the truth or falsity of a KIND atom 14⟩; break;
            case PREDICATE_ATOM:
                switch (pl->arity) {
                    case 1: ⟨Assert the truth or falsity of a unary predicate 17⟩; break;
                    case 2: ⟨Assert the truth or falsity of a binary predicate 18⟩; break;
                }
                break;
            case HERE_ATOM: ⟨Assert the truth or falsity of a HERE atom 16⟩; break;
            case EVERYWHERE_ATOM: ⟨Assert the truth or falsity of an EVERYWHERE atom 15⟩; break;
            case ISAKIND_ATOM: case ISAKOV_ATOM: case ISAVAR_ATOM:
                if (now_negated) internal_error("ISA... atoms cannot be negated");
                break;
        }
    }
}
```

§**6.** The certainty, the initial interpretation slate, and the proposition are combined into a single line in the log:

⟨Record the proposition in the debugging log 6⟩ ≡

```
int i;
LOGIF(ASSERTIONS, "::");
switch(prevailing_mood) {
    case IMPOSSIBLE_CE: LOGIF(ASSERTIONS, " (impossible)"); break;
    case UNLIKELY_CE: LOGIF(ASSERTIONS, " (unlikely)"); break;
    case UNKNOWN_CE: LOGIF(ASSERTIONS, " (no certainty)"); break;
    case LIKELY_CE: LOGIF(ASSERTIONS, " (likely)"); break;
    case CERTAIN_CE: break;
    default: LOG(" (unknown certainty)"); break;
}
for (i=0; i<26; i++) {
    if (current_interpretation_as_wo[i]) {
        LOGIF(ASSERTIONS, " %c = $O", pcalc_vars[i], current_interpretation_as_wo[i]);
    } else if (current_interpretation_as_spec[i]) {
        LOGIF(ASSERTIONS, " %c = $S", pcalc_vars[i], current_interpretation_as_spec[i]);
    }
}
LOGIF(ASSERTIONS, " $D\n", prop);
```

This code is used in §5.

§**7.** It's surprisingly hard to get this problem message, because the assertion-maker rejects most of the obvious ways to try it with more direct problems. It took me about twenty sentences to get there ("The car is a vehicle in most rooms which are dark" will do it).

⟨Issue a problem message explaining that the proposition isn't exact enough 7⟩ ≡

```
sentence_problem(_P_(C6CantAssertQuantifier),
    "the relationship you describe is not exact enough",
    "so that I cannot be sure of the initial situation. A specific "
    "relationship would be something like 'the box is a container in "
    "the Attic', rather than 'the box is a container in a room which "
    "is dark' (fine, but which dark room? You must say).");
return;
```

This code is used in §5.

§**8.** Almost all propositions derive from sentences in the source text, but a crucial exception is the first one to be asserted: $\exists x : isakind(x)$, which creates the kind "kind". Type-checking problems never arise with this in any case, so it doesn't matter that we wouldn't know what text to use in them.

⟨Typecheck the proposition, in case this has not already been done 8⟩ ≡

```
int w1 = -1, w2 = -1;
if ((kind_kind) && (current_sentence)) { [[w1, w2 <-- current_sentence]]; }
if (prop_type_check(prop, tc_problem_reporting(w1, w2, "be asserting something"))
    != ALWAYS_MATCH)
    return;
```

This code is used in §5.

§**9.** This does nothing functional, except that it allows an interpretation as a world object to trump one as a specification; useful since the A-parser often specifies O and V as the object and value referred to by a given node in the parse tree, and since an object is also a value, this often means that both are given. If we have O, then, we cancel V.

As we shall see, it's permitted to interpret a bound variable *after* its quantifier, but not before, and in particular not at the start of the proposition. So we require that the slate identify exactly the free variables, and no others.

⟨Check the identification slate against variable usage in the proposition 9⟩ ≡

```
int i, valid = TRUE, var_states[26];
vars_determine_status(prop, var_states, &valid);
if (valid == FALSE) internal_error("tried to assert malformed proposition");
for (i=0; i<26; i++) {
    int set = FALSE;
    if (current_interpretation_as_spec[i]) set = TRUE;
    if (current_interpretation_as_wo[i]) {
        if (current_interpretation_as_spec[i]) current_interpretation_as_wo[i] = NULL;
        set = TRUE;
    }
    if ((var_states[i] == UNUSED_VST) && (set))
        internal_error("tried to set an unused variable");
    if ((var_states[i] == BOUND_VST) && (set))
        internal_error("tried to set a bound variable");
    if ((var_states[i] == FREE_VST) && (set == FALSE))
        internal_error("failed to set a free variable");
}
```

This code is used in §5.

§**10. Creations.** To assert the truth of $\exists x$, we must create an object to become x; that will provide a value in subsequent uses of x in the same proposition, so the new value has to be added to the identification slate.

⟨Assert the truth or falsity of a QUANTIFIER atom 10⟩ ≡

```
int v = pl->terms[0].variable; if (v == -1) internal_error("bad QUANTIFIER atom");
if (now_negated) internal_error("tried to negate existence");

int name1 = -1, name2 = -1;
int is_a_kind = FALSE, is_a_var = FALSE, is_a_kov = FALSE;
kind_of_value *kov = NULL;

⟨Scan subsequent atoms to find the name, nature and kind of what is to be created 11⟩;
⟨Create the object and add to the identification slate 12⟩;
⟨Record the new creation in the debugging log 13⟩;
```

This code is used in §5.

§**11.** Note that all five of these atoms are optional; the proposition might consist of just $\exists x$ alone, which creates a nameless object, since as usual we interpret no indication of a kind as meaning "object".

⟨Scan subsequent atoms to find the name, nature and kind of what is to be created 11⟩ ≡

```
TRAVERSE_VARIABLE(lookahead);
TRAVERSE_PROPOSITION(lookahead, pl)
    if ((lookahead->arity == 1) && (lookahead->terms[0].variable == v)) {
        switch(lookahead->element) {
            case KIND_ATOM: kov = lookahead->assert_kind_of_value; break;
            case CALLED_ATOM: atom_CALLED_get_name(lookahead, &name1, &name2); break;
            case ISAKIND_ATOM: is_a_kind = TRUE; break;
            case ISAKOV_ATOM: is_a_kov = TRUE; break;
            case ISAVAR_ATOM: is_a_var = TRUE; break;
        }
    }
```

This code is used in §10.

§**12.** There are really four cases: new KOV, new global variable, new world object or kind of object, and new constant value.

⟨Create the object and add to the identification slate 12⟩ ≡

```
if (is_a_kov) {
    kov = make_new_atomic_kind_of_value(name1, name2);
    current_interpretation_as_spec[v] = new_generic_CONSTANT_type(kov);
} else if (is_a_var) {
    if (kov == NULL) kov = kova(OBJECT_TY);
    quantity *q = new_model_quantity(name1, name2, kov, TRUE);
    current_interpretation_as_spec[v] = new_actual_NONLOCAL_VARIABLE_type(q);
} else {
    if ((kov == NULL) || (is_kova(kov, OBJECT_TY))) {
        current_interpretation_as_wo[v] = create_world_object(name1, name2, is_a_kind);
    } else {
        quantity *q = new_model_quantity(name1, name2, kov, FALSE);
        current_interpretation_as_spec[v] = spec_copy(qty_get_initial_value(q));
    }
}
```

This code is used in §10.

§**13.** It's useful to log the new creation, especially for objects which have duplicate names to others already made:

⟨Record the new creation in the debugging log 13⟩ ≡

```
if (current_interpretation_as_spec[v]) {
    LOGIF(ASSERTIONS, ":: %c <-- $S\n", pcalc_vars[v], current_interpretation_as_spec[v]);
} else if (current_interpretation_as_wo[v]) {
    LOGIF(ASSERTIONS, ":: %c <-- $O\n", pcalc_vars[v], current_interpretation_as_wo[v]);
}
```

This code is used in §10.

§14. Asserting kinds. Note that we never assert the KOV of anything. Typechecking won't allow such an atom to exist unless it states something already true, so there is no need. We are only interested if there is a kind of object `ko` here.

Once again, the problem messages in this section for negated attempts are really quite hard to generate, because the A-parser usually gets there first. "There is a banana which is something which is not a door." will fall through here, but it isn't exactly an everyday sentence.

⟨Assert the truth or falsity of a KIND atom 14⟩ ≡

```
world_object *ko = kovko_get_kind(pl->assert_kind_of_value);
world_object *ox = wo_of_term(pl->terms[0]);
if (now_negated) {
    sentence_problem(_P_(C6CantAssertNonKind),
        "that seems to say what kind something doesn't have",
        "which is too vague. You must say what kind it does have.");
    return;
}
if ((ko) && (ox)) set_kind(ox, ko);
```

This code is used in §5.

§15. Asserting HERE and EVERYWHERE. Two special cases. The first, EVERYWHERE, declares that something is found in every room; we generate a non-room-specific sort of `FOUNDIN_INF` inference. While we could simply deduce that the object must be a backdrop (and `set_kind` to make it so), this is such an extreme business, so rarely needed, that it seems better to make the user spell out that we're dealing with a backdrop. So we play dumb.

⟨Assert the truth or falsity of an EVERYWHERE atom 15⟩ ≡

```
world_object *ox = wo_of_term(pl->terms[0]);
if ((ox == NULL) || (wo_of_kind(ox, kind_backdrop) == FALSE)) {
    sentence_problem(_P_(C6EverywhereNonBackdrop),
        "only a backdrop can be everywhere",
        "and no other kind of object will do. For instance, 'The sky is "
        "a backdrop which is everywhere.' is allowed, but 'The travelator "
        "is a vehicle which is everywhere.' is not.");
    return;
}
if (now_negated) {
    sentence_problem(_P_(C6CantAssertNegatedEverywhere),
        "that seems to say that something isn't everywhere",
        "which is too vague. You must say where it is.");
    return;
}
inference *i = create_inference(FOUNDIN_INF, prevailing_mood);
join_inference(i, inference_subject_wo(ox));
```

This code is used in §5.

§**16.** HERE means "this object is in the current room", which is not as easy to resolve as it looks, because at this point we don't know for certain what will be a room and what won't. So we record a special inference and put the problem aside for now.

⟨Assert the truth or falsity of a HERE atom 16⟩ ≡

```
world_object *ox = wo_of_term(pl->terms[0]);
if (ox == NULL) internal_error("HERE on null object");                    typechecking prevents this
if (now_negated) {
    sentence_problem(_P_(BelievedImpossible),
        "that seems to say that something isn't here",
        "which is too vague. You must say where it is.");
    return;
}
inference *i = create_inference(PARENTAGE_HERE_INF, CERTAIN_CE);
inf_set_object_reference(i, get_current_subject());
join_inference(i, inference_subject_wo(ox));
i = create_inference(ISAROOM_INF, IMPOSSIBLE_CE);
join_inference(i, inference_subject_wo(ox));
```

This code is used in §5.

§**17. Asserting predicates.** First, asserting *adjective*(t). We know that t evaluates to a kind of value over which *adjective* is defined, or the proposition would not have survived type-checking. But only some adjectives can be asserted; "open" can, but "visible" can't, for instance. `aph_assert` returns a success flag.

Note that if the adjective applies to an object `ox` then we supply its kind of value to the adjective-asserter as `kovko(ox)`, not as `ox->kind`. This ensures that (a) if `ox` is an physical object then a definition applying to `ox` alone will be used, and (b) if `ox` is a kind, then a definition applying to that kind will be used.

⟨Assert the truth or falsity of a unary predicate 17⟩ ≡

```
adjective_list_entry *tr = RETRIEVE_POINTER_adjective_list_entry(pl->predicate);
adjectival_phrase *aph = get_adjective_from_list_entry(tr);
int parity = (now_negated)?FALSE:TRUE, found;
if (adjective_used_positively(tr) == FALSE) parity = (parity)?FALSE:TRUE;
world_object *ox = wo_of_term(pl->terms[0]);
specification *ots = spec_of_term(pl->terms[0]);
if (ox) found = aph_assert(aph, kovko(ox), ox, NULL, parity);
else found = aph_assert(aph, spec_get_kind_of_value(ots), NULL, ots, parity);
if (found == FALSE) {
    quote_source(1, current_sentence);
    quote_words(2, aph->word_ref1, aph->word_ref2);
    handmade_problem(_P_(C6CantAssertAdjective));
    issue_problem_segment(
        "In the sentence %1, you ask me to arrange for something to be '%2' "
        "at the start of play. There are some adjectives ('open' or 'dark', "
        "for instance) which I can fix, but others are just too vague. For "
        "example, saying 'Peter is visible.' isn't allowed, because it "
        "doesn't tell me where Peter is. Like 'visible', being '%2' is "
        "something I can test during play at any time, but not something "
        "I can arrange at the start.");
    issue_problem_end();
}
```

This code is used in §5.

§**18.** Binary predicates, unlike unary ones, can only be asserted positively. This is because $\neg P(x)$ tells you something fairly definite, whereas $\neg Q(x, y)$ gives no information about what z might exist, if any, such that $Q(x, z)$. For instance, knowing that X is not part of Y gives us no help in determining where X is.

Another difference is that $R(x, y)$ can give you definite information about the kinds of x and y, where they are objects, because binary predicates have single definitions. (Knowing *locked*(x), by contrast, doesn't tell you whether x is a door or a container – adjectives can have multiple domains in which they have differing definitions.) In the case of a proposition produced by sentence conversion, that information is redundant since appropriate kind atoms were added to the proposition anyway. But we also assert propositions generated from tree conversion, which don't have these kind atoms.

⟨Assert the truth or falsity of a binary predicate 18⟩ ≡

```
if (now_negated) {
    sentence_problem(_P_(C6CantAssertNegatedRelations),
        "that seems to make a negative statement about a relationship",
        "which is too vague. You must make positive assertions.");
    return;
}
binary_predicate *bp;
pcalc_term pt0, pt1;
⟨Determine the BP and terms to be asserted 19⟩;
specification *spec0 = spec_of_term(pt0), *spec1 = spec_of_term(pt1);
world_object *wo0 = wo_of_term(pt0), *wo1 = wo_of_term(pt1);
if (bp != a_region_contains_b_predicate) {
    if (bp_term_kind(bp, 0)) cautiously_set_kind(wo0, bp_term_kind(bp, 0));
    if (bp_term_kind(bp, 1)) cautiously_set_kind(wo1, bp_term_kind(bp, 1));
}
if (bp_assert(bp, wo0, spec0, wo1, spec1) == FALSE) {
    LOG("$2 on ($O, $S; $O, $S)\n", bp, wo0, spec0, wo1, spec1);
    sentence_problem(_P_(BelievedImpossible),
        "that is an assertion I can't puzzle out",
        "which seems to involve placing two things in some sort of "
        "relationship, but if so then I can't make it work. Perhaps the "
        "sentence is too complicatedly phrased, and could be broken up "
        "into two or more sentences?");
}
```

This code is used in §5.

§**19.** The "is" predicate is not usually assertable, but $is(x, f_R(y))$ can be asserted since it is equivalent to $R(x, y)$ – this is where we unravel that. We reject compound uses of functions in this way, but in practice they hardly ever arise, and could only do so with quite complex sentences where it seems reasonable to tell the user to write something simpler and clearer.

⟨Determine the BP and terms to be asserted 19⟩ ≡

```
bp = RETRIEVE_POINTER_binary_predicate(pl->predicate);
pt0 = pl->terms[0]; pt1 = pl->terms[1];
if (bp == a_is_b_predicate) {
    pcalc_func *the_fn = pt0.function; int side = 1;
    if (the_fn == NULL) { the_fn = pt1.function; side = 0; }
    if (the_fn) {
        if ((pl->terms[side].function) || (the_fn->fn_of.function)) {
            sentence_problem(_P_(BelievedImpossible),
                "that is too complicated an assertion",
                "and cannot be declared as part of the initial situation. (It "
                "does make sense, and could be tested with 'if' - it's just "
                "too difficult to get right as an instruction about the starting "
                "situation.");
            return;
        }
        bp = the_fn->bp; pt0 = pl->terms[side]; pt1 = the_fn->fn_of;
    }
}
```

This code is used in §18.

§**20.** As we've already seen, we have to be cautious about the mechanism to draw inferences about kinds based on the relationships which objects have. Some cases are easy: if A is worn by B, then B is a person. But "in" can be very problematic. When one region is in another, we want to suppress any inferences which might wrongly be drawn about "in": this is a different kind of containment from the three-dimensional spatial one suggested by containers and rooms. It also complicates things that a backdrop can be "in" a region. So we play very safe and make no guesses about regions or the first term of `a_region_contains_b_predicate`.

We also never deduce "thing" as the kind by this mechanism. This is because world objects with no apparent declared kind are made into things by default anyway; so there is no need to risk setting the kind here at this stage.

```
void cautiously_set_kind(world_object *wo, world_object *k) {
    if ((wo == NULL) || (k == NULL) || (wo->kind_flag)) return;
    if (k == kind_thing) return;
    if (wo_of_kind(wo, kind_region)) return;
    set_kind(wo, k);
}
```

§**21. Evaluating terms.** In asserting a proposition, we are in effect acting as an interpreter rather than a compiler. Given any term, we need to produce either an object O or a more general value V. Recall that a term can be

(a) a constant C,
(b) a variable v, or
(c) a function $f_R(t)$ for another term t.

We are unable, at compile-time, to evaluate $f_R(t)$ for any relation R, and won't even try. We can evaluate a variable using the interpretation slate – that was its whole purpose. So the only case left is a constant:

```
specification *spec_of_term(pcalc_term pt) {
    if (pt.function) return NULL;
    if (pt.variable >= 0) return current_interpretation_as_spec[pt.variable];
    return pt.constant;
}
```

§**22.** The analogous routine to extract a world object, which normally takes precedence, is more convoluted. First, we could be looking at the name of a kind – in "A door is usually closed", "door" will appear here as a `DESCRIPTION_SPC` type, and we need to extract the world object of the kind as our return value. Second, we want to divert all assertions about "the player" so that they refer to the player object, not to the global variable "the player".

Users tend to expect that they can talk about properties of things as values, when setting up the world, and since a property value might be an object, we are going to be careful to reject a `PROPERTY_VALUE_SPC` type with a problem message. In practice the A-parser gets there first, but just in case.

```
world_object *wo_of_term(pcalc_term pt) {
    if (pt.function) return NULL;
    if (pt.variable >= 0) return current_interpretation_as_wo[pt.variable];
    specification *spec = pt.constant;
    if (species_is(spec, CONSTANT_SPC)) return wo_of_CONSTANT_OBJECT_if_any(spec);
    if (species_is(spec, DESCRIPTION_SPC)) {
        if (spec_get_described_object(spec)) return spec_get_described_object(spec);
        if (spec_get_described_kind(spec)) return spec_get_described_kind(spec);
    }
    if ((species_is(spec, NONLOCAL_VARIABLE_SPC)) &&
        (RETRIEVE_FROM_SPEC(spec, quantity) == player_quantity))
        return wo_yourself;
    if (species_is(spec, PROPERTY_VALUE_SPC)) {
        if (problem_count == 0)
            sentence_problem(_P_(BelievedImpossible),
                "that seems to refer to a property of something in a way that I "
                "can't follow",
                "perhaps because I've misread the word 'of' here, or perhaps "
                "because verbs are missing which a human reader can manage "
                "without, but I can't.");
        return NULL;
    }
    return NULL;
}
```

I6 Schemas 6/sch

Purpose

To create, and later expand upon, short prototypes of I6 syntax for such run-time tasks as the setting, unsetting or testing of a relation.

Definitions

¶1. An I6 schema is an intermediate-level code for the final stages of compiling to Inform 6 syntax. Its "prototype" is a C string encoded as ISO Latin-1, in which the asterisk `*` acts as an escape character.

"Expanding" an I6 schema is essentially a form of macro expansion. A caller supplies us with a schema and a number of parameters, each of which is either a literal piece of text or a predicate calculus term. We then copy the schema's prototype into the output, except as specified:

(1) `**` expands to a literal asterisk.

(2) `*1`, `*2`, ..., `*9` expands to the 1st to 9th parameter, where a literal text parameter is copied straight through, whereas a term parameter is compiled as a value. Expanding a parameter which was not supplied does nothing, but is not an error.
   (a) The modifier `!`, as in `*!1` to `*!9`, enables the use of local variables in any text substitutions compiled in the course of the term.
   (b) The modifier `#`, as in `*#1` to `*#9`, causes us to expand to the ID number of the kind of value of the parameter, not to the parameter itself. (If the parameter is literal text rather than a term, we do nothing.)

(3) `*=-` and `*=+` turn "dereference pointers" mode off and on, respectively. This has effect only when compiling a value whose content is stored on the heap; Inform ordinarily compiles this by making a new copy of the value and using a pointer to it, but if "dereference pointers" is off then the pointer to the original data is used instead. It's a sort of macro-expansion version of the difference between call-by-value and call-by-reference. The effect lasts only while the expander is running; when the expander finishes, it restores the mode to its setting at the start.

(4) `*-` means a single character backspace, which allows us to erase the last character of the I6 source generated by the expansion of an immediately preceding `*1` or `*2`. (This can be used to tack an optional call parameter onto a routine: by deleting the close bracket in `Example(45)` and then continuing with `,7)` we effectively change the call to `Example(45,7)`.) If the chosen output is a file rather than a string in memory, then `*-` is unavailable, since we aren't able to undo having written a character. (Yes, on some platforms we could do this, but we don't need to, so we won't.)

(5) `*##` is reserved for the use of higher-level code in building schemas – it has to do with locations of data on the heap – but is not strictly speaking legal in a schema. Attempting to expand it will cause an internal error.

Any other occurrence of an asterisk is illegal, and will throw an internal error.

¶2. The I6 schema structure is very simple, then:

```
define MAX_I6_SCHEMA_LENGTH 128
```
in fact 40 is plenty, but to be on the safe side

```
typedef struct i6_schema {
    char prototype[MAX_I6_SCHEMA_LENGTH];
} i6_schema;
```

The structure i6_schema is private to this section.

---

§**1. Building schemas.** The numerous versions of essentially similar construction routines are intended to make the relation-creating code a little cleaner and easier to read. We could try to use variadic macros, or a variable argument list, but this would only invite compiler warnings on some platforms.

This is where all schemas originate:

```
i6_schema *sch_new(char *text) {
    i6_schema *sch = CREATE(i6_schema);
    sch_write_to_existing(sch, text);
    return sch;
}
void sch_write_to_existing(i6_schema *sch, char *text) {
    if (strlen(text) >= MAX_I6_SCHEMA_LENGTH) internal_error("i6 schema overlong");
    strcpy(sch->prototype, text);
}
```

The function sch_new is called from 9/spabp, 10/qnbp and 12/cinv.

The function sch_write_to_existing is called from 5/aph, 6/equal, 6/atoms, 6/cdefp, 7/kov, 7/data and 9/provr.

§**2.** Now for some convenient routines to create new schemas with given contents:

define MAX_I6_SCHEMA_ATTEMPT 512 *plenty of room for conjectural schema overruns*

```
i6_schema *sch_new_1(char *text, char *str1) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1);
    return sch_new(temp);
}
i6_schema *sch_new_1d(char *text, int d1) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, d1);
    return sch_new(temp);
}
i6_schema *sch_new_2(char *text, char *str1, char *str2) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1, str2);
    return sch_new(temp);
}
i6_schema *sch_new_3(char *text, char *str1, char *str2, char *str3) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1, str2, str3);
    return sch_new(temp);
}
```

The function sch_new_1 is called from 5/rel, 9/mapbp and 9/vpbp.

The function sch_new_1d is called from 5/rel and 10/libp.

The function sch_new_2 is called from 5/rel and 9/vpbp.

The function sch_new_3 is called from 9/cmpbp.

§**3.** And lastly some routines to write new contents to an existing schema:

```
void sch_write_to_existing_1(i6_schema *sch, char *text, char *str1) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_1d(i6_schema *sch, char *text, int d1) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, d1);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_2(i6_schema *sch, char *text, char *str1, char *str2) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1, str2);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_1s(i6_schema *sch, char *text, char *str1) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_1s1d(i6_schema *sch, char *text, char *str1, int d1) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1, d1);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_2s(i6_schema *sch, char *text, char *str1, char *str2) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1, str2);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_2sd(i6_schema *sch, char *text, char *str1, char *str2, int d1) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, str1, str2, d1);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_2d(i6_schema *sch, char *text, int d1, int d2) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, d1, d2);
    sch_write_to_existing(sch, temp);
}
void sch_write_to_existing_3d(i6_schema *sch, char *text, int d1, int d2, int d3) {
    char temp[MAX_I6_SCHEMA_ATTEMPT];
    sprintf(temp, text, d1, d2, d3);
    sch_write_to_existing(sch, temp);
}
```

The function sch_write_to_existing_1 is called from 6/equal, 6/atoms, 9/prop and 12/def.
The function sch_write_to_existing_1d is called from 6/atoms and 7/data.
The function sch_write_to_existing_2 is called from 9/cmpbp.
The function sch_write_to_existing_1s is called from 5/bp.
The function sch_write_to_existing_1s1d is called from 9/qty.
The function sch_write_to_existing_2s is called from 5/bp.
The function sch_write_to_existing_2sd is called from 9/madj.
The function sch_write_to_existing_2d is called from 7/kov and 9/prop.
The function sch_write_to_existing_3d is called from 5/aph and 9/qty.

§**4. Emptiness.** A schema is empty if its prototype is the null string.

```
int sch_empty(i6_schema *sch) {
    if (sch == NULL) return TRUE;
    if (sch->prototype[0] == 0) return TRUE;
    return FALSE;
}
```

The function sch_empty is called from 5/aph.

§**5. Expansion.** We provide two routines as a sort of API for expanding schemas. The user can either specify two parameters, both of them terms...

```
void sch_expand(i6_schema *sch, OUTPUT_STREAM, pcalc_term *pt1, pcalc_term *pt2) {
    STREAM *save_dl = dl;
    if (OUT == NULL) return;
    TEMPORARY_STREAM;
    if (OUT == dl) dl = TEMP;
    sch_expand_inner(sch, TEMP, pt1, NULL, pt2, NULL);
    STREAM_COPY(OUT, TEMP);
    CLOSE_TEMPORARY_STREAM;
    dl = save_dl;
}
```

The function sch_expand is called from 5/aph, 6/atoms, 6/cind, 6/cdefp and 12/cinv.

§**6.** ...or two parameters, both of them strings.

```
void sch_expand_textual(i6_schema *sch, OUTPUT_STREAM, char *str1, char *str2) {
    STREAM *save_dl = dl;
    if (OUT == NULL) return;
    TEMPORARY_STREAM;
    if (OUT == dl) dl = TEMP;
    sch_expand_inner(sch, TEMP, NULL, str1, NULL, str2);
    STREAM_COPY(OUT, TEMP);
    CLOSE_TEMPORARY_STREAM;
    dl = save_dl;
}
```

The function sch_expand_textual is called from 12/cinv and 13/gtok.

§**7.** The actual expander is here:

```
void sch_expand_inner(i6_schema *sch, OUTPUT_STREAM,
    pcalc_term *pt1, char *str1, pcalc_term *pt2, char *str2) {
    STREAM_MUST_BE_IN_MEMORY(OUT);
    if (sch == NULL) internal_error("Expanded null I6 schema");
    sch_type_parameter(pt1);
    sch_type_parameter(pt2);
    char *schematic_text = sch->prototype;
    int cmode = 0, i = 0;
    if ((schematic_text[0] == '*') && (schematic_text[1] == '=') &&
        (schematic_text[2] == '-')) {
        cmode = DEREFERENCE_POINTERS_CMODE; i = 3;
    }
    BEGIN_COMPILATION_MODE;
    COMPILATION_MODE_EXIT(cmode);
    for (; schematic_text[i]; i++) {
        if (schematic_text[i] == '*') {
            ⟨Act on an asterisk expansion in the schema 8⟩;
            continue;
        }
        WRITE("%c", schematic_text[i]);
    }
    END_COMPILATION_MODE;
}
```

§**8.** At present we never expand on terms 3 to 9, but they are reserved for possible future use.

⟨Act on an asterisk expansion in the schema 8⟩ ≡

```
    BEGIN_COMPILATION_MODE;
    int give_kov_id = FALSE;
    if ((schematic_text[i+2]) && (isdigit(schematic_text[i+2]))) {
        switch (schematic_text[i+1]) {
            case '!': COMPILATION_MODE_ENTER(PERMIT_LOCALS_IN_TEXT_CMODE); i++; break;
            case '#': give_kov_id = TRUE; i++; break;
        }
    }
    switch(schematic_text[++i]) {
        case '-': STREAM_BACKSPACE(OUT); break;
        case '1': sch_expand_parameter(OUT, pt1, str1, give_kov_id); break;
        case '2': sch_expand_parameter(OUT, pt2, str2, give_kov_id); break;
        case '3': case '4': case '5': case '6': case '7': case '8': case '9': break;
        case '#':
            if (schematic_text[++i] == '#') internal_error("can't expand *## in schema");
            else internal_error("schema syntax error");
            break;
        case '*': WRITE("*"); break;
        default: internal_error("schema syntax error");
    }
    END_COMPILATION_MODE;
```

This code is used in §7.

§**9.**

```
void sch_expand_parameter(OUTPUT_STREAM, pcalc_term *pt, char *str, int give_kov_id) {
    if (give_kov_id) {
        if (pt) {
            int id = kov_I6_ID(pt->term_checked_as_kov);
            WRITE("%d", id);
        }
    } else {
        if (str) WRITE("%s", str);
        else if (pt) term_compile(OUT, *pt);
    }
}
```

§**10.** Last and very much least: in case we receive an untypechecked term, we fill in its KOV.

```
void sch_type_parameter(pcalc_term *pt) {
    if ((pt) && (pt->constant) && (pt->term_checked_as_kov == NULL))
        pt->term_checked_as_kov = spec_evaluates_to(pt->constant);
}
```

§**11. Logging schemas.**

```
void log_i6_schema(i6_schema *sch) {
    if (sch == NULL) LOG("<null schema>");
    else LOG("<schema: %s>", sch->prototype);
}
void log_i6_schema_applied(i6_schema *sch, pcalc_term *pt1) {
    if (sch == NULL) { LOG("<null schema>"); return; }
    sch_expand(sch, dl, pt1, NULL);
}
```

The function log_i6_schema is called from 2/dl.
The function log_i6_schema_applied is called from 6/term.

Compile Atoms 6/atoms

Purpose

In this section, given an atom of a proposition we compile I6 code as required for any of three possible outcomes: (i) to test whether it is true, (ii) to make it henceforth true, or (iii) to make it henceforth false.

6/atoms.§2-4 Stage 1; §5 Stage 2; §6-14 Constructing the schema

---

Definitions

¶1. The compilation method is to look at the atom, work out a suitable I6 schema involving code to be applied to the one or two terms attaching to the atom, and then expand this. In some circumstances, the process of finding the schema will reveal that we need to apply it to different terms from those originally found in the atom, however, so we also need to keep track of that; and also of whether a condition is being regarded negatively.

```
typedef struct annotated_i6_schema {
    struct i6_schema *schema;
    int negate_schema;                    true if atom is to be tested with the opposite parity
    struct pcalc_term pt0;                terms on which the I6 schema is to be expanded
    struct pcalc_term pt1;
    int involves_action_variables;
} annotated_i6_schema;
```

The structure annotated_i6_schema is shared with 5/bp, 6/equal, 9/provr and 9/cmpbp.

¶2. Some constants to enumerate the three cases of what we are to do. This looks asymmetrical – shouldn't we also test to see whether an atom is false, a fourth case?

The answer is that there's no need, since "test false" can be done by compiling "test true" and applying the I7 negation operator ~~ to the result. No similar trick can be used to combine *making* something true or false into a single operation.

```
define TEST_ATOM_TASK 1
define NOW_ATOM_TRUE_TASK 2
define NOW_ATOM_FALSE_TASK 3
```

---

§**1.** So, then:

```
void atom_compile(OUTPUT_STREAM, int task, pcalc_prop *pl) {
    i6_schema sch;
    annotated_i6_schema asch;
    switch (task) {
        case TEST_ATOM_TASK: LOGIF(WORKINGS, "Compiling condition: $o\n", pl); break;
        case NOW_ATOM_TRUE_TASK: LOGIF(WORKINGS, "Compiling 'now': $o\n", pl); break;
        case NOW_ATOM_FALSE_TASK: LOGIF(WORKINGS, "Compiling 'now' false: $o\n", pl); break;
        default: internal_error("unknown compile task");
    }
    ⟨Stage 1: make an annotated schema from the atom 2⟩;
    ⟨Stage 2: expand that schema to the output stream 5⟩;
}
```

The function atom_compile is called from 6/defer and 6/cdefp.

§2. Stage 1.

⟨Stage 1: make an annotated schema from the atom 2⟩ ≡
```
int problem_count_before = problem_count;
asch = i6_schema_of_atom(&sch, pl, task);
if (asch.schema == NULL) {
    if (problem_count == problem_count_before)
        ⟨Issue a fallback problem message, since the schema-maker evidently didn't 3⟩;
    return;
}
⟨Reject all discussion of the action variables in the past tense 4⟩;
```

This code is used in §1.

§3.

⟨Issue a fallback problem message, since the schema-maker evidently didn't 3⟩ ≡
```
if (task == TEST_ATOM_TASK)
    sentence_problem(_P_(BelievedImpossible),
        "this is not a condition I am able to test",
        "or at any rate not during play.");
else
    sentence_problem(_P_(C6CantForceRelation),
        "this is not something I can make true with 'now'",
        "because it is too vague about the underlying cause which would "
        "need to be arranged.");
```

This code is used in §2.

§4. This is in the user's own best interest.

⟨Reject all discussion of the action variables in the past tense 4⟩ ≡
```
if ((asch.involves_action_variables) && (phsf_used_for_past_tense())) {
    if (problem_count == problem_count_before)
        sentence_problem(_P_(C6ActionVarsPastTense),
            "it is misleading to talk about the noun, the second noun "
            "or the person asked to do something in past tenses",
            "because in the past, those were different things and "
            "people, or may have been nothing at all. Writing "
            "'if the noun has been unlocked' tends not to do what we "
            "might hope because the value of 'noun' changes every turn. "
            "So such conditions are not allowed, although to get around "
            "this we can instead write 'if we have unlocked the noun', "
            "which uses a special mechanism to remember everything which "
            "has happened to every object.");
    return;
}
```

This code is used in §2.

§**5. Stage 2.** A valid I6 condition has to be bracketed, so we surround the output with brackets if testing; and a valid I6 statement has to end with a semicolon, so we terminate with that if making true or false.

⟨Stage 2: expand that schema to the output stream 5⟩ ≡

```
if (task == TEST_ATOM_TASK) {
    WRITE("(");
    if (asch.negate_schema) WRITE("~~(");
}
sch_expand(asch.schema, OUT, &(asch.pt0), &(asch.pt1));
if (task == TEST_ATOM_TASK) {
    if (asch.negate_schema) WRITE(")");
    WRITE(")");
} else {
    WRITE(";");
}
```

This code is used in §1.

§6. Constructing the schema.

```
annotated_i6_schema i6_schema_of_atom(i6_schema *sch, pcalc_prop *pl, int task) {
    annotated_i6_schema asch;
    sch_write_to_existing(sch, " ");                    a non-NULL return in case problems occur
    asch.schema = sch;
    asch.negate_schema = FALSE;
    asch.pt0 = pl->terms[0]; asch.pt1 = pl->terms[1];
    asch.involves_action_variables = atom_involves_action_variables(pl);
    switch(pl->element) {
        case CALLED_ATOM: ⟨Make an annotated schema for a CALLED atom 7⟩;
        case KIND_ATOM: ⟨Make an annotated schema for a KIND atom 8⟩;
        case EVERYWHERE_ATOM: ⟨Make an annotated schema for an EVERYWHERE atom 9⟩;
        case HERE_ATOM: ⟨Make an annotated schema for a HERE atom 10⟩;
        case PREDICATE_ATOM:
            switch(pl->arity) {
                case 1: ⟨Make an annotated schema for a unary predicate 11⟩;
                case 2: ⟨Make an annotated schema for a binary predicate 12⟩;
            }
    }
    asch.schema = NULL;                                 signal that the atom cannot be compiled simply
    return asch;
}
```

§**7.** We are now able to look at the different types of atom one at a time.

CALLED atoms cannot be asserted, and to test them, we simply copy the value into the local variable of the given name. Note then that here the I6 `=` (set equal) operator is being used in a condition context: there's a good chance that the value set is non-zero (since all objects and enumerated values are non-zero), but it isn't necessarily so – in Inform it's legal to quantify over times and truth states, for instance, where 0 is a legal I6 value. So we use the comma operator to throw away the result of the assignment, and evaluate the condition to `true`.

⟨Make an annotated schema for a CALLED atom 7⟩ ≡

```
    switch(task) {
        case TEST_ATOM_TASK: {
            int w1, w2;
            atom_CALLED_get_name(pl, &w1, &w2);
            sch_write_to_existing_1d(sch, "t_%d=(*1), true",
                ensure_called_local(w1, w2, pl->assert_kind_of_value));
            return asch;
        }
        default: asch.schema = NULL; return asch;
    }
```

This code is used in §6.

§**8.** In any type-checked proposition, a `KIND` atom can only exist where it is always at least sometimes true. In particular, if K is a kind of value, then the atom $K(v)$ can only exist where v is of that kind of value, so that the atom is always true when tested. But if K is a kind of object, then $K(O)$ may occur in the proposition for any object O, where O need not belong to K at all: so there is something substantive to check, which we do using the I6 `ofclass` operator.

⟨Make an annotated schema for a KIND atom 8⟩ ≡

```
switch(task) {
    case TEST_ATOM_TASK: {
        world_object *ko = kovko_get_kind(pl->assert_kind_of_value);
        if (ko) sch_write_to_existing_1(sch, "*1 ofclass %s", wo_get_I6_representation(ko));
        else sch_write_to_existing(sch, "true");
        return asch;
    }
    case NOW_ATOM_TRUE_TASK:
    case NOW_ATOM_FALSE_TASK:
        sentence_problem(_P_(C6CantChangeKind),
            "the kind of something is fixed",
            "and cannot be changed during play with a 'now'.");
        asch.schema = NULL; return asch;
}
```

This code is used in §6.

§**9.** An easy case. Note that `FoundEverywhere` is a template routine existing to provide a common value of the I6 `found_in` property – common that is to all backdrops which are currently everywhere.

⟨Make an annotated schema for an EVERYWHERE atom 9⟩ ≡

```
switch(task) {
    case TEST_ATOM_TASK:
        sch_write_to_existing(sch, "*1.found_in == FoundEverywhere");
        return asch;
    case NOW_ATOM_TRUE_TASK:
    case NOW_ATOM_FALSE_TASK:
        sentence_problem(_P_(C6CantChangeEverywhere),
            "being 'everywhere' is not something which can be changed during play",
            "so it cannot be brought about or cancelled out with 'now'.");
        asch.schema = NULL; return asch;
}
```

This code is used in §6.

§**10.** And another. (In fact, at present HERE atoms are never included in propositions to be compiled, so this code is never used.)

⟨Make an annotated schema for a HERE atom 10⟩ ≡

```
switch(task) {
    case TEST_ATOM_TASK:
        sch_write_to_existing(sch, "LocationOf(*1) == location");
        return asch;
    case NOW_ATOM_TRUE_TASK:
    case NOW_ATOM_FALSE_TASK:
        sentence_problem(_P_(BelievedImpossible),
            "being 'here' is not something which can be changed during play",
            "so it cannot be brought about or cancelled out with 'now'.");
        asch.schema = NULL; return asch;
}
```

This code is used in §6.

§**11.** The last unary atom is an adjective, for which we hand over to the general adjective apparatus.

⟨Make an annotated schema for a unary predicate 11⟩ ≡

```
int atask = 0;                                   redundant assignment to appease gcc -O2
adjective_list_entry *tr = RETRIEVE_POINTER_adjective_list_entry(pl->predicate);
adjectival_phrase *aph = get_adjective_from_list_entry(tr);
if (adjective_used_positively(tr) == FALSE) asch.negate_schema = TRUE;
if ((pl->terms[0].constant) && (pl->terms[0].term_checked_as_kov == NULL))
    pl->terms[0].term_checked_as_kov = spec_evaluates_to(pl->terms[0].constant);
switch(task) {
    case TEST_ATOM_TASK: atask = TEST_ADJECTIVE_TASK; break;
    case NOW_ATOM_TRUE_TASK: atask = NOW_ADJECTIVE_TRUE_TASK; break;
    case NOW_ATOM_FALSE_TASK: atask = NOW_ADJECTIVE_FALSE_TASK; break;
}
asch.schema = aph_get_i6_schema(aph, pl->terms[0].term_checked_as_kov, atask);
return asch;
```

This code is used in §6.

§**12.** Delegation is similarly the art of compiling a BP:

⟨Make an annotated schema for a binary predicate 12⟩ ≡

```
binary_predicate *bp = RETRIEVE_POINTER_binary_predicate(pl->predicate);
binary_predicate *bp_to_assert = NULL;
⟨Undo any functional simplification of the relation 13⟩;
asch.schema = bp_get_i6_schema(task, bp_to_assert, &asch);
return asch;
```

This code is used in §6.

§**13.** When a relation $R(x, y)$ has been simplified to $is(x, f_R(y))$ or $is(g_R(x), y)$, it can be tested but not asserted true or false; we have to re-establish $R(x, y)$ before we can proceed.

⟨Undo any functional simplification of the relation 13⟩ ≡

```
    if ((task != TEST_ATOM_TASK) && (bp == a_is_b_predicate)) {
        if (pl->terms[0].function) {
            bp_to_assert = pl->terms[0].function->bp;
            asch.pt0 = pl->terms[0].function->fn_of;
        } else if (pl->terms[1].function) {
            bp_to_assert = pl->terms[1].function->bp;
            asch.pt1 = pl->terms[1].function->fn_of;
        }
        if (bp_to_assert == a_is_b_predicate)
            internal_error("contraction of predicate applied to equality");
    }
    if (bp_to_assert == NULL) bp_to_assert = bp;
```

This code is used in §12.

§**14.**

```
int atom_involves_action_variables(pcalc_prop *pl) {
    int i;
    for (i=0; i<pl->arity; i++) {
        specification *operand = term_constant_underlying(&(pl->terms[i]));
        if (qty_is_an_I6_library_variable(operand)) return TRUE;
    }
    return FALSE;
}
```

Deciding to Defer 6/defer

Purpose

To decide whether a proposition can be compiled immediately, in the body of the current routine, or whether it must be deferred to a routine of its own, which is called from the current routine.

Template interpreter commands

```
1   {-callv:allow_no_further_deferrals}
```

Definitions

¶1. So far in this chapter, we have written code which suggests that there are basically only three ways to compile a proposition: as a test ("if the tree is blossoming"), as code forcing it to be true ("now the tree is blossoming") or as code forcing it to be false ("now the tree is not blossoming"). That's not quite true, and so deferral can happen for a number of different reasons, enumerated as follows:

```
define CONDITION_DEFER 1                          "if S", where S is a sentence
define NOW_ASSERTION_DEFER 2                      "now S"
define EXTREMAL_DEFER 3                           "the heaviest X", where X is a description
define LOOP_DOMAIN_DEFER 4                        "repeat with I running through X"
define NUMBER_OF_DEFER 5                          "the number of X"
define TOTAL_DEFER 6                              "the total P of X"
define RANDOM_OF_DEFER 7                          "a random X"
define MULTIPURPOSE_DEFER 100                     potentially any of the above

typedef struct pcalc_prop_deferral {
    int reason;                                   what we intend to do with it: one of the reasons above
    struct pcalc_prop *proposition_to_defer;      the proposition
    struct parse_node *deferred_from;             remember where it came from, for Problem reports
    struct general_pointer defn_ref;              sometimes we must remember other things too
    struct kind_of_value *cinder_kovs[16];        the kinds of value being cindered (see below)
    MEMORY_MANAGEMENT
} pcalc_prop_deferral;
```

The structure pcalc_prop_deferral is shared with 6/cind and 6/cdefp.

---

§**1. The guillotine.** We must be careful not to request a fresh deferral after the point at which all deferral requests are redeemed – they would then never be reached.

```
int no_further_deferrals = FALSE;
void allow_no_further_deferrals(void) {
    no_further_deferrals = TRUE;
}
```

The function allow_no_further_deferrals is invoked by a command in a `.i6t` template file.

§**2. Deferral requests.** The following fills out the paperwork to request a deferred proposition.

```
pcalc_prop_deferral *new_deferred_proposition(pcalc_prop *prop, int reason) {
    pcalc_prop_deferral *pdef = CREATE(pcalc_prop_deferral);
    pdef->proposition_to_defer = prop;
    pdef->reason = reason;
    pdef->deferred_from = current_sentence;
    if (no_further_deferrals) internal_error("Too late now to defer propositions");
    return pdef;
}
```

§**3.** It's worth cacheing deferral requests in the case of loop domains, because they are typically needed in the case of repeat-through loops where the same proposition is used three times in a row.

```
pcalc_prop *cache_loop_proposition = NULL;
pcalc_prop_deferral *cache_loop_pdef = NULL;
pcalc_prop_deferral *defer_loop_domain(pcalc_prop *prop) {
    pcalc_prop_deferral *pdef;
    if (prop == cache_loop_proposition) return cache_loop_pdef;
    pdef = new_deferred_proposition(prop, LOOP_DOMAIN_DEFER);
    cache_loop_proposition = prop;
    cache_loop_pdef = pdef;
    return pdef;
}
```

§**4.** The following shorthand routine takes a description SP, converts it to a proposition $\phi(x)$, then defers this and returns the number `n` such that the resulting routine will be called `Prop_n`.

```
int compile_deferred_description_test(specification *spec) {
    pcalc_prop_deferral *pdef;
    spec_convert_docket_to_proposition(spec);
    pdef = new_deferred_proposition(spec_get_proposition(spec), CONDITION_DEFER);
    return pdef->allocation_id;
}
```

The function compile_deferred_description_test is called from 11/av.

§**5. Testing, or deferring a test.** Given a proposition ϕ, and a value v, we compile a valid I6 condition to decide whether or not $\phi(v)$ is true. ϕ can either be a sentence with all variables bound, in which case v must be null, or can have just variable x free, in which case v must not be null.

We defer the proposition to a routine of its own if and only if it contains quantification.

```
void compile_test_of_proposition(OUTPUT_STREAM,
    specification *substitution, pcalc_prop *prop) {
    LOGIF(WORKINGS, "Compiling as test: $D\n", prop);
    WRITE("(");
    if (prop_contains_quantifier(prop)) {
        ⟨Defer test of proposition instead 6⟩;
    } else {
        if (substitution) substitute_var_0_in(prop, substitution);
        TRAVERSE_VARIABLE(pl);
        TRAVERSE_PROPOSITION(pl, prop) {
            if (implied_conjunction_between(pl_prev, pl)) WRITE(" && ");
            switch(pl->element) {
                case NEGATION_OPEN_ATOM: WRITE("~~("); break;
                case NEGATION_CLOSE_ATOM:
                    if (pl_prev->element == NEGATION_OPEN_ATOM) WRITE("true");
                    WRITE(")"); break;
                default: atom_compile(OUT, TEST_ATOM_TASK, pl); break;
            }
        }
    }
    WRITE(")");
}
```

The function compile_test_of_proposition is called from 7/cosp, 11/ap, 12/cinv and 13/nft.

§**6.** Since this is the first of our deferrals, let's take it slowly. We are compiling code in some outer routine – let's call it `R` – and the idea is to compile a function call `Prop_19(...)` into `R` where the test should be; this function will return either `true` or `false`, and its job is to test the proposition for us. (Deferred propositions are numbered in order of deferral; for the sake of example, we'll suppose ours in number 19.)

⟨Defer test of proposition instead 6⟩ ≡

```
    pcalc_prop_deferral *pdef;
    ⟨If the proposition is a negation, take care of that now 7⟩;
    pdef = new_deferred_proposition(prop, CONDITION_DEFER);
    ⟨Compile the call to the test-proposition routine 8⟩;
    ⟨Compile code to retrieve the values of any callings 9⟩;
```

This code is used in §5.

§**7.** This is done purely for the sake of compiling tidier code: if $\phi = \neg(\psi)$ then we defer ψ instead, negating the result of testing it.

⟨If the proposition is a negation, take care of that now 7⟩ ≡

```
    if (prop_is_a_group(prop, NEGATION_OPEN_ATOM)) {
        prop = prop_remove_topmost_group(prop);
        WRITE("~~");
    }
```

This code is used in §6.

§**8.** All of the subtlety here is to do with the fact that `R` and `Prop_19` have access to different values – in particular, they have different sets of local variables.

Because code in `Prop_19` cannot see the local variables of `R`, any such values needed must be passed from `R` to `Prop_19` as call parameters. These passed values are called "cinders".

In addition, `R` might not be able to evaluate the substitution value v for itself, so that must also be a call parameter. It will then become the initial value of the local variable `x` in `Prop_19`, and since x is free in the proposition, `x` never changes in `Prop_19`: thus we effect a substitution of $x = v$.

For example, `R` might contain the function call:

```
Prop_19(t_6, t_2, O13_sphinx)
```

and the function header of `Prop_19` might then look like so:

```
[ Prop_19 const_0 const_1 x;
```

The value of `cinder_count` would then be 2.

⟨Compile the call to the test-proposition routine 8⟩ ≡

```
WRITE("Prop_%d(", pdef->allocation_id);
int cinder_count = cind_find(OUT, prop, pdef);
if (substitution) {
    if (cinder_count > 0) WRITE(",");
    spec_compile(OUT, substitution);
}
WRITE(")");
```

This code is used in §6.

§**9.** When we defer a test, we make "called" more tricky to achieve. Suppose we are compiling a condition for

> if a woman (called the moll) has a weapon (called the gun), ...

This needs to set two local variables, "moll" and "gun", but those have to be locals in `R` – they are inaccessible to `Prop_19`. Somehow, they need to be return values, but I6 supports only a single return value from a routine, and that needs to be either `true` or `false`. What to do?

The answer is that `Prop_19` copies these values onto a special I6 array called the "deferred calling list". The very last thing that `Prop_19` does before it returns is to fill in this list; the very first thing we do on receiving that return is to extract what we want from it. (Because no other activity takes place in between, there is no risk that some recursive use of propositions will overwrite the list.)

For example, `R` might this time contain a call like so:

```
(Prop_19() && (t_2=deferred_calling_list-->0, t_3=deferred_calling_list-->1, true))
```

which safely transfers the values to locals `t_2` and `t_3` of `R`. Note that I6 evaluates conditions joined by `&&` from left to right, so we can be certain that `Prop_19` has been called and has returned before we get to the setting of `t_2` and `t_3`.

⟨Compile code to retrieve the values of any callings 9⟩ ≡

```
int calling_count=0;
TRAVERSE_VARIABLE(pl);
TRAVERSE_PROPOSITION(pl, prop) {
    switch(pl->element) {
        case CALLED_ATOM: {
            int local;
            ⟨Find which local variable in R needs the value, creating it if necessary 10⟩;
            if (calling_count == 0) WRITE(" && (");
            if (calling_count > 0) WRITE(", ");
```

```
                WRITE("t_%d=deferred_calling_list-->%d",
                    local, calling_count++);
                break;
            }
        }
    }
    if (calling_count > 0) WRITE(", true)");
```

This code is used in §6.

§**10.** `ensure_called_local` is so called because it ensures that a local of the right name and kind of value exists in `R`.

⟨Find which local variable in R needs the value, creating it if necessary 10⟩ ≡

```
    int w1, w2;
    atom_CALLED_get_name(pl, &w1, &w2);
    local = ensure_called_local(w1, w2, pl->assert_kind_of_value);
```

This code is used in §9.

§**11.** The following wrapper contributes almost nothing, but it checks some consistency assertions and writes to the debugging log.

```
void compile_test_if_var_matches_description(OUTPUT_STREAM,
    specification *var, specification *matches) {
    if (matches == NULL) internal_error("VMD against null description");
    if (var == NULL) internal_error("VMD on null variable");
    if ((spec_get_storage_form(var) != NONLOCAL_VARIABLE_SPC) &&
        (spec_get_storage_form(var) != LOCAL_VARIABLE_SPC))
        internal_error("VMD on non-variable");
    STREAM_INDENT(dl);
    STREAM_INDENT(dl);
    LOGIF(DESCRIPTION_COMPILATION, "[VMD: $S matches $S?]\n", var, matches);
    compile_test_of_proposition(OUT, var, prop_from_spec(matches, FALSE));
    STREAM_OUTDENT(dl);
    STREAM_OUTDENT(dl);
}
```

The function compile_test_if_var_matches_description is called from 12/cinv and 13/nft.

§**12. Forcing with now, or deferring the force.** For example, compiling code to achieve something like:

now the Marble Door is closed;

(which does not need to be deferred) or

now all the women are in the Dining Room;

(which does, since it contains a quantifier).

This is simpler than testing, because a "now" does not have callings, and because it always acts on whole sentences – no substitution is ever needed; the only call parameters for our `Prop_19` are the cinders, if any; and we never need to extract from the `deferred_calling_list`.

Once again the question arises of how to force $\neg(\phi \wedge \psi)$ to be true. It would be sufficient to falsify either one of ϕ or ψ alone, but for the sake of symmetry we falsify both. (We took the same decision when asserting propositions about the initial state of the model.)

```
void compile_now_proposition(OUTPUT_STREAM, pcalc_prop *prop) {
    int quantifier_count = 0;
    LOGIF(WORKINGS, "Compiling as 'now': $D\n", prop);
    ⟨Count quantifiers in, and generally vet, the proposition to be forced 13⟩;
    if (quantifier_count > 0) {
        pcalc_prop_deferral *pdef = new_deferred_proposition(prop, NOW_ASSERTION_DEFER);
        WRITE("Prop_%d(", pdef->allocation_id);
        cind_find(OUT, prop, pdef);
        WRITE(");");
    } else {
        int parity = TRUE;
        TRAVERSE_VARIABLE(pl);
        TRAVERSE_PROPOSITION(pl, prop) {
            switch (pl->element) {
                case NEGATION_OPEN_ATOM: case NEGATION_CLOSE_ATOM:
                    parity = (parity)?FALSE:TRUE;
                    break;
                default:
                    atom_compile(OUT, (parity)?NOW_ATOM_TRUE_TASK:NOW_ATOM_FALSE_TASK, pl);
                    break;
            }
        }
    }
}
```

The function compile_now_proposition is called from 7/cosp.

§**13.** We reject multiple quantifiers as too much work, and $\exists x$ because it would either require us to judge the x most likely to be meant – tricky – or to create an x out of nothing, which it's too late for, since Inform does not have run-time object or value creation.

⟨Count quantifiers in, and generally vet, the proposition to be forced 13⟩ ≡

```
TRAVERSE_VARIABLE(pl);
TRAVERSE_PROPOSITION(pl, prop) {
    switch(pl->element) {
        case QUANTIFIER_ATOM:
            if (atom_is_existence_quantifier(pl)) {
                sentence_problem(_P_(C6CantForceExistence),
                    "this is not explicit enough",
                    "and should set out definite relationships between specific "
                    "things, like 'now the cat is in the bag', not something "
                    "more elusive like 'now the cat is carried by a woman.' "
                    "(Which woman? That's the trouble.)");
                return;
            }
            if (atom_is_now_assertable_quantifier(pl) == FALSE) {
                sentence_problem(_P_(C6CantForceGeneralised),
                    "this can't be made true with 'now'",
                    "because it is too vague about what it applies to. It's fine "
                    "to say 'now all the doors are open' or 'now none of the doors "
                    "is open', because that clearly tells me which doors are "
                    "affected; but if you write 'now six of the doors are open' "
                    "or 'now almost all the doors are open', what am I to do?");
                return;
            }
            quantifier_count++;
            break;
        case CALLED_ATOM:
            sentence_problem(_P_(C6CantForceCalling),
                "a 'now' is not allowed to call names",
                "and it wouldn't really make sense to do so anyway. 'if "
                "a person (called the victim) is in the Trap Room' makes "
                "sense, because it gives a name - 'victim' - to someone "
                "whose identity we don't know. But 'now a person (called "
                "the victim) is in the Trap Room' won't be allowed, "
                "because 'now' can only talk about people or things whose "
                "identities we do know.");
            return;
    }
}
```

This code is used in §12.

§**14. Multipurpose descriptions.** Descriptions in the form $\phi(x)$, where x is free, are also sometimes converted into values – this is the kind of value "description". The I6 representation is (the address of) a routine `D` which, in general, performs task u on value v when called as `D(u, v)`, where u is expected to be one of the following values. (Note that v is only needed in the first two cases.)

These numbers *must* be negative, since they need to be different from every valid member of a quantifiable domain (objects, enumerated KOVs, truth states, times of day, and so on).

define `CONDITION_DUSAGE -1`	*return* `true` *iff* $\phi(v)$
define `LOOP_DOMAIN_DUSAGE -2`	*return the next* x *after* v *such that* $\phi(x)$
define `NUMBER_OF_DUSAGE -3`	*return the number of* w *such that* $\phi(w)$
define `RANDOM_OF_DUSAGE -4`	*return a random* w *such that* $\phi(w)$*, or 0 if none exists*
define `TOTAL_DUSAGE -5`	*return the total value of a property among* w *such that* $\phi(w)$
define `EXTREMAL_DUSAGE -6`	*return the maximal property value among such* w

§**15.** Multi-purpose description routines are pretty dandy, then, but they have one big drawback: they can't be passed cinders, because they might be called from absolutely anywhere. Hence the following:

```
void compile_multiple_use_proposition(OUTPUT_STREAM, specification *spec) {
    pcalc_prop *prop = prop_from_spec(spec, FALSE);
    if (prop_detect_locals(prop) > 0) {
        LOG("Offending proposition: $D\n", prop);
        sentence_problem(_P_(C6LocalInDescription),
            "descriptions used as values are not allowed to contain "
            "references to temporary variables defined by 'let' or by loops",
            "because they may very well not exist any more when the description "
            "needs to be used, in another time and another place.");
    } else {
        pcalc_prop_deferral *pdef = new_deferred_proposition(prop, MULTIPURPOSE_DEFER);
        WRITE("Prop_%d", pdef->allocation_id);
    }
}
```

The function compile_multiple_use_proposition is called from 7/vasp.

§**16.** Because multipurpose descriptions have this big drawback, we want to avoid them if we possibly can. Fortunately something much simpler will often do. For example, consider:

[1] the number of members of S

[2] the number of closed doors

where S, in [1], is a description which appears as a parameter in a phrase. In [1] we have no way of knowing what S might be, but we can safely assume that it has been compiled as a multi-purpose description routine, and therefore compile the function call:

```
D(NUMBER_OF_DUSAGE)
```

But in case [2] it is sufficient to take $\phi(x) = door(x) \wedge closed(x)$, defer it to a proposition with reason `NUMBER_OF_DEFER`, and then compile just

```
Prop_19()
```

to perform the calculation. We never need a multi-purpose description routine for $\phi(x)$ because it only occurs in this one context.

§**17.** We now perform this trick for "number of":

```
void compile_number_of_S(OUTPUT_STREAM, specification *spec) {
    if (spec_is_variable_of_KOV_description(spec)) {
        WRITE("(");
        spec_compile(OUT, spec);
        WRITE(")(%d)", NUMBER_OF_DUSAGE);
    } else {
        pcalc_prop *prop = prop_from_spec(spec, FALSE);
        prop_verify_descriptive(prop, "a number of things matching a description", spec);
        compile_call_to_deferred_desc(OUT, prop, NUMBER_OF_DEFER, NULL_GENERAL_POINTER);
    }
}
```

The function compile_number_of_S is called from 12/cinv.

§**18.** Where we employ:

```
int spec_is_variable_of_KOV_description(specification *spec) {
    if ((family_is(spec, STORAGE_FMY)) &&
        ((is_kova(spec_evaluates_to(spec), OBJECT_DESCRIPTION_TY)) ||
            (is_kova(spec_evaluates_to(spec), VALUE_DESCRIPTION_TY))))
        return TRUE;
    return FALSE;
}
void compile_call_to_deferred_desc(OUTPUT_STREAM, pcalc_prop *prop,
    int reason, general_pointer data) {
    pcalc_prop_deferral *pdef = new_deferred_proposition(prop, reason);
    pdef->defn_ref = data;
    WRITE("(Prop_%d(", pdef->allocation_id);
    cind_find(OUT, prop, pdef);
    WRITE("))");
}
```

§**19.** The pattern is repeated for "a random ...":

```
void compile_random_of_S(OUTPUT_STREAM, specification *spec) {
    if (spec_is_variable_of_KOV_description(spec)) {
        WRITE("(");
        spec_compile(OUT, spec);
        WRITE(")(%d)", RANDOM_OF_DUSAGE);
    } else {
        pcalc_prop *prop = prop_from_spec(spec, FALSE);
        prop_verify_descriptive(prop, "a random thing matching a description", spec);
        kind_of_value *kov = prop_describes_KOV(prop);
        if ((kov) && (kov_compile_domain_possible(kov) == FALSE))
            sentence_problem(_P_(C6RandomImpossible),
                "this asks to find a random choice from a range which is too "
                "large or impractical",
                "so can't be done. For instance, 'a random person' is fine - "
                "it's clear exactly who all the people are, and the supply is "
                "limited - but not 'a random text'.");
        else
```

```
            compile_call_to_deferred_desc(OUT, prop, RANDOM_OF_DEFER, NULL_GENERAL_POINTER);
    }
}
```

The function compile_random_of_S is called from 12/cinv.

§**20.** And similarly for "total of":

```
void compile_total_of_S(OUTPUT_STREAM, property_name *prn, specification *spec) {
    if (prn == NULL) internal_error("total of on non-property");
    if (spec_is_variable_of_KOV_description(spec)) {
        WRITE("(property_to_be_totalled=%s,(", prn_get_i6_identifier(prn));
        spec_compile(OUT, spec);
        WRITE(")(%d))", TOTAL_DUSAGE);
    } else {
        pcalc_prop *prop = prop_from_spec(spec, FALSE);
        prop_verify_descriptive(prop,
            "a total property value for things matching a description", spec);
        compile_call_to_deferred_desc(OUT, prop, TOTAL_DEFER,
            STORE_POINTER_property_name(prn));
    }
}
```

The function compile_total_of_S is called from 12/cinv.

§**21.** Also for the occasionally useful task of seeing if the current value of the I6 variable `subst__v` (the "substitution variable") is within the domain of $\phi(x)$.

```
void compile_test_of_subst__v(OUTPUT_STREAM, specification *spec) {
    if (spec_is_variable_of_KOV_description(spec)) {
        WRITE("(");
        spec_compile(OUT, spec);
        WRITE(")(%d,subst__v)", CONDITION_DUSAGE);
    } else {
        compile_test_of_proposition(OUT,
            new_QUANTITY_spec(subst_variable_quantity),
            prop_from_spec(spec, FALSE));
    }
}
```

The function compile_test_of_subst__v is called from 7/cosp and 12/cinv.

§**22.** And the extremal case is pretty well the same, too, with only some fuss over identifying which superlative is meant. We get here from code like

```
let X be the heaviest thing in the wooden box;
```

where there has previously been a definition of "heavy".

```
void compile_extremal_of_S(OUTPUT_STREAM, specification *spec,
    property_name *prn, int sign) {
    if (prn == NULL) internal_error("extremal of on non-property");
    if (spec_is_variable_of_KOV_description(spec)) {
        WRITE("(property_to_be_totalled=%s,property_loop_sign=%d,(",
            prn_get_i6_identifier(prn), sign);
        spec_compile(OUT, spec);
        WRITE(")(%d))", EXTREMAL_DUSAGE);
    } else {
        measurement_definition *mdef_found = NULL, *mdef;
        LOOP_OVER(mdef, measurement_definition) {
            property_name *def_prn;
            int def_prn_sign;
            validate_mdef(mdef);
            mdef_read_property_details(mdef, &def_prn, &def_prn_sign);
            if ((def_prn == prn) && (def_prn_sign == sign)) {
                LOGIF(WORKINGS, "Def: prop $Y, sign %d\n", def_prn, def_prn_sign);
                mdef_found = mdef; break;
            }
        }
        if (mdef_found) {
            pcalc_prop *prop = prop_from_spec(spec, FALSE);
            prop_verify_descriptive(prop,
                "an extreme case of something matching a description", spec);
            validate_mdef(mdef);
            compile_call_to_deferred_desc(OUT, prop, EXTREMAL_DEFER,
                STORE_POINTER_measurement_definition(mdef_found));
        } else internal_error("Unable to match extremal to definition");
    }
}
```

The function compile_extremal_of_S is called from 12/cinv.

§23. Domains of loops. Here we define an I6 `for` loop header to handle a repeat loop through all of the x matching a given description $\phi(x)$.

We are allowed to use two local variables in the current stack frame: `t_v1` and `t_v2`, where the numbers v_1 and v_2 are supplied to us. We mark them as available for reuse once the loop has been exited, by setting their scope to the code block for the loop.

We use v_1 as the current value and v_2 as the one which will follow it. Always evaluating one step ahead protects us in case the body of the loop takes action which moves v_1 out of the domain – e.g., in the case of

```
repeat with T running through items on the table: now T is in the box.
```

This is the famous "broken `objectloop`" hazard of Inform 6, which typically occurs because the mechanism to move from one value to the next uses `sibling` in the I6 object tree, and that relies on v_1 being an object which is still in the same location at the end of the loop as at the beginning.

Thus a typical loop header has the form

```
for (t_1=D(0), t_2=D(t_1): t_1: t_1=t_2, t_2=D(t_1))
```

where `D` is a routine such that at 0 it produces the first element of the domain, and then given `x` in the domain, `D(x)` produces the next element until it returns 0, when the domain is exhausted.

```
void compile_repeat_over_S(OUTPUT_STREAM, specification *spec, int v1, int v2) {
    pcalc_prop *domain_prop = NULL; int use_as_is = FALSE;
    set_scope_of_local_to_current_block(v1);
    set_scope_of_local_to_current_block(v2);
    if (spec_is_variable_of_KOV_description(spec)) use_as_is = TRUE;
    else {
        domain_prop = prop_from_spec(spec, FALSE);
        if (prop_contains_callings(domain_prop))
            sentence_problem(_P_(C6CalledInRepeat),
                "this tries to use '(called ...)' to give names to values "
                "arising in the course of working out what to repeat through",
                "but this is not allowed. (Sorry: it's too hard to get right.)");
    }
    WRITE("for (t_%d=", v1);
    if (use_as_is) compile_repeat_call(OUT, spec, -1);
    else compile_repeat_domain(OUT, domain_prop, -1);
    WRITE(", t_%d=", v2);
    if (use_as_is) compile_repeat_call(OUT, spec, v1);
    else compile_repeat_domain(OUT, domain_prop, v1);
    WRITE(": t_%d: t_%d=t_%d, t_%d=", v1, v1, v2, v2);
    if (use_as_is) compile_repeat_call(OUT, spec, v2);
    else compile_repeat_domain(OUT, domain_prop, v2);
    WRITE(")");
}
```

The function compile_repeat_over_S is called from 12/cinv.

§**24.** If the description D is not explicitly known – because it sits inside a variable – then the following compiles code to call `D` in order to calculate the next value in the domain after the one stored in `fromv`.

Here, once again, we know that D has been compiled to a general-purpose deferred description routine, and we simply call that routine with the `LOOP_DOMAIN_DUSAGE` task.

```
void compile_repeat_call(OUTPUT_STREAM, specification *spec, int fromv) {
    WRITE("(");
    spec_compile(OUT, spec);
    WRITE(")(%d,", LOOP_DOMAIN_DUSAGE);
    if (fromv >= 0) WRITE("t_%d", fromv); else WRITE("0");
    WRITE(")");
}
```

§**25.** But if the description $D = \phi(x)$ is an explicitly known proposition, then we defer it to a routine specifically tailored to loop domains – it will never be needed for anything else.

```
void compile_repeat_domain(OUTPUT_STREAM, pcalc_prop *prop, int fromv) {
    pcalc_prop_deferral *pdef = defer_loop_domain(prop);
    WRITE("Prop_%d(", pdef->allocation_id);
    int nc = cind_find(OUT, prop, pdef);
    if (nc > 0) WRITE(",");
    if (fromv >= 0) WRITE("t_%d", fromv); else WRITE("0");
    WRITE(")");
}
```

§**26. Checking the validity of a description.** The following utility routine checks that a proposition contains exactly one unbound variable, producing problem messages if not, and that it passes type-checking successfully.

```
void prop_verify_descriptive(pcalc_prop *prop, char *billing,
    specification *constructor) {
    if (constructor == NULL) internal_error("description with null constructor");
    best guess at the text to quote in any problem message
    int ew1 = constructor->word_ref1, ew2 = constructor->word_ref2;
    if ((ew1 < 0) && (spec_get_argc(constructor) >= 1) && (spec_get_argument(constructor, 0))) {
        ew1 = spec_get_argument(constructor, 0)->word_ref1;
        ew2 = spec_get_argument(constructor, 0)->word_ref2;
    }
    if (prop_is_well_formed(prop) == FALSE)
        internal_error("malformed proposition in description verification");
    int N = vars_number_free(prop);
    if (N == 1)
        prop_type_check(prop,
            tc_problem_reporting(ew1, ew2,
            "involve a range of objects matching a description"));
    if (N > 1) {
        quote_source(1, current_sentence);
        quote_text(2, billing);
        quote_words(3, ew1, ew2);
        handmade_problem(_P_(BelievedImpossible));
```

```
        issue_problem_segment(
            "In %1, you are asking for %2, but this should range over a "
            "simpler description than '%3', please - it should not include any "
            "determiners such as 'at least three', 'all' or 'most'. "
            "(The range is always taken to be all of the things matching "
            "the description.)");
        issue_problem_end();
        return;
    }
    if (N < 1) {
        quote_source(1, current_sentence);
        quote_text(2, billing);
        quote_words(3, ew1, ew2);
        handmade_problem(_P_(BelievedImpossible));
        issue_problem_segment(
            "In %1, you are asking for %2, but '%3' looks as if it ranges "
            "over only a single specific object, not a whole collection of "
            "objects.");
        issue_problem_end();
    }
}
```

The function prop_verify_descriptive is called from 11/ap.

Cinders and Deferrals 6/cind

Purpose

To compile terms, having carefully preserved any constants which might have been lost in the process of deferring a proposition (such tricky constants being called "cinders").

---

§**1. About cinders.** Any proposition which includes quantification will, in general, need to be deferred: the quantifier will become a loop, and the loop variable will be a local variable in the deferred routine. Instead of compiling explicit code in the current routine `R`, we will compile a call to, say, `Prop_19`.

It is both good and bad that `Prop_19` has its own set of local variables. Good because this means it can have loop variables and counters to help it to implement quantifiers, without having to use up scarce locals in `R`. (Recall that I6 allows only 15 locals in any one routine.) But bad because the proposition may itself involve mention of local variables in `R`, which do not exist inside `Prop_19`.

There are two issues here. Suppose we have:

> if a dark room contains the painting

This compiles to code quantifying over rooms x, requiring a loop, so it will be deferred to a routine. "The painting" is, in predicate calculus terms, a constant – in that it does not depend on x – but that does not mean it's a value known at compile time. If it is a local variable in the current routine, then it won't exist in the deferred one, as mentioned above. But it might also be a phrase to decide something, which has side-effects, so that it might be important not to evaluate it more than once.

Any such constants are compiled into the call to `Prop_19` as parameters: then, when the latter is compiled, they become locals `const_0`, `const_1`, ..., whose evaluation will be rapid and without side-effects.

§**2.** As part of the deferral process, then, we scan through a proposition to look for constants which might cause trouble. These are called "cinders", which is a contraction of "constants in deferred routines".

Within any given proposition, the cinders are numbered 0, 1, 2, ...; these numbers are recorded in the `cinder` field of the relevant `pcalc_term` structure. A constant term with `cinder` set to -1 is harmless, and can be compiled in `Prop_19` as it stands: a literal number, for instance.

At any given moment, we can only be working on the compilation of a single deferred proposition routine. The following records the information noted down at the time when the proposition was deferred:

```
pcalc_prop_deferral *current_pdef = NULL;
```
used only in this section

§**3. Finding cinders.** In this operation, conducted when we defer a proposition, we look for constant terms which need to be cindered, do so, compile their values as a comma-separated list of I6 expressions (which can be used in a function call), note down their kinds of value in the record of the deferral, and return the number of cinders made.

```
int cind_find(OUTPUT_STREAM, pcalc_prop *prop, pcalc_prop_deferral *pdef) {
    TRAVERSE_VARIABLE(pl);
    int i, cinder_number = 0;
    current_pdef = pdef;
    TRAVERSE_PROPOSITION(pl, prop)
        for (i=0; i<pl->arity; i++)
            cinder_number =
                cind_find_in_term(OUT, &(pl->terms[i]), cinder_number);
    return cinder_number;
}
int cind_find_in_term(OUTPUT_STREAM, pcalc_term *pt, int cinder_number) {
    do not clear the local I6 stream
    if (pt->function)
        return cind_find_in_term(OUT, &(pt->function->fn_of), cinder_number);
    if (pt->constant) {
        if (spec_needs_to_be_cindered(pt->constant)) {
            pt->cinder = cinder_number++;
            if (STREAM_EXTENT(OUT) > 0) WRITE(",");
            spec_compile(OUT, pt->constant);
            current_pdef->cinder_kovs[pt->cinder] =
                spec_evaluates_to(pt->constant);
        } else pt->cinder = -1;
    }
    return cinder_number;
}
```

The function cind_find is called from 6/defer.

§**4.** Which leaves us to decide, given any specification, whether it represents a value needing to be cindered. If in doubt, we should cinder, but we don't want to go mad since there's a limit to how many cinders can be passed as parameters. Currently we do cinder these:

(a) phrases to decide values, cindered because they might be slow or have side-effects to evaluate;
(b) stacked non-local variables, such as variables attached to actions or activities, cindered because they are only allowed in certain routines, and the eventual deferred proposition routine might not qualify;
(c) local variables, cindered since they won't exist in the deferred routine;
(d) list and table entries, cindered since they are relatively slow to look up.

But we do not cinder these, since their evaluation never depends on context and never needs more than a single array entry lookup at run-time:

(a) constants from literal numbers to names of scenes, rulebooks, and so on;
(b) global variables.

```
int spec_needs_to_be_cindered(specification *spec) {
    if (species_is(spec, CONSTANT_SPC)) return FALSE;
    if (spec_is_global_variable(spec)) return FALSE;
    return TRUE;
}
```

§**5. Declaring cinder parameters.** Symmetrically, when we come to compiled our deferred proposition routine `Prop_19`, we need to place suitable cinder variables in its I6 header. We print their names, separated by spaces, since that's the somewhat assembler-like syntax used by I6 routine headers.

We also set `current_pdef`, since this is the first action taken in starting a new deferred routine.

```
void cind_declare(OUTPUT_STREAM, pcalc_prop *prop, pcalc_prop_deferral *pdef) {
    TRAVERSE_VARIABLE(pl);
    int i, cinder_number = 0;
    current_pdef = pdef;
    TRAVERSE_PROPOSITION(pl, prop)
        for (i=0; i<pl->arity; i++)
            cinder_number = cind_declare_in(OUT, cinder_number, &(pl->terms[i]));
}
int cind_declare_in(OUTPUT_STREAM, int cinder_number, pcalc_term *pt) {
    if (pt->function)
        return cind_declare_in(OUT, cinder_number, &(pt->function->fn_of));
    if ((pt->constant) && (pt->cinder >= 0))
        if (species_is(pt->constant, CONSTANT_SPC) == FALSE) {
            WRITE(" const_%d", cinder_number++);
        }
    return cinder_number;
}
```

The function cind_declare is called from 6/cdefp.

§**6. The KOV of terms.** We are now finally able to say what the kind of value of a term to be compiled is. The only troublesome case is when the term is a cinder; its KOV is then part of the information recorded at deferral time.

```
kind_of_value *cind_kind_of_value_of_term(pcalc_term pt) {
    if (pt.variable >= 0) return kova(OBJECT_TY);
    if (pt.constant) {
        if (pt.cinder >= 0) return current_pdef->cinder_kovs[pt.cinder];
        if (spec_is_phrasal(pt.constant)) typecheck_without_expectations(pt.constant);
        return spec_evaluates_to(pt.constant);
    }
    if (pt.function) return kova(OBJECT_TY);
    internal_error("Broken pcalc term");
    return NULL;
}
```

The function cind_kind_of_value_of_term is called from 6/equal, 9/provr and 9/cmpbp.

§**7. Compiling terms.** We are now ready to compile a general predicate-calculus term, which may be a constant (perhaps with a cinder marking), a variable or a function of another term.

Variables are compiled to I6 locals `x`, `y`, `z`, ...; cindered constants to `const_0`, `const_1`, ... These will only be valid inside a deferred routine like `Prop_19`, but that is fine because they cannot arise anywhere else. If we are compiling an undeferred proposition then all constants are uncindered and there are no variables (if there were, it would have been deferred).

Functions $f_R(t)$ are compiled by expanding an I6 schema for f_R with t as parameter.

One small wrinkle is that we type-check any use of a phrase to decide a value, because this might not yet have been checked otherwise.

```
void term_compile(OUTPUT_STREAM, pcalc_term pt) {
    if (logging_to_I6_text) { log_pcalc_term(&pt); return; }
    if (pt.variable >= 0) {
        WRITE("%c", pcalc_vars[pt.variable]);
        return;
    }
    if (pt.constant) {
        if (pt.cinder >= 0) {
            WRITE("const_%d", pt.cinder);
        } else {
            if (spec_is_phrasal(pt.constant)) typecheck_without_expectations(pt.constant);
            spec_compile(OUT, pt.constant);
        }
        return;
    }
    if (pt.function) {
        i6_schema *fn;
        binary_predicate *bp = (pt.function)->bp;
        fn = bp_get_term_as_function_of_other(bp, 0);
        if (fn == NULL) fn = bp_get_term_as_function_of_other(bp, 1);
        if (fn == NULL) internal_error("Function of non-functional predicate");
        sch_expand(fn, OUT, &(pt.function->fn_of), NULL);
        return;
    }
    internal_error("Broken pcalc term");
}
```

The function term_compile is called from 6/sch and 6/cdefp.

§**8. Detect locals.** Properly speaking, this has nothing to do with either cinders or deferrals, but it solves essentially the same problem in another context.

Here we search a proposition to look for any term involving a local variable. This is used to verify past tense propositions, which cannot rely on local values because their contents may have been wiped and reused many times since the time with which the proposition is concerned.

```
int prop_detect_locals(pcalc_prop *prop) {
    TRAVERSE_VARIABLE(pl);
    int i, locals_count = 0;
    TRAVERSE_PROPOSITION(pl, prop)
        for (i=0; i<pl->arity; i++)
            locals_count =
                detect_local_in_term(&(pl->terms[i]), locals_count);
    return locals_count;
}
int detect_local_in_term(pcalc_term *pt, int locals_count) {
    if (pt->function)
        locals_count += detect_local_in_term(&(pt->function->fn_of), locals_count);
    if (pt->constant)
        locals_count += detect_local_in_spec(pt->constant, locals_count);
    return locals_count;
}
int detect_local_in_spec(specification *spec, int locals_count) {
    int i;
    if (spec_get_storage_form(spec) == LOCAL_VARIABLE_SPC) return ++locals_count;
    if (spec_is_phrasal(spec)) {
        INVOCATION_VARIABLE(inv);
        LOOP_THROUGH_INVOCATION_LIST(inv, spec_invocation_list(spec)) {
            specification *param;
            LOOP_THROUGH_TOKENS_PARSED_IN_INV(inv, param)
                locals_count +=
                    detect_local_in_spec(param, locals_count);
        }
    }
    for (i=0; i<spec_get_argc(spec); i++)
        locals_count += detect_local_in_spec(spec_get_argument(spec, i), locals_count);
    return locals_count;
}
```

The function prop_detect_locals is called from 5/mlc, 6/defer and 11/chron.

Compile Deferred Propositions 6/cdefp

Purpose

To compile the I6 routines needed to perform the tests or tasks deferred as being too difficult in their original contexts.

Template interpreter commands

```
2   {-callv:compile_deferred_propositions}
```

§**1. Comment.** The following compiles an I6 comment noting the reason for a deferral.

```
void compile_comment_about_deferral_reason(OUTPUT_STREAM, int reason) {
    switch(reason) {
        case CONDITION_DEFER:
            WRITE("! True or false?\n"); break;
        case NOW_ASSERTION_DEFER:
            WRITE("! Force this to be true via 'now':\n"); break;
        case EXTREMAL_DEFER:
            WRITE("! Find the extremal x satisfying:\n"); break;
        case LOOP_DOMAIN_DEFER:
            WRITE("! Find next x satisfying:\n"); break;
        case NUMBER_OF_DEFER:
            WRITE("! How many x satisfy this?\n"); break;
        case TOTAL_DEFER:
            WRITE("! Find a total property value over all x satisfying:\n"); break;
        case RANDOM_OF_DEFER:
            WRITE("! Find a random x satisfying:\n"); break;
        case MULTIPURPOSE_DEFER:
            WRITE("! Abstraction for set of x such that:\n"); break;
        default: internal_error("Unknown proposition deferral reason");
    }
}
```

§**2. Preliminaries.** We have seen that propositions are deferred for diverse reasons. Here we take our medicine, and actually compile the deferred propositions into routines. The basic structure of a proposition routine is the same for all of the various reasons, but with considerable variations affecting (mainly) the initial setup and the returned value.

Note that the unchecked array bounds of 26 are safe here because propositions may only use 26 different variables at most (`x`, `y`, `z`, `a`, ..., `w`). There therefore can't be more than 26 callings, or 26 quantifiers, either.

```
void compile_deferred_propositions(OUTPUT_STREAM) {
    pcalc_prop_deferral *pdef;
    LOOP_OVER(pdef, pcalc_prop_deferral) {
        int ct_locals_problem_thrown = FALSE, negated_quantifier_found = FALSE;
        current_sentence = pdef->deferred_from;
        pcalc_prop *proposition = prop_copy(pdef->proposition_to_defer);
        int multipurpose_routine = (pdef->reason == MULTIPURPOSE_DEFER)?TRUE:FALSE;
        int reason = CONDITION_DEFER;                    redundant assignment to appease gcc -O2
        ⟨Simplify the proposition by flipping negated quantifiers, if possible 3⟩;
        phsf_create_nonphrase_stack_frame();
        ⟨Write some explanatory comments into the output 4⟩;
        WRITE("[ Prop_%d ", pdef->allocation_id);
        ⟨Declare the I6 local variables which will be needed by this deferral routine 7⟩;
        INDENT;
        ⟨Compile the code inside this deferral routine 8⟩;
        ⟨Issue a problem message if the table-lookup locals were needed 5⟩;
        ⟨Issue a problem message if a negated quantifier was needed 6⟩;
        OUTDENT; WRITE("];\n\n");
        phsf_remove_nonphrase_stack_frame();
    }
}
```

The function compile_deferred_propositions is invoked by a command in a `.i6t` template file.

§**3.** Just in case this hasn't already been done:

⟨Simplify the proposition by flipping negated quantifiers, if possible 3⟩ ≡

```
    int changed = FALSE;
    proposition = simp_negated_determiners(proposition, &changed, TRUE);
    if (changed) {
        LOGIF(CALCULUS, "simp_negated_determiners: $D\n", proposition);
    }
```

This code is used in §2.

§**4.** The following does nothing except to log details of the routine to the debugging log, and also in I6 comments in the generated I6 code.

⟨Write some explanatory comments into the output 4⟩ ≡

```
LOGIF(CALCULUS, "compile_deferred_propositions: %d: $D\n",
    pdef->allocation_id, proposition);
compile_comment_about_deferral_reason(OUT, pdef->reason);
STREAM *save_dl = dl; dl = OUT; logging_to_I6_text = TRUE;
LOG("! $D", proposition);
dl = save_dl; logging_to_I6_text = FALSE;
WRITE("\n");
if ((current_sentence) && (current_sentence->word_ref1 >= 0)) {
    save_dl = dl; dl = OUT;
    LOG("! in '$W'\n", current_sentence->word_ref1, current_sentence->word_ref2);
    dl = save_dl;
}
```

This code is used in §2.

§**5.** While unfortunate in a way, this is for the best, because a successful match on a condition looking up a table would record the table and row in local variables within the deferred proposition: they would then be wrong in the calling routine, where they are needed.

⟨Issue a problem message if the table-lookup locals were needed 5⟩ ≡

```
if ((do_we_need_ct_locals()) && (!ct_locals_problem_thrown)) {
    ct_locals_problem_thrown = TRUE;
    sentence_problem(_P_(C6CantLookUpTableInDeferred),
        "I am not able to look up table entries in this complicated "
        "condition",
        "which seems to involve making a potentially large number "
        "of checks in rather few words (and may perhaps result from "
        "a misunderstanding such as writing the name of a kind where "
        "an individual object is intended?).");
}
```

This code is used in §2.

§**6.** This looks like a horrible restriction, but in fact propositions are built and simplified in such a way that it never bites. (Quantifiers are always moved outside of negation where possible, and it is almost always possible.)

⟨Issue a problem message if a negated quantifier was needed 6⟩ ≡

```
if (negated_quantifier_found) {
    sentence_problem(_P_(BelievedImpossible),
        "this involves a very complicated negative thought",
        "which I'm not able to untangle. Perhaps you could rephrase "
        "this more simply, or split it into more than one sentence?");
}
```

This code is used in §2.

§**7.** Recall that an I6 function header consists of a `[`, then an identifier name for the function – in this case always `Prop_N` for some number `N` – and then a space-delimited list of local variable names, the initial of which are used to receive function arguments. The order of the variables is: any cinders (constants evaluated back at deferral time and being handed forward on the stack as function arguments); then any variables in the predicate calculus sense, of which the first may or may not be being used as a function argument, depending on whether or not it is bound; then the enumeration variables needed to compile generalised quantifiers, if any; and finally any oddball variables needed by code specific to particular deferral reasons.

⟨Declare the I6 local variables which will be needed by this deferral routine 7⟩ ≡

```
int j, var_states[26], no_extras;
if (multipurpose_routine) WRITE("reason");                    no cinders exist here
else cind_declare(OUT, proposition, pdef);
WRITE(" ");
vars_determine_status(proposition, var_states, NULL);
for (j=0; j<26; j++)
    if (var_states[j] != UNUSED_VST)
        WRITE("%c %c_ix ", pcalc_vars[j], pcalc_vars[j]);
no_extras = 0;
TRAVERSE_VARIABLE(pl);
TRAVERSE_PROPOSITION(pl, proposition)
    if (pl->element == DOMAIN_OPEN_ATOM) {
        WRITE("qcy_%d qcn_%d ", no_extras, no_extras);
        no_extras++;
    }
⟨Declare the I6 locals needed by adaptations to particular deferral cases 29⟩;
WRITE(";\n");
```

This code is used in §2.

§**8.**

⟨Compile the code inside this deferral routine 8⟩ ≡

```
if (multipurpose_routine) {
    int use;
    WRITE("if (reason >= 0) { x = reason; reason = %d; }\n",
        CONDITION_DUSAGE);
    WRITE("switch (reason) {\n");
    INDENT;
    pcalc_prop *safety_copy = prop_copy(proposition);
    for (use = EXTREMAL_DUSAGE; use <= CONDITION_DUSAGE; use++) {
        if (use > EXTREMAL_DUSAGE) proposition = prop_copy(safety_copy);
        switch (use) {
            case CONDITION_DUSAGE: reason = CONDITION_DEFER; break;
            case LOOP_DOMAIN_DUSAGE: reason = LOOP_DOMAIN_DEFER; break;
            case NUMBER_OF_DUSAGE: reason = NUMBER_OF_DEFER; break;
            case RANDOM_OF_DUSAGE: reason = RANDOM_OF_DEFER; break;
            case TOTAL_DUSAGE: reason = TOTAL_DEFER; break;
            case EXTREMAL_DUSAGE: reason = EXTREMAL_DEFER; break;
        }
        WRITE("%d: ", use);
        compile_comment_about_deferral_reason(OUT, reason);
        INDENT;
        ⟨Compile body of deferred proposition for the given reason 9⟩;
```

```
        OUTDENT;
    }
    OUTDENT;
    WRITE("}\n");
} else {
    reason = pdef->reason;
    ⟨Compile body of deferred proposition for the given reason 9⟩;
}
```

This code is used in §2.

§**9.** From here on, we compile the body of a routine to handle the deferral case in the variable `reason`.

What these different cases have in common is that each is basically a search of all possible values of the bound variables in the expression. There will be some initialisation, something to do with each successfully found combination, and eventually some winding-up code. For example, "number of..." initialises by setting `counter` to 0, on each success it performs `counter++`, and at the end of the search it performs `return counter`.

⟨Compile body of deferred proposition for the given reason 9⟩ ≡

```
property_name *prn = NULL;
property_name *def_prn = NULL;
int def_prn_sign = 0;
switch(reason) {
    case NOW_ASSERTION_DEFER: break;
    case CONDITION_DEFER: ⟨Initialisation before CONDITION search 30⟩; break;
    case EXTREMAL_DEFER: ⟨Initialisation before EXTREMAL search 42⟩; break;
    case LOOP_DOMAIN_DEFER: ⟨Initialisation before LOOP search 46⟩; break;
    case NUMBER_OF_DEFER: ⟨Initialisation before NUMBER search 33⟩; break;
    case TOTAL_DEFER: ⟨Initialisation before TOTAL search 39⟩; break;
    case RANDOM_OF_DEFER: ⟨Initialisation before RANDOM search 36⟩; break;
}
⟨Compile code to search for valid combinations of variables 11⟩;
switch(reason) {
    case NOW_ASSERTION_DEFER: break;
    case CONDITION_DEFER: ⟨Winding-up after CONDITION search 32⟩; break;
    case EXTREMAL_DEFER: ⟨Winding-up after EXTREMAL search 44⟩; break;
    case LOOP_DOMAIN_DEFER: ⟨Winding-up after LOOP search 48⟩; break;
    case NUMBER_OF_DEFER: ⟨Winding-up after NUMBER search 35⟩; break;
    case TOTAL_DEFER: ⟨Winding-up after TOTAL search 41⟩; break;
    case RANDOM_OF_DEFER: ⟨Winding-up after RANDOM search 38⟩; break;
}
```

This code is used in §8.

§**10. The Search.** We can now begin the real work. Given ϕ, we compile I6 code which contains a magic position M (for "match") such that M is visited exactly once for every combination of possible substitutions into the bound variables such that ϕ is true. For example,

$$\exists x : door(x) \wedge open(x) \wedge \exists y : room(y) \wedge in(x, y)$$

might compile to code in the form:

```
blah, blah, blah {
    M
} rhubarb, rhubarb
```

such that execution reaches `M` exactly once for each combination of open door x and room y such that x is in y. (Position `M` is where we will place the case-dependent code for what to do on a successful match.) In the language of model theory, this is a loop over all interpretations in which ϕ is true.

We will do this by compiling the proposition from left to right. If there are k atoms in ϕ, then there are $k + 1$ positions between atoms, counting the start and the end. Then:

Invariant. Let ψ be any syntactically valid subproposition of ϕ (that is, a contiguous sequence of atoms from ψ which would be a valid proposition in its own right). Then there are before and after positions `B` and `A` in the compiled I6 code for searching ϕ such that

(a) `A` cannot be reached except from `B`, and
(b) at execution time, on every occasion `B` is reached, `A` is then reached exactly once for each combination of possible substitutions into the $\exists$-bound variables of ψ such that ψ is then true.

In particular, in the case when $\psi = \phi$, `B` is the start of our compiled I6 code (before anything is done) and `A` is the magic match position `M`.

The restriction to syntactically valid subpropositions is important. Suppose ϕ arises from "all doors are open" and is stored in memory as:

```
Forall x IN[ door(x) IN] open(x)
```

Then `door(x)` and `Forall x IN[ door(x) IN]` are valid, for instance, but `IN] open(x)` is not.

Lemma. If the Invariant holds for two adjacent syntactically valid subpropositions μ and ν, then it holds for the subproposition $\mu\nu$.

Proof. There are now three positions in the code: `B1`, before μ; `B2`, before ν, which is the same position as after μ; and `A`, after ν. Execution reaches `B2` m times for each visit to `B1`, where m is the number of combinations of viable bound variable values in μ. Execution reaches `A` n times for each visit to `B2`, where n is the similar number for ν. Therefore execution reaches `A` a total of nm times for each visit to `B1`, the product of the number of variable combinations in μ and ν, which is exactly the number of combinations in total.

Corollary. If the Invariant holds for subpropositions in each of the following forms, then it will hold overall.

(a) `Exists v`, for some variable v, or `Q v IN[ ... IN]`, for some quantifier other than $\exists$.
(b) `NOT[ ... NOT]`.
(c) any single predicate-like atom.

Proof. Because all valid subpropositions are concatenations of these, and we then apply the Lemma.

It follows that if we can prove our algorithm maintains the invariant in cases (a) to (d), we can be sure it will correctly construct code leading to the match point `M`.

§**11.** We will make use of three stacks:

(a) The R-stack, which holds the current "reason": the goal being pursued by the I6 code currently being compiled.
(b) The Q-stack, which holds details of quantifiers being searched on.
(c) The C-stack, which holds details of callings of variables.

Since each is tied to a quantifier, each of which is tied to a distinct variable, and there are at most 26 variables, we need a worst-case capacity of 27 slots on the R-stack (counting the initial `reason`) and 26 on the Q-stack and C-stack.

⟨Compile code to search for valid combinations of variables 11⟩ ≡

```
int block_nesting = 0;                          how many { ... } blocks are open in I6 code being compiled
```

The R-stack

```
int R_stack_reason[27];
int R_stack_parity[27];
int R_sp = 0;
```

The Q-stack

```
quantifier *Q_stack_quantifier[26];
int Q_stack_parameter[26];
int Q_stack_C_stack_level[26];
int Q_stack_block_nesting[26];
int Q_sp = 0;
```

The C-stack

```
pcalc_term C_stack_term[26];                    the term to which a called-name is being given
int C_stack_index[26];                          its index in the deferred_calling_list
int C_sp = 0;
```

⟨Push initial reason onto the R-stack 12⟩;
we now begin compiling the search code
⟨Compile the proposition into a search algorithm 15⟩;
`while (Q_sp > 0)` ⟨Pop the Q-stack 24⟩;
`while (C_sp > 0)` ⟨Pop the C-stack 26⟩;
we are now at the magic match point `M` *in the search code*
⟨Pop the R-stack 14⟩;
`while (block_nesting > 0)`
    ⟨Close a block in the I6 code compiled to perform the search 28⟩;
we have now finished compiling the search code

```
if (R_sp != 0) internal_error("R-stack failure");
if (Q_sp != 0) internal_error("Q-stack failure");
if (C_sp != 0) internal_error("C-stack failure");
```

This code is used in §9.

§**12. The R-stack.** This is a sort of "split goals into sub-goals" mechanism. In order to determine

if all but one of the closed doors are unlocked, ...

our main goal is to determine the truth of the "are unlocked" part. This is reason `CONDITION_DEFER`, and it is pushed onto the R-stack at the start of the compilation:

⟨Push initial reason onto the R-stack 12⟩ ≡
```
R_stack_reason[R_sp] = reason;
R_stack_parity[R_sp] = TRUE;
R_sp++;
```
This code is used in §11.

§**13.** But in order to work this out, we have to work out which doors are closed, and this is a subgoal to which we give the pseudo-reason `FILTER_DEFER`. We push this new sub-goal onto the R-stack, leaving the original to be resumed when we're done.

define `FILTER_DEFER 10000` *pseudo-reason value used only inside this routine*

⟨Push domain-opening onto the R-stack 13⟩ ≡
```
R_stack_reason[R_sp] = FILTER_DEFER;
R_stack_parity[R_sp] = TRUE;
R_sp++;
```
This code is used in §15.

§**14.** The R-stack is then popped when the goal is accomplished (or rather, when the I6 code we are compiling has reached a point which will be executed when its goal has been accomplished).

In the case of `FILTER_DEFER`, when scanning domains of quantifiers, we increment the count of the domain set size – the number of closed doors, in the above example. (See below.)

⟨Pop the R-stack 14⟩ ≡
```
R_sp--; if (R_sp < 0) internal_error("R stack underflow");
switch(R_stack_reason[R_sp]) {
    case FILTER_DEFER:
        WRITE("qcn_%d++;\n", Q_sp-1);
        break;
    case NOW_ASSERTION_DEFER: break;
    case CONDITION_DEFER: ⟨Act on successful match in CONDITION search 31⟩; break;
    case EXTREMAL_DEFER: ⟨Act on successful match in EXTREMAL search 43⟩; break;
    case LOOP_DOMAIN_DEFER: ⟨Act on successful match in LOOP search 47⟩; break;
    case NUMBER_OF_DEFER: ⟨Act on successful match in NUMBER search 34⟩; break;
    case TOTAL_DEFER: ⟨Act on successful match in TOTAL search 40⟩; break;
    case RANDOM_OF_DEFER: ⟨Act on successful match in RANDOM search 37⟩; break;
}
```
This code is used in §11,15,11,15,11.

§15. Compiling the search. In the following we run through the proposition from left to right, compiling I6 code as we go, but preserving the Invariant.

```
⟨Compile the proposition into a search algorithm 15⟩ ≡
    TRAVERSE_VARIABLE(pl);
    int run_of_conditions = FALSE;
    int no_deferred_callings = 0;                    how many CALLED atoms have been found to date
    TRAVERSE_PROPOSITION(pl, proposition) {
        switch (pl->element) {
            case NEGATION_OPEN_ATOM:
            case NEGATION_CLOSE_ATOM:
                ⟨End a run of predicate-like conditions, if one is under way 18⟩;
                R_stack_parity[R_sp-1] = (R_stack_parity[R_sp-1])?FALSE:TRUE;        reverse parity
                break;
            case QUANTIFIER_ATOM:
                ⟨End a run of predicate-like conditions, if one is under way 18⟩;
                if (R_stack_parity[R_sp-1] == FALSE) negated_quantifier_found = TRUE;
                quantifier *quant = RETRIEVE_POINTER_quantifier(pl->predicate);
                int param = pl->calling_data;
                if (quant != exists_quantifier) ⟨Push the Q-stack 22⟩;
                ⟨Compile a loop through possible values of the variable quantified 20⟩;
                break;
            case DOMAIN_OPEN_ATOM:
                ⟨End a run of predicate-like conditions, if one is under way 18⟩;
                ⟨Push domain-opening onto the R-stack 13⟩;
                break;
            case DOMAIN_CLOSE_ATOM:
                ⟨End a run of predicate-like conditions, if one is under way 18⟩;
                ⟨Pop the R-stack 14⟩;
                break;
            case CALLED_ATOM:
                ⟨Push the C-stack 25⟩;
                break;
            default:
                if (R_stack_reason[R_sp-1] == NOW_ASSERTION_DEFER)
                    ⟨Compile code to force the atom 19⟩
                else
                    ⟨Compile code to test the atom 17⟩;
                break;
        }
    }
    ⟨End a run of predicate-like conditions, if one is under way 18⟩;
```

This code is used in §11.

§16. Predicate runs and their negations. Or, cheating Professor de Morgan.

If we have a run of predicate-like atoms – say X, Y, Z – then this amounts to a conjunction: $X \wedge Y \wedge Z$. The obvious way to compile code for this would be to take one term at a time:

```
if (X)
    if (Y)
        if (Z)
```

That satisfies the Invariant, and is clearly correct. But we want to use the same mechanism when looking at a negation, and then it would go wrong.

Note that if ϕ contains $\neg(\psi)$ then ψ must be a conjunction of predicate-like atoms. (Otherwise a problem message would be issued and in that case it doesn't matter what code we compile, so long as we don't crash: it will never be run.) Thus we can assume that between `NEGATION_OPEN_ATOM` and `NEGATION_CLOSE_ATOM` is a predicate run.

Between negation brackets, then, we must interpret X, Y, Z as $\neg(X \wedge Y \wedge Z)$, and we need to compile that to

```
if (~~(X && Y && Z))
```

rather than

```
if (~~X)
    if (~~Y)
        if (~~Z)
```

which gets de Morgan's laws wrong.

§**17.** That means a little fancy footwork to start and finish the compound `if` statement properly:

⟨Compile code to test the atom 17⟩ ≡

```
if (run_of_conditions == FALSE) {
    WRITE("if ");
    if (R_stack_parity[R_sp-1] == FALSE) WRITE("(~~");
    WRITE("(");
    run_of_conditions = TRUE;
} else WRITE(" && ");
atom_compile(OUT, TEST_ATOM_TASK, pl);
```

This code is used in §15.

§**18.**

⟨End a run of predicate-like conditions, if one is under way 18⟩ ≡

```
if (run_of_conditions) {
    if (R_stack_parity[R_sp-1] == FALSE) WRITE(")");
    WRITE(")");
    run_of_conditions = FALSE;
    ⟨Open a block in the I6 code compiled to perform the search 27⟩;
}
```

This code is used in §15.

§**19.** The `NOW_ASSERTION_DEFER` reason is different from all of the others, because rather than searching for a given situation it tries force it to happen (or not to). Forcing rather than testing is easy here: we just supply a different task when calling `atom_compile`.

In the negated case, we again cheat de Morgan, by falsifying ϕ more aggressively than we need: we force $\neg(X) \wedge \neg(Y) \wedge \neg(Z)$ to be true, though strictly speaking it would be enough to falsify X alone. (We do it that way for consistency with the same convention when asserting about the model world.)

We don't need to consider runs of predicates for that; we can take the atoms one at a time.

⟨Compile code to force the atom 19⟩ ≡

```
atom_compile(OUT, (R_stack_parity[R_sp-1])?NOW_ATOM_TRUE_TASK:NOW_ATOM_FALSE_TASK, pl);
WRITE("\n");
```

This code is used in §15.

§**20. Quantifiers and the Q-stack.** It remains to deal with quantifiers, and to show that the Invariant is preserved by them. There are two cases: $\exists$, and everything else.

The existence case is the easiest. Given $\exists v : \psi(v)$ we compile

```
loop header for v to run through its domain set {
    ...
```

and note that execution reaches the start of the loop body once for each possible choice of v, as required by the Invariant – indeed the Invariant pretty much requires that this is what we compile.

⟨Compile a loop through possible values of the variable quantified 20⟩ ≡

```
pl = compile_loop_header(OUT, pl->terms[0].variable, pl,
    (R_stack_reason[R_sp-1] == NOW_ASSERTION_DEFER)?TRUE:FALSE,
    (quant != exists_quantifier)?TRUE:FALSE);
⟨Open a block in the I6 code compiled to perform the search 27⟩;
```

This code is used in §15.

§**21.** Generalised quantifiers – "at least three", "all but four", and so on – make quantitative statements about the number of valid or invalid cases over a domain set. These need more elaborate code. Suppose we have $\phi = Qv \in \{v \mid \psi(v)\} : \theta(v)$, which in memory looks like this:

```
QUANTIFIER --> DOMAIN_OPEN --> psi --> DOMAIN_CLOSE --> theta
```

We compile that to code in the following shape:

```
set count of domain size to 0
set count of valid cases to 0
loop header for v to run through its domain set {
    if psi holds {
        increment count of domain size
        if theta holds {
            increment count of valid cases
        }
    }
}
if the counts are such that the quantifier is satisfied {
    ...
```

We don't always need both counts. For instance, to handle "at least three doors are unlocked" we count both the domain size (the number of doors) and the number of valid cases (the number of unlocked doors), but only need the latter. This might be worth optimising some day, to save local variables.

§**22.** The domain size and valid case counts are stored in locals called `qcn_N` and `qcy_N` respectively, where `N` is the index of the quantifier – 0 for the first one in the proposition, 1 for the second and so on.

On reading a non-existence `QUANTIFIER` atom, we compile code to zero the counts, and push details of the quantifier onto the Q-stack, so that we can recover them later. We then compile a loop header exactly as above.

The test of ψ, which acts as a filter on the domain set – e.g., only doors, not all objects – is handled by pushing a suitable goal onto the R-stack, but we don't need to do anything to make that happen here, because the `DOMAIN_OPEN` atom does it.

⟨Push the Q-stack 22⟩ ≡

```
if (R_stack_reason[R_sp-1] == NOW_ASSERTION_DEFER)
    ⟨Handle "not exists" as "for all not" 23⟩;
Q_stack_quantifier[Q_sp] = quant;
Q_stack_parameter[Q_sp] = param;
Q_stack_block_nesting[Q_sp] = block_nesting;
Q_stack_C_stack_level[Q_sp] = C_sp;
WRITE("qcy_%d = 0;\n", Q_sp);
WRITE("qcn_%d = 0;\n", Q_sp);
Q_sp++;
```

This code is used in §15.

§**23.** It is always true that $\nexists x : \psi(x)$ is equivalent to $\forall x : \neg(\phi(x))$, so the following seems pointless. We do this, in the case of "now" only, in order to make $\nexists$ legal in a "now", which it otherwise wouldn't be. Most quantifiers aren't, because they are too vague: "now fewer than six doors are open", for instance, is not allowed. But we do want to allow "now nobody likes Mr Wickham", say, which asserts $\nexists x : person(x) \wedge likes(x, W)$.

⟨Handle "not exists" as "for all not" 23⟩ ≡

```
if (quant == not_exists_quantifier) {
    R_stack_parity[R_sp-1] = (R_stack_parity[R_sp-1])?FALSE:TRUE;
    quant = for_all_quantifier;
}
```

This code is used in §22.

§**24.** To resume the narrative of what happens when we read:

```
QUANTIFIER --> DOMAIN_OPEN --> psi --> DOMAIN_CLOSE --> theta
```

We zeroed the counters, compiled the loop headers and pushed details to the Q-stack at the `QUANTIFIER` atom; pushed a filtering goal onto the R-stack at the `DOMAIN_OPEN` atom; popped it again as accomplished at `DOMAIN_CLOSE`, compiling a line which increments the domain size to celebrate; and then compiled code to test θ.

Now we are at the end of the line, and still have the quantifier code half-done, as we know because the Q-stack is not empty. We first compile an increment of the valid cases count, because if execution of the I6 code gets to the end of testing θ then it must have found a valid case: in the "at least three doors are unlocked" example, it will have found an unlocked one among the doors making up the domain. We then need to record any "called" values for later retrieval by whoever called this proposition routine: see below. That leaves just this part:

```
            }
        }
    }
    if the counts are such that the quantifier is satisfied {
        ...
```

left to compile, and we will be done: execution will reach the ... if and only if it is true at run-time that three or more of the doors is unlocked.

Thus this elaborate generalised-quantifier case satisfies the Invariant because it transfers execution from before to ... either 0 times (if the counts don't satisfy us), or once. Unlike in the $\exists v$ case, it's not a question of enumerating which v work and which do not; the whole thing works, or doesn't, and is more like testing a single `if`.

⟨Pop the Q-stack 24⟩ ≡

```
Q_sp--; if (Q_sp < 0) internal_error("Q stack underflow");
WRITE("qcy_%d++;\n", Q_sp);
while (C_sp > Q_stack_C_stack_level[Q_sp])
    ⟨Pop the C-stack 26⟩;
while (block_nesting > Q_stack_block_nesting[Q_sp])
    ⟨Close a block in the I6 code compiled to perform the search 28⟩;
WRITE("if (");
quant_compile_test(OUT, Q_stack_quantifier[Q_sp], Q_sp, Q_stack_parameter[Q_sp]);
WRITE(")");
⟨Open a block in the I6 code compiled to perform the search 27⟩;
```

This code is used in §11.

§25. The C-stack. When a CALLED atom in the proposition gives a name to a variable, we have to transcribe that to the `deferred_calling_list` for the benefit of the code calling this proposition routine. Each time we discover that a term t is to be given a name, we stack it up. These are not always variables:

> if a person (called the dupe) is in a dark room (called the lair), ...

gives names to x ("dupe") and $f(x)$ ("lair"), because simplification has eliminated the variable y which appears to be being given a name.

⟨Push the C-stack 25⟩ ≡

```
C_stack_term[C_sp] = pl->terms[0];
C_stack_index[C_sp] = no_deferred_callings++;
C_sp++;
```

This code is used in §15.

§26. When does the compiled search code record values into `deferred_calling_list`? In two situations:

(a) when a domain-search has successfully found a viable case for a quantifier, the values of any variables called in that domain are recorded;
(b) and otherwise the values of called variables are recorded just before point `M`, that is, immediately before acting on a successful match.

For example, when reading:

> if a person (called the dupe) is in a lighted room which is adjacent to exactly one dark room (called the lair), ...

the value of "dupe" is transferred just before `M`, but the value of "lair" is transferred as soon as a dark room is found. The code looks like this:

```
set count of domain size to 1
loop through domain (i.e., dark rooms adjacent to the person's location) {
    increment count of domain size
    record the lair value
}
if the count of domain size is 1 {
```

```
        record the dupe value
        M
    }
```

If we waited until point `M` to record the lair value, it would have disappeared, because `M` is outside the loop which searches the domain of the "exactly one" quantifier.

⟨Pop the C-stack 26⟩ ≡

```
    C_sp--; if (C_sp < 0) internal_error("C stack underflow");
    WRITE("deferred_calling_list-->%d = ", C_stack_index[C_sp]);
    term_compile(OUT, C_stack_term[C_sp]);
    WRITE(";\n");
```

This code is used in §11,24,11,24,11,24.

§**27.** That just leaves the blocking, which follows the One True Brace Style. Thus:

⟨Open a block in the I6 code compiled to perform the search 27⟩ ≡

```
    WRITE("{\n");
    INDENT;
    block_nesting++;
```

This code is used in §18,20,24,18,20,24,18,20,24.

§**28.** and:

⟨Close a block in the I6 code compiled to perform the search 28⟩ ≡

```
    OUTDENT;
    WRITE("}\n");
    block_nesting--;
```

This code is used in §11,24,11,24,11,24.

§29. Adaptations. That completes the general pattern of searching according to the proposition's instructions. It remains to adapt it to different needs, by providing, in each case, some setting-up code; some code to execute when a viable set of variable values is found; and some winding-up code.

In some of the cases, additional local variables are needed within the `Prop_N` routine, to keep track of counters or totals. These are they:

⟨Declare the I6 locals needed by adaptations to particular deferral cases 29⟩ ≡

```
if (multipurpose_routine) WRITE("total counter selection best best_with");
else {
    switch (pdef->reason) {
        case NUMBER_OF_DEFER: WRITE("counter"); break;
        case RANDOM_OF_DEFER: WRITE("counter selection"); break;
        case TOTAL_DEFER: WRITE("total"); break;
        case EXTREMAL_DEFER: WRITE("best best_with"); break;
    }
}
```

This code is used in §7.

§30. Adaptation to CONDITION. The first and simplest of our cases to understand: where ϕ is a sentence, with all variables bound, and we have to return `true` if it is true and `false` if it is false. There is no initialisation:

⟨Initialisation before CONDITION search 30⟩ ≡

```
;
```

This code is used in §9.

§31. As soon as we find any valid combination of the variables, we return `true`:

⟨Act on successful match in CONDITION search 31⟩ ≡

```
WRITE("rtrue;\n");
```

This code is used in §14.

§32. So we only reach winding-up if every case failed, and then we return `false`:

⟨Winding-up after CONDITION search 32⟩ ≡

```
WRITE("rfalse;\n");
```

This code is used in §9.

§33. Adaptation to NUMBER. In the remaining cases, ϕ has variable x (only) left free, but the use we want to make will be a loop over all objects x, and we compile this "outer loop" here: the loop opens in the initialisation code, closes in the winding-up code, and therefore completely encloses the code generated by the searching mechanism above.

In the first case, we want to count the number of x for which $\phi(x)$ is true. The local `counter` holds the count so far; it starts out automatically at 0, since all I6 locals do.

⟨Initialisation before NUMBER search 33⟩ ≡

```
proposition = compile_loop_header(OUT, 0, proposition, FALSE, FALSE);
WRITE("{\n");
INDENT;
```

This code is used in §9.

§**34.** Recall that we get here for *each possible way* that $\phi(x)$ could be true, that is, once for each viable set of values of bound variables in ϕ. But we only want to increment `counter` once, so having done so, we exit the searching code and continue the outer loop.

The `jump` to a label is forced on us since I6, unlike, say, Perl, has no syntax to break or continue a loop other than the innermost one.

⟨Act on successful match in NUMBER search 34⟩ ≡
```
WRITE("counter++;\n");
WRITE("jump NextOuterLoop_%d;\n", reason);
```
This code is used in §14.

§**35.** The continue-outer-loop labels are marked with the reason number so that if code is compiled for each reason in turn within a single routine – which is what we do for multipurpose deferred propositions – the labels do not have clashing names.

⟨Winding-up after NUMBER search 35⟩ ≡
```
WRITE(".NextOuterLoop_%d;\n", reason);
OUTDENT;
WRITE("}\n");
WRITE("return counter;\n");
```
This code is used in §9.

§**36. Adaptation to RANDOM.** To choose a random x such that $\phi(x)$, we essentially run the same code as for NUMBER searches, but twice over: first to count how many such x there are, then to run through again to find the nth of these, where n is a uniformly random number such that $1 \le n \le x$.

This avoids needing to store the full list of matches anywhere, which would be impossible since (a) it's potentially a lot of storage and (b) it can only safely live on the current stack frame, and I6 does not allow arrays on the current stack frame (because of restrictions in the Z-machine). This means that, on average, the compiled code takes 50% longer to find its random x than it ideally would, but we accept the trade-off.

⟨Initialisation before RANDOM search 36⟩ ≡
```
WRITE("selection = -1;\n");
WRITE("while (true) {\n");
INDENT;
WRITE("counter = 0;\n");
proposition = compile_loop_header(OUT, 0, proposition, FALSE, FALSE);
WRITE("{\n");
INDENT;
```
This code is used in §9.

§**37.** Again we exit the searcher as soon as a match is found, since that guarantees that $\phi(x)$.

Note that we can only return here on the second pass, since `selection` is -1 throughout the first pass, whereas `counter` is non-negative.

⟨Act on successful match in RANDOM search 37⟩ ≡
```
WRITE("counter++;\n");
WRITE("if (counter == selection) return %c;\n", pcalc_vars[0]);
WRITE("jump NextOuterLoop_%d;\n", reason);
```
This code is used in §14.

§**38.** We return `nothing` – the non-object – if `counter` is zero, since that means the set of possible x is empty. But we also return if `selection` has been made already, because that means that the second pass has been completed without a return – something which in theory cannot happen, but just might do if testing part of the proposition had some side-effect changing the state of the objects and thus the size of the set of possibilities.

⟨Winding-up after RANDOM search 38⟩ ≡

```
WRITE(".NextOuterLoop_%d;\n", reason);
OUTDENT;
WRITE("}\n");
WRITE("if ((counter == 0) || (selection >= 0)) return nothing;\n");
WRITE("selection = random(counter);\n");
OUTDENT;
WRITE("}\n");
```

This code is used in §9.

§**39. Adaptation to TOTAL.** Here the task is to sum the values of property P attached to each object in the domain $\{x \mid \phi(x)\}$. (At the moment, this is guarded so that the domain set must indeed contain world objects, not values.)

⟨Initialisation before TOTAL search 39⟩ ≡

```
proposition = compile_loop_header(OUT, 0, proposition, FALSE, FALSE);
WRITE("{\n");
INDENT;
```

This code is used in §9.

§**40.** The only wrinkle here is the way the compiled code knows which property it should be totalling. If we know that ourselves, we can compile in a direct reference. But if we are compiling a multipurpose deferred proposition, then it might be used to total any property over the domain, and we won't know which until runtime – when its identity will be found in the I6 variable `property_to_be_totalled`.

⟨Act on successful match in TOTAL search 40⟩ ≡

```
char *source_of_property;
if (multipurpose_routine)
    source_of_property = "property_to_be_totalled";
else {
    prn = RETRIEVE_POINTER_property_name(pdef->defn_ref);
    source_of_property = prn_get_i6_identifier(prn);
}
if (source_of_property == NULL) internal_error("No property name");
WRITE("total = total + %c.%s;\n", pcalc_vars[0], source_of_property);
WRITE("jump NextOuterLoop_%d;\n", reason);
```

This code is used in §14.

§**41.**

⟨Winding-up after TOTAL search 41⟩ ≡

```
WRITE(".NextOuterLoop_%d;\n", reason);
OUTDENT;
WRITE("}\n");
WRITE("return total;\n");
```

This code is used in §9.

§**42. Adaptation to EXTREMAL.** This is rather similar. We find the member of $\{x \mid \phi(x)\}$ which either minimises, or maximises, the value of some property P. We use two local variables: `best`, the extreme P value found so far; and `best_with`, the member of the domain set which achieves that.

If two or more x achieve the optimal P-value, it is deliberately left undefined which one is returned. The user may be typing "the heaviest thing on the table", but what he gets is "a heaviest thing on the table".

We open the search with `best_with` equal to `nothing`, the non-object, which is what we will return if the domain set turns out to be empty; and with `best` set to the furthest-from-optimal value possible. For a search maximising P, `best` starts at the lowest number representable in the virtual machine; for a minimisation, it starts at the highest. That way, if any member of the domain is found, its P-value must be at least as good as the starting value of `best`.

Again the only nuisance is that sometimes we know P, and whether we are maximising or minimising, at compile time; but for a multipurpose routine we don't, and have to look that up at run-time.

⟨Initialisation before EXTREMAL search 42⟩ ≡

```
if (multipurpose_routine) {
    WRITE("if (property_loop_sign>0) best=MIN_NEGATIVE_NUMBER;\n");
    WRITE("else best=MAX_POSITIVE_NUMBER;\n");
} else {
    measurement_definition *mdef =
        RETRIEVE_POINTER_measurement_definition(pdef->defn_ref);
    mdef_read_property_details(mdef, &def_prn, &def_prn_sign);
    if (def_prn_sign == 1) {
        WRITE("best = MIN_NEGATIVE_NUMBER;\n");
    } else {
        WRITE("best = MAX_POSITIVE_NUMBER;\n");
    }
}
proposition = compile_loop_header(OUT, 0, proposition, FALSE, FALSE);
WRITE("{\n");
INDENT;
```

This code is used in §9.

§**43.** It might look as if we could speed up the multipurpose case by multiplying by `property_loop_sign`, thus combining the max and min versions into one, and saving an `if`. But (a) the multiplication is as expensive as the `if` (remember that on a VM there's no real branch penalty), and (b) we need to watch out because -1 times -32768, on a 16-bit machine, is -1, not 32768: so it is *not* always true that multiplying by -1 is order-reversing.

⟨Act on successful match in EXTREMAL search 43⟩ ≡

```
char *source_of_property;
if (multipurpose_routine) source_of_property = "property_to_be_totalled";
else source_of_property = prn_get_i6_identifier(def_prn);
if (multipurpose_routine) {
    WRITE("if (property_loop_sign>0) {\n");
    INDENT;
    WRITE("if (%c.%s >= best) {\n", pcalc_vars[0], source_of_property);
    INDENT;
    WRITE("best = %c.%s;\n", pcalc_vars[0], source_of_property);
    WRITE("best_with = %c;\n", pcalc_vars[0]);
    OUTDENT;
    WRITE("}\n");
    OUTDENT;
```

```
        WRITE("} else {\n");
        INDENT;
        WRITE("if (%c.%s <= best) {\n", pcalc_vars[0], source_of_property);
        INDENT;
        WRITE("best = %c.%s;\n", pcalc_vars[0], source_of_property);
        WRITE("best_with = %c;\n", pcalc_vars[0]);
        OUTDENT;
        WRITE("}\n");
        OUTDENT;
        WRITE("}\n");
    } else {
        WRITE("if (%c.%s %s best) {\n",
            pcalc_vars[0], source_of_property, (def_prn_sign == 1)?">=":"<=");
        INDENT;
        WRITE("best = %c.%s;\n", pcalc_vars[0], source_of_property);
        WRITE("best_with = %c;\n", pcalc_vars[0]);
        OUTDENT;
        WRITE("}\n");
    }
```

This code is used in §14.

§**44.**

⟨Winding-up after EXTREMAL search 44⟩ ≡

```
    WRITE(".NextOuterLoop_%d;\n", reason);
    OUTDENT;
    WRITE("}\n");
    WRITE("return best_with;\n");
```

This code is used in §9.

§**45. Adaptation to LOOP.** Here the proposition is used to iterate through the members of the domain set $\{x \mid \phi(x)\}$. Two local variables exist: `x` and `x_ix`. One of the following is true:

(1) The domain set contains only objects, so that `x` is non-zero if it represents a member of that set. In this case `x_ix` may or may not be used, and we will not rely on it.
(2) The domain set contains only values, and then `x` might easily be zero, but `x_ix` is always the index within the domain set: 1 if `x` is the first value, 2 for the second and so on.

The proposition is called with a pair of values `x`, `x_ix` and returns the next value `x` in the domain set, or 0 if the domain is exhausted. (In case (2) it's not safe to regard 0 as an end-of-set sentinel value because 0 can be a valid member of the set; so in looping through (2) we should first find the size of the set using NUMBER OF, then keep calling for members until the index reaches the size.) There is no need to return the next `x_ix` value since it is always the present value plus 1.

If the proposition is called with `x` set to `nothing`, in case (1), or with `x_ix` equal to 0, in case (2), it returns the first value in the domain.

§**46.** Snarkily, this is how we do it:

```
if we're called with a valid member of the domain, go to Z
loop x over members of the domain {
    return x
    label Z is here
}
```

Which is not really a loop at all, but is a cheap way to extract either the initial value or the successor value from a loop header. (The trick actually caused some consternation for I6 hackers when early drafts of I7 came out, because they had been experimenting with a patch to I6 which protected `objectloop` from object-tree rearrangements but which assumed that nobody ever used `jump` to enter a loop body bypassing its header. But the DM4, which defines I6, doesn't forbid this. The designer of I6 has learned his lesson, though: I7 has no goto or jump instruction, and I7 loops can be proved to be entered and exited cleanly.)

⟨Initialisation before LOOP search 46⟩ ≡

```
WRITE("if (%c_ix > 0) {\n", pcalc_vars[0]);
INDENT;
WRITE("%c_ix--;\n", pcalc_vars[0]);
WRITE("jump NextOuterLoop_%d;\n", reason);
OUTDENT;
WRITE("}\n");
WRITE("if (%c) jump NextOuterLoop_%d;\n", pcalc_vars[0], reason);
proposition = compile_loop_header(OUT, 0, proposition, FALSE, FALSE);
WRITE("{\n");
INDENT;
```

This code is used in §9.

§**47.**

⟨Act on successful match in LOOP search 47⟩ ≡

```
WRITE("return %c;\n", pcalc_vars[0]);
```

This code is used in §14.

§**48.**

⟨Winding-up after LOOP search 48⟩ ≡

```
WRITE(".NextOuterLoop_%d;\n", reason);
OUTDENT;
WRITE("}\n");
WRITE("return nothing;\n");
```

This code is used in §9.

§**49. Compiling loop headers.** The final task of this entire chapter is to compile an I6 loop header which causes a given variable v to range through a domain set D – which we have to deduce by looking at the proposition ψ in front of us.

We want this loop to run as quickly as possible: efficiency here makes a very big difference to the running time of compiled I7 code. Most optimisations aren't worth the risk in added complexity – but these are.

Loops through kinds of value are not in general optimisable. The problem cases involve loops through objects. Consider:

> if everyone in the Dining Room can see an animal, ...

Code like this will run very slowly:

```
loop over objects (x)
    loop over objects (y)
        if x is a person
            if x is in the Dining Room
                if y is an animal
                    if x can see y
                        success!
```

This is folly in so many ways. Most objects aren't people or animals, so almost all combinations of x and y are wasted. We test the eligibility of x for every possible y. And there are quick ways to find what is in the Dining Room, so we're missing a trick there, too. What we want is:

```
loop over objects in the Dining Room (x)
    if x is a person
        loop over animals (y)
            if x can see y
                success!
```

§**50.** Part of the work is done already: we generate propositions with quantifiers as far forwards as they can be, so we won't loop over y before checking the validity of x. The rest of the work comes from two basic optimisations:

(1) if a loop over v is such that $K(v)$ holds in every case, where K is a kind, then loop v over K rather than all objects, and
(2) if a loop over v is such that $R(v, t)$ holds in every case, then loop over all v such that $R(v, t)$ in cases where R has a run-time representation making this quick and easy.

In each case we can then delete $K(v)$ or $R(v, t)$ from the proposition as redundant, since the loop header has taken care of it.

Case (1) is called "kind optimisation"; case (2), "parent optimisation", because the prototype case is R being containment – we exploit that the object-tree parent of v is known, and that I6 has a fast form of `objectloop` to visit the children of a given node in the object tree. Case (2) has to be avoided if we are compiling code to force a proposition, rather than test it, because then $R(v, t)$ is not an accomplished fact but is something we have yet to make come true. This is why the loop-compiler takes a flag `avoid_parent_optimisation`. Case (1) doesn't suffer from this since kinds cannot be changed at run-time.

§**51.** So here is the code. We write an I6 schema for the loop into `loop_schema`, then expand it into the output.

```
i6_schema loop_schema;
pcalc_prop *compile_loop_header(OUTPUT_STREAM, int var, pcalc_prop *proposition,
    int avoid_parent_optimisation, int grouped) {
    kind_of_value *kov = NULL;
    pcalc_prop *kind_position = NULL;
    pcalc_term var_term = term_new_variable(var);
    pcalc_term second_term = term_new_variable(var);          this value is never used, but just in case
    int parent_optimised = FALSE;
    the default, if we are unable to provide either kind or parent optimisation
    sch_write_to_existing(&loop_schema, "objectloop (*1 ofclass Object)");
    ⟨Scan the proposition to find the domain of the loop, and look for opportunities 52⟩;
    if ((kov) && (parent_optimised == FALSE)) {          parent optimisation is stronger, so we prefer that
        kov_write_loop_schema(&loop_schema, kov, TRUE);
        proposition = prop_delete_atom(proposition, kind_position);
    }
    sch_expand(&loop_schema, OUT, &var_term, &second_term);
    return proposition;
}
```

§**52.** The following looks more complicated than it really is. Sometimes it's called to compile a loop arising from a quantifier with a domain, in which case `grouped` is set and `proposition` points to:

```
QUANTIFIER --> DOMAIN_OPEN --> psi --> DOMAIN_CLOSE --> ...
```

so that ψ, the part in the domain group, defines the range of the variable. But sometimes the call is to compile a loop not arising from a quantifier, so there is no domain group to scan; instead the whole proposition makes up ψ, and now `grouped` is clear.

⟨Scan the proposition to find the domain of the loop, and look for opportunities 52⟩ ≡

```
int bl = 0, enabled = FALSE;
TRAVERSE_VARIABLE(pl);
TRAVERSE_PROPOSITION(pl, proposition) {
    switch (element_get_group(pl->element)) {
        case OPEN_OPERATORS_GROUP: bl++; break;
        case CLOSE_OPERATORS_GROUP: bl--; break;
    }
    if (grouped) {
        if (pl->element == DOMAIN_OPEN_ATOM) enabled = TRUE;
        if (pl->element == DOMAIN_CLOSE_ATOM) enabled = FALSE;
        if (bl < 0) break;
        if (enabled == FALSE) continue;
        if (bl != 1) continue;
    } else {
        if (bl < 0) break;
        if (bl > 0) continue;
    }
    ⟨Scan $\psi$, the part of the proposition establishing the domain 53⟩;
}
```

This code is used in §51.

§**53.** In either case, we scan ψ looking for $K(v)$ atoms, which would tell us the domain set for the variable v, or for $R(v,t)$ atoms for parent-optimisable relations R.

⟨Scan ψ, the part of the proposition establishing the domain 53⟩ ≡

```
if ((pl->element == KIND_ATOM) && (pl->terms[0].variable == var)) {
    kov = pl->assert_kind_of_value;
    kind_position = pl_prev;
}
if ((avoid_parent_optimisation == FALSE) &&
    (pl->element == PREDICATE_ATOM) && (pl->arity == 2))
    ⟨Consider parent optimisation on this binary predicate 54⟩;
```

This code is used in §52.

§**54.** We give the relation R an opportunity to write a loop which runs v through all possible x such that $R(x,t)$, by writing a schema for the loop in which `*1` denotes the variable v and `*2` the term t.

For example, the worn-by relation writes the schema:

```
objectloop (*1 in *2) if (WearerOf(*1)==parent(*1))
```

where v runs quickly through the object-tree children of t, but items carried rather than worn are skipped.

We have to check three possible cases: $R(v,t)$ direct, and then $is(f_R(v),t)$ or $is(t,f_R(v))$, which can arise from simplifications. We set `optimise_on` to R and `parent` to t.

⟨Consider parent optimisation on this binary predicate 54⟩ ≡

```
binary_predicate *bp = RETRIEVE_POINTER_binary_predicate(pl->predicate);
if (bp == a_is_b_predicate) {
    int chk;
    for (chk=0; chk<=1; chk++) {
        pcalc_func *pf = pl->terms[chk].function;
        if ((pf) && (pf->fn_of.variable == var) &&
            (bp_write_optimised_loop_schema(&loop_schema, pf->bp))) {
            second_term = pl->terms[1-chk];
            parent_optimised = TRUE;
            proposition = prop_delete_atom(proposition, pl_prev);
            break;
        }
    }
} else if ((pl->terms[0].variable == var) &&
    (bp_write_optimised_loop_schema(&loop_schema, bp))) {
    second_term = pl->terms[1];
    parent_optimised = TRUE;
    proposition = prop_delete_atom(proposition, pl_prev);
}
```

This code is used in §53.

§**55.** And that concludes the predicate-calculus engine at the heart of Inform, and with it Chapter 6.

7 Kinds and Specifications

`7/itsp`: *Introduction to Specifications.w* A general introduction to kinds of value and specifications.

`7/tids`: *Table of ID Numbers.w* To manage a table of details about the ID numbers used to enumerate families and species of specifications, and kinds of value.

`7/kov`: *Kinds of Value.w* To manage the `kind_of_value` structure, representing the possible categories into which eventual I6 values can be placed; to determine which KOVs contain which others, and what their characteristics are.

`7/data`: *Data Types.w* To manage the built-in set of data types, which are used as the atomic kinds of value and therefore characterise fundamental kinds of data – numbers, times, texts, and so on – and to create new ones as required.

`7/dti`: *Data Type Interpreter.w* To read in details of the built-in data types from the template file "Types.i6t", setting them up ready for use.

`7/dim`: *Dimensions.w* To keep a small database indicating the physical dimensions of numerical values, and how they combine: for instance, allowing us to specify that a length times a length is an area.

`7/kix`: *Kinds Index.w* To produce most of the Kinds page in the Index for a project: the chart at the top, and the detailed entries below.

`7/spec`: *Specifications.w* To create, manage and compare specifications.

`7/ttts`: *Text to Specifications.w* Complete forms of parsing from excerpts of text to specifications.

`7/specv`: *Specification Versions of Other Structures.w* To see how specifications correspond to other structures which they conceptually include.

`7/cfsp`: *Compiling from Specifications.w* To compile specifications into Inform 6 values, conditions or void expressions.

`7/masp`: *MATCHING Specifications.w* Documentation on and functions handling specifications which fall into the MATCHING family.

`7/vasp`: *VALUE Specifications.w* Documentation on and functions handling specifications which fall into the VALUE family.

`7/stsp`: *STORAGE Specifications.w* Documentation on and functions handling specifications which fall into the STORAGE family.

`7/cosp`: *CONDITION Specifications.w* Documentation on and functions handling specifications which fall into the CONDITION family.

`7/cmsp`: *COMMAND Specifications.w* Documentation on and functions handling specifications which fall into the COMMAND family.

`7/tc`: *Type Checking.w* To decide whether a given specification, representing a value or construct found in the source text, can be used in a given context: the possible answers being yes, no, or "possibly, contingent on run-time type checking".

`7/inv`: *Invocations.w* Specifications which ask to use a phrase (which are "phrasal") indicate which phrase they intend by means of a list of "invocations". This list goes on to record the outcome of type-checking and provides instructions for code generation, as we see here.

Introduction to Specifications 7/itsp

Purpose

A general introduction to kinds of value and specifications.

§**1. Specifications.** A "specification" describes a single unambiguous meaning. It is a very general concept, covering not only what other programming languages would call "values" but also what they would call "types". It is a Swiss Army knife of representation.

Specifications arise in two ways. First, they are the outcome of successful parsing of an excerpt of text. "201", "the player", "a number", "a closed door", "award 6 points" and "an existing variable" all produce specifications. Each one is marked with a reference to the words it came from, so that wherever it travels through Inform it can always be used to construct a useful problem message related back to its origin.

Second, though this happens less frequently, they are created internally to describe something – usually to describe what is needed in a particular context. A specification provides a natural way to say "I would like a phrase to decide a value here".

§**2.** The reader might be feeling a certain déjà vu here. Weren't meaning lists also data structures which unified a great range of possible meanings for excerpts of texts? Why do we need this new concept?

There are several answers. One is simply that specifications are much more compact in memory than meaning lists, which are bloated by having to hold rival interpretations of the same text. (This is why meaning lists are thrown away when parsing is done.) Another is that meaning lists are basically linguistic in their structure – they make trees like those drawn by grammarians. Specifications, on the other hand, are organised around the basic concepts of Inform. So they are much easier for us to use.

A more satisfying answer is that specifications are *unambiguous*, but we need to define that word carefully. In the case of phrases, they can contain multiple possible "invocations". For instance, the phrase

```
let exemplum be 10;
```

has a subtly different meaning if the value "exemplum" already exists than if it doesn't. The specification (SP) will be unambiguous that this is a phrase, but will carry a list of alternative invocations describing different possible ways it could be carried out at run-time. The reason such ambiguities are allowed to persist into the SP, rather than being resolved at the meaning list stage, is that some ambiguities are impossible to sort out at compile time: instead, run-time code must be compiled to get matters right when the code is executed. The SP must therefore be allowed to contain exactly that range of ambiguities potentially insoluble until run-time, and no other. In design terms, this is the principle behind the meaning list/specification boundary.

§**3. Kinds of value.** A value is something which could eventually exist as a value in some variable at run-time. The number 17, the time "3:15 PM", the every turn rulebook, etc., are all values. A value may either be self-contained when stored at run-time (a "word value", occupying one word of memory) or be a pointer to a larger array of data (a "pointer value"). For instance, times are word values; lists are pointer values.

A kind of value (often abbreviated "KOV") categorises values. (KOVs are closely analogous to what C-like programming languages call "types".) For instance, the KOV of 17 is "number", the KOV of 3:15 PM is "time", and so on. If the source text defines

```
Paint colour is a kind of value. The paint colours are mauve, duck-white and peach.
```

then "duck-white" is a value and "paint colour" is its KOV.

§**4.** Some kinds of value contain each other – for instance a "rulebook" is a special case of a "rule" – so that it is possible for a value V to belong to more than one kind of value at once. When we talk about its own kind of value, we implicitly mean the narrowest kind of value containing it. If two kinds of value K_1 and K_2 are such that K_1 contains K_2, we say that K_2 "implicitly casts" to K_1 – meaning that by doing nothing at all at run-time, a K_2 value can simply be treated as if it were a K_1 value, because it already is one. Of course, most pairs of KOV are simply incomparable – "number" and "text", for instance – so that neither can implicitly cast to the other.

KOVs thus form a hierarchy. At the top is "value", which matches any value at all, so that every other KOV is contained within it. The other special point in the hierarchy is the kind of value "object", which matches all rooms, things, directions, regions and so on. If the source text says

```
A wheelbarrow is a kind of vehicle. The blue garden barrow is a wheelbarrow.
```

then the value "blue garden barrow" has kind "wheelbarrow", which is within "vehicle", within "thing", within "object", within "value". The "object" KOV is unusual because values with any kind at or below it in the hierarchy – in other words objects – are mutually distinguishable at run-time. The I6 value of a specific wheelbarrow can never coincide with that of a specific door, for instance. This allows us to be much looser in type-checking below "object", and we get a great deal of flexibility that way. When a KOV represents a kind of object, it is called a KOVKO ("kind of value which is a kind of object").

Kinds of value are stored in a `kind_of_value` structure, which is usually a lightweight packet of data, but can in principle be quite a large tree. "List of lists of numbers", for instance, is represented by a `kind_of_value` marked "list of" which points to another `kind_of_value` marked "list of" which points to a `kind_of_value` marked "number". This is an example of a "constructed KOV" or KOVCON, since it has been made out of other KOVs. A more basic one is called an "atomic KOV" or KOVA.

`kind_of_value` structures are identified internally with numerical constants called "data type IDs" and written with the `_TY` suffix: thus, `TEXT_TY`, `NUMBER_TY`, `LIST_OF_TY`, for instance.

§**5.** Even on a minimal run, Inform's KOV hierarchy is already quite rich, setting up the hierarchy which is the main display in the Kinds index. There are about 45 basic KOVs built in – about 15 KOVKOs (kinds of object), declared in the Standard Rules, and about 30 KOVAs used for data, whose relationships and specifics are laid out in the `Types.i6t` template file. The format of this file amounts to a mini-language just to set up KOVAs, and much of the section "Data Types.w" consists of the interpreter for that mini-language.

But the hierarchy is not *all that* rich. Inform also supports much more complicated ways to describe values than any KOV can represent. "Door" is a KOV, in fact a KOVKO, but "open door" is not a KOV, and nor is "even number", or

```
a woman in a lighted room
```

It seems at first appealing to decide that "open door" (say) ought to be a KOV, but no variable with this KOV would be safe: merely by opening a door somewhere during play, the player could make its current value no longer fit its KOV.

In order to preserve type safety, Inform forces its storage objects (variables, table entries, and so on) to have fixed KOVs decided at compile time. We are allowed to create a "number that varies", but not an "even number that varies", because the former is a KOV and the latter is not. This is rather like C, where variables might be declared like so:

```
int width, height; char *name;
```

In C, the range of types which can be stored is the same as the range of types which can be function arguments, so for instance:

```
int area(int width, int height) { return width*height; }
```

But whereas Inform's variables are much like C's, Inform's phrase definitions are not like C's functions, and they can have much more general arguments:

```
To jemmy open (the barrier - a closed door): ...
```

To repeat (P - a phrase) indefinitely: ...

We therefore need a much more general way to describe what text can appear in phrase arguments than a KOV can provide, and this is what leads us to the idea of a "specification". In fact, though, even these examples are not general enough. Natural language is very slippery about concepts which, in most computing theories, are formally separate. Consider for instance the overloaded definition of a phrase like this one:

To appreciate (composer - a person): ...

To appreciate (composer - Alessandro Striggio): ...

The early design of Inform did not permit this, since it clearly confused values and types, but this lack was in fact reported as a bug – always a sign that users considered it a natural thing to do. Specifications therefore needed to be able to represent not only vague descriptions like "person", but also explicit identities like "Alessandro Striggio".

§**6.** The enormous variety of specifications means that we need some sort of taxonomy to sort them out.

(a) Each SP is either "actual" or "generic". Actual SPs describe structures explicitly referred to in the source. Generic SPs are patterns against which these are matched: "number", for instance, or "existing text variable". Actual SPs contain specifics, often including pointers to further actual SPs. The actual SP for "award 6 points" includes a pointer to an actual SP for "6"; it matches the generic SP "phrase", which has no specifics.

(b) Like the animal kingdom, the realm of SPs is classified on several levels.

(b1) There are five "families", identified with a `*_FMY` constant. For instance, the family `STORAGE_FMY` contains all forms of storage item – variables local and global, table entries and the like.

(b2) Within each family are a number of "species", identified with a constant in the form `*_SPC`. For instance, local variables belong to the species `LOCAL_VARIABLE_SPC` of family `STORAGE_FMY`.

(b3) Some species are still further subdivided according to a kind of value associated with them, though most are not. For instance, "number that varies" is a generic member of the species `NONLOCAL_VARIABLE_SPC` of family `STORAGE_FMY` with the KOV "number".

While the source text can and almost always does create many new KOVs, the families and species are fixed, and built into Inform.

It's useful to have a shorthand notation for writing these distinctions, especially for the debugging log. So: `(G)VALUE_FMY/CONSTANT_SPC` means "a generic SP of family `VALUE_FMY` and species `CONSTANT_SPC`", and so forth.

§**7.** Whereas source text can create new KOVs, this hierarchy of SPs is hard-wired into Inform and is the same for every run.

The following table shows that every combination of actual/generic and of family is used in Inform, with just one exception.

Family	**Generic**	**Actual**
`MATCHING_FMY`	nonexisting number variable	*no actual matching SPs exist*
`VALUE_FMY`	number	102
`STORAGE_FMY`	time that varies	time of day
`CONDITION_FMY`	condition	the player is in a dark room
`COMMAND_FMY`	phrase	award 5 points

Values and their kinds form only a small part of this picture. A constant value is an `(A)VALUE_FMY/CONSTANT_SPC`, a kind of value a `(G)VALUE_FMY/CONSTANT_SPC`.

§**8.** Lastly, it seems worth recording the fact that the classification of these ideas into families and species was constantly revised in the course of writing and testing Inform. While the actual semantics of the Inform language were not changing, the SP representations used for it were in constant flux between public builds, in a process which amounted to a sort of investigation into what the "true" concepts of the language were. Numerous species and even whole families have come and gone. (Who now remembers `KIND_OF_VARIABLE_SPC`, or `OBJECT_SPEC_FMY` of which the only documentation once read "this enigmatic data type holds things like property numbers"?)

Broadly, though, there is a choice in setting up the classification of SPs between grouping together those with similar data in their structures, and on the other hand grouping together SPs which play a similar semantic role in the Inform language. For instance, the former regards "award 5 points" and "location of the harpsichord" as similar (both are phrases to be compiled), but the latter strategy sees them as very different – one performs a command, whereas the other determines a value.

For the first four years of its life, Inform classified SPs around data structures, which made parsing simpler but resulted in a type-checker festooned with exceptional cases; now it classifies SPs by semantic purpose, which makes parsing harder but simplifies type-checking. The change is not as odd as it might seem – in the early years, it was the parsing apparatus which gave the most trouble; but in later years, with the type system becoming richer, type-checking was the biggest source of "difficult" bugs.

§**9. Architecture of the type-checker.** The type-checker is the part of Inform which examines a "found SP" against an "expected SP", and decides whether this is permissible. In some cases, it issues problem messages if not: in others, it simply reports back. And in a few cases, it performs a "coercion" to modify the found SP to match the expected one: the type-checker is not a neutral observer, but actively tries to make the source fit.

The type-checker has three concentric levels, each of which can be independently used by the rest of Inform:

(1) The innermost level checks SPs which evaluate to values. The test is made by `can_we_cast_kovs` in "Kinds of Value.w", which tests whether one KOV can be used where another KOV is expected. There is no coercion at this level, and no problem messages are issued: failures are simply reported back to the calling routine.

(2) The middle level checks SPs which evaluate or describe values. For instance, this level might deduce that "Marble Door" can be used where "closed openable door" is expected. The tests are performed in "Value Checking.w". Again, there is no coercion at this level, and no problem messages are issued: failures are simply reported back.

(3) The outermost level checks SPs in general. This is done in "Type Checking.w", and is a much more active process. SPs are coerced if need be, and problem messages issued to the user.

§**10.** All three levels use a set of three constants to describe outcomes:

```
define ALWAYS_MATCH    2                 provably correct at compile time
define SOMETIMES_MATCH 1                 provably reduces to a check feasible at run-time
define NEVER_MATCH     0                 neither of the above
```

§**11.** The term "type-checking" is perhaps a little misleading – "specification matching" might be better, since level (1) alone is the equivalent of a conventional programming language's type-checker. But it's a familiar term and, after all, the whole process is analogous.

Table of ID Numbers 7/tids

Purpose

To manage a table of details about the ID numbers used to enumerate families and species of specifications, and kinds of value.

Template interpreter commands

```
1   {-callv:make_type_IDs_table}
12   {-callv:complete_type_IDs_table}
21   {-callv:compile_I6_constants_for_typenames}
28   {-callv:report_pairs_observed}
29   {-callv:report_pairs_allowed}
```

Definitions

¶1. As the Introduction showed, a "specification" can hold a very large range of concepts. Each individual SP will have its own "family" and "species", and some will also have a kind of value (KOV) attached. KOVs can themselves describe quite a range of values, and these are in turn are sorted out with "data type IDs".

That gives us three sets of ID numbers, and given how complex all this is, we want to be careful never to confuse these different categorisations. We therefore choose the IDs so that none of them overlap, i.e., no family ID is numerically the same as a species ID, and so on: this makes it easier to catch bugs where IDs have been confused together.

In general we call these numerical codes "type IDs", and they divide up as follows:

(i) The `UNKNOWN` special value, which can be used only to indicate that no family or species is given.

(ii) The `*_FMY` family identifiers.

(iii) The `*_SPC` species identifiers.

(iv) The `*_TY` data type identifiers, which can only be used to mark KOVAs. (`UNKNOWN` is not valid here.)

The values of these constants are not significant, except that they must all be different, and that some routines require `FALSE` to be a distinct value from all type IDs, so it is important that 0 never be used.

We conventionally use the range 1 to 49 for the families and species, 50 to 99 for built-in data type IDs, and 100 upwards for data type IDs arising from newly created kinds of value in the source text.

¶2. The UNKNOWN type ID. Uniquely, this can be used both as a family and as a species. As a family, it means that the meaning of the SP is unknown: such a SP is sometimes returned by a routine to mean "could not understand this text". As a species, `UNKNOWN` means nothing: it simply indicates that no species is supplied. It is also used as a default return value by some routines which would otherwise return a valid data type ID.

define `UNKNOWN 1` *"arfle barfle gloop"*

¶3. The MATCHING family. No actual SPs have this family: it is used only for generic SPs matching against raw textual material, something we do very little of, but which is conceptually so different that it earns a family of its own. Since all SPs are generic, there are never any specific details.

define MATCHING_FMY 5
define NEW_LOCAL_VARIABLE_NAME_SPC 6 *"nonexisting number variable"*

¶4. The VALUE family. VALUE specifications are "rvalues", that is, they express I6 values – numbers, objects, text and so on – but cannot be assigned to, so that in an assignment of the form "change L to R" they can be used only as R, not L. This is not the same thing as a constant: for instance, "location of the player" evaluates differently at different times, but cannot be changed in an assignment and so qualifies as a VALUE.

define VALUE_FMY 10
define CONSTANT_SPC 11 *"7", "the can't lock a locked door rule", etc.*
define PHRASE_TO_DECIDE_VALUE_SPC 12 *"holder of the black box"*

¶5. The STORAGE family. STORAGE specifications represented stored I6 data at run-time, which means that they can be used not only as rvalues but also lvalues: they can be assigned to, that is. For instance, a table entry qualifies because it can be both read and changed. To qualify as STORAGE, a type must exactly specify the storage location referred to: "Table of Corvettes" only indicates a table, not an entry in a table, so is merely a VALUE. Similarly, "carrying capacity" (as a property name not indicating an owner) is a mere VALUE.

define STORAGE_FMY 20
define LOCAL_VARIABLE_SPC 21 *"the running total", say*
define NONLOCAL_VARIABLE_SPC 22 *"the location"*
define PROPERTY_VALUE_SPC 23 *"the carrying capacity of the cedarwood box"*
define TABLE_ENTRY_SPC 24 *"tonnage in row X of the Table of Corvettes"*
define LIST_ENTRY_SPC 25 *"item 4 in L"*

¶6. The CONDITION family. This is an I7 condition which can be compiled into an I6 condition: for instance, "the bronze gate is open", or "eating the biscuit".

define CONDITION_FMY 30
define LOGICAL_AND_SPC 31 *"A and B"*
define LOGICAL_OR_SPC 32 *"A or B"*
define TEST_PROPOSITION_SPC 33 *if "the cat is on the mat"*
define TEST_PHRASE_OPTION_SPC 34 *"giving full details", say*
define TEST_ACTION_SPC 35 *"going nowhere in the Confusing Labyrinth"*
define TEST_PAST_ACTION_SPC 36 *"we have gone nowhere"*
define NOW_PROPOSITION_SPC 37 *now "the cat is on the mat"*
define PHRASE_TO_DECIDE_IF_SPC 38 *"in darkness"*
define DESCRIPTION_SPC 39 *"open door which is lockable", "a container"*

¶7. The COMMAND family. Compiles to one or more I6 statements in void context inside a routine. The most obvious examples are "to..." phrases, but there are other possibilities too.

define COMMAND_FMY 40
define TO_PHRASE_SPC 41 *"award 5 points"*
define END_BLOCK_SPC 42 *"end while"*
define OTHERWISE_SPC 43 *"otherwise"*
define CASE_SPC 44 *"– V" value in a switch*
define RULEBOOK_OUTCOME_PHRASE_SPC 45 *"persuasion succeeds"*
define TRY_ACTION_SPC 46 *"try dropping the eustace diamonds"*

¶8. That only leaves the data type IDs. Those come from two sources: built-in ones like "number", set out in the template file "Types.i6t" and given IDs in the range 50 to 99, and new ones created in the source text (by text like "Air pressure is a kind of value").

There are broadly five groups of data type ID:
(1) built-in data types used in matching, but which have no instances as such – for instance ANY_VALUE_TY: any value matches this, but no value has this as its own kind;
(2) built-in data types whose instances are stored as word-value data, where a single I6 value holds the whole thing, like NUMBER_TY;
(3) built-in data types whose instances are stored as pointers to larger blocks of data on the heap, like INDEXED_TEXT_TY;
(4) enumerations added in the source text, with a finite known number of named constant values, internally numbered upwards from 1; and
(5) units added in the source text, with literal patterns to give them notation.

The "Types.i6t" template file consists almost entirely of commands for the Data Type Interpreter, which sets up groups (1), (2) and (3) accordingly. This template file contains as much as possible of the specifics about the various types, so that a great deal can be changed about the interplay of types without altering the compiler itself.

Some of the built-in data types need to referred to in the Inform source code, and these have defined constant values below. Others never do, and these are shown as comments in the discussion below – they could be deleted from "Types.i6t" or given different meanings and Inform would have no difficulty.

¶9. Group 1: Data types used in matching.

ANY_VALUE. This is a superhero among data types: it exists only for type-checking purposes, and matches any value of any data type. Use of it basically makes the type-checking machinery switch off, so in fact when it is used other arrangements need to be made to validate what is going on. In the Standard Rules, the data type for w in the following:

    To change (tr - table-reference) to (w - value): ...

...is ANY_VALUE: but that does not mean it is necessarily sensible to write any value to a given table entry, so we need to be careful.

ASSIGNABLE_VALUE_TY represents any value except the name of a property: it is needed because of the ambiguity arising in a phrase like

    change the current safe to unlocked

where we clearly intend not an assignment to the variable "current safe" but a modification of an either/or property held by the object which is the present value of that variable.

The finer distinctions ANY_WORD_VALUE and ANY_POINTER_VALUE divide all values into those which are word data in themselves, and those which are pointers to blocks of data on the heap.

To handle some of the casts from values to pointers-to-block-structures, we also need to store kinds of value at run-time as values in their own right: that is, we need to store code numbers like NUMBER_TY as I6 values.

The two kinds of value KIND_OF_WORD_VALUE and KIND_OF_POINTER_VALUE represent these, though they are used only for matching purposes.

define ANY_VALUE_TY 50

ANY_WORD_VALUE_TY
ANY_POINTER_VALUE_TY
define ASSIGNABLE_VALUE_TY 51
define KIND_OF_WORD_VALUE_TY 52
define KIND_OF_POINTER_VALUE_TY 53

¶10. DESCRIPTION_OF_ACTION is used in type-checking to represent gerunds: that is, actions described by what appear to be participles but which are in context nouns ("if taking something, ...").

define DESCRIPTION_OF_ACTION_TY 54

¶11. VALUE_DESCRIPTION is used only in type-checking to distinguish value from object descriptions; it's the difference between "even **number**" and "open **door**".

define VALUE_DESCRIPTION_TY 55

¶12. A little bit of voidology theory here: when the source text uses the notation { }, that refers to the empty list. But this is a constant whose kind of value, uniquely, can't be determined: what is it an empty list of – numbers, texts, rooms? So it acquires the NO_ENTRIES (it means, no entries: it isn't an abbreviation for number of entries) kind of value.

define NO_ENTRIES_TY 56

¶13. CLASSIFIED. Not in any sense of being secret, though, at the same time, I don't really want people to find out about it and use it. I6 is not a typed language but it has what amounts to a data type in its generalised sense of object: a value which can be any of 0, an object, a class, a packed string or a routine. Given an arbitrary value of this type, I6 can determine at run-time which of these five possibilities is the case. We want to exploit this ability to perform run-time type-checking, so we need an umbrella I7 data type which means "anything stored at run-time in one of these I6 formats". This data type is called CLASSIFIED since it can be resolved by looking at the I6 metaclass at run time. (Okay, so perhaps it ought to be called "metaclassified".)

We cannot decide simply to ignore CLASSIFIED in the interests of a simpler life since, though its use is deprecated, we need it to deal with the return value of a rulebook – something currently rather fuzzy in Inform's design: eventually we shall probably have rulebooks which specify explicitly the kind of value they return, and then CLASSIFIED can at last go.

/* CLASSIFIED_TY */

¶14. Group 2: Data types for basic word-sized values.

NUMBER. An integer. Constants can be written either in words (up to twelve), or signed decimal numbers.

define NUMBER_TY 57

¶15. TIME. "Men can do nothing without the make-believe of a beginning. Even Science, the strict measurer, is obliged to start with a make-believe unit, and must fix on a point in the stars' unceasing journey when his sidereal clock shall pretend that time is at Nought. His less accurate grandmother Poetry has always been understood to start in the middle; but on reflection it appears that her proceeding is not very different from his; since Science, too, reckons backwards as well as forwards, divides his unit into billions, and with his clock-finger at Nought really sets off in medias res" (George Eliot, *Daniel Deronda*). Our make-believe here is midnight, our unit is divided not into billions but into 1240, and a value of this kind holds one of two possibilities:

(i) an absolute time, measured as the number of minutes since midnight;
(ii) a relative time, measured in minutes.

Thus the value 70 might mean 1:10 AM, or it might mean 70 minutes, and type-checking does not try to distinguish the two. (This is so that arithmetic will be easier – we can add 70 minutes to 1:10 AM to get 2:20 AM, but if they had different kinds, this would be illegal.) The ambiguity is occasionally unhelpful, though: we have to supplement the "[a time]" Understand token, which parses an absolute time, with a special "[a time period]" one, so that users are able to parse relative times as well.

define TIME_TY 58

¶16. TEXT, TEXT_ROUTINE, QUOT, SNIPPET. Inform 6 code was designed to be compiled for the Z-machine, a virtual computer with very unusual memory access rules but with support for several kinds of textual matter. This means that string-handling in I6 code is a messy business. Many things which would be routine in most languages are essentially impossible in I6 code (for instance, concatenating arbitrary strings of text, or extracting a character at a given position in an arbitrary string). The I7 type system tries to hide some of this nightmare vision from us, but as a result is pretty complicated.

TEXT is the native type of a piece of double-quoted text without substitutions, and for type checking purposes it also matches a TEXT-ROUTINE, which is double-quoted text which does have substitutions. (These compile into I6 packed strings and routines respectively: since they can be distinguished using `metaclass`, I6 can treat them as if they were a single type without breaking type safety, so it is safe for variables to have the kind of value TEXT, say.) A QUOT is the double-quoted text used for displaying boxed quotations, which has different line-breaking conventions, and has to be handled in a type of its own. Finally, a SNIPPET represents a selection of words from the player's command, recording both the word number to start at and the number of words included in the snippet. This must be handled with care, because when the player's command changes, all old SNIPPET values become meaningless. It therefore cannot be stored meaningfully in global variables, except for a couple defined by I7's own code and which are automatically updated each time the command changes.

define TEXT_TY 59
define TEXT_ROUTINE_TY 60
define QUOT_TY 61
define SNIPPET_TY 62

¶17. UNICODECHAR. A character referred to by its Unicode number, or by a name defined in the Unicode standard: for instance, "unicode 65" is a capital A. Characters are not really a data type in I7: rather, we deal with one-character strings if we need to access individual letters, and this type exists to refer to constants only.

define UNICODECHAR_TY 63

¶18. OBJECT. An object (a thing, room, direction, etc.): something which compiles to either an Object in I6 code. (Thus, not a kind, which compiles to a Class in I6 code, even though objects and kinds of object share the same structure, world_object, in NI.)

There is normally one FORMLESS reference: a world_object * pointer to the object in question. If this is absent (i.e., there are no references), then one of the flags is used...

```
define OBJECT_TY 64
```

¶19. I6_DESCRIPTION_ROUTINE corresponds to the "description" kind of value, and compiles as an I6 value to the routine name for a general-purpose deferred proposition.

```
define OBJECT_DESCRIPTION_TY 65
```

¶20. USEOPTION. The named use options can actually be values at run-time, though the Inform documentation does not exactly stress this point. We need the possibility in order to be able to define the phrase

To decide whether using the (UO - use-option): ...

VALUE/USEOPTION SPs have one FORMLESS reference: a use_option * pointer.

```
define USEOPTION_TY 66
```

¶21. PROPERTY. The name of a property can itself be used as a value on occasion, as for instance in the "if X provides P" condition. An actual property has a single reference, to the relevant property_name structure.

```
define PROPERTY_TY 67
```

¶22. RULE, RULEBOOK, RULE_OUTCOME, RULEBOOK_OUTCOME. Rules are values at run-time, and names such as "can't reach inside closed containers rule" are constants evaluating to RULE_TY. (They are compiled to names of routines in I6 code.) Rulebooks are also values, but are numbered from 1 upwards.

Each rule has a unique identifying number at run-time. If this ID number is less than or equal to the number of rulebooks created then the number refers to a rulebook, which are numbered 0, 1, 2, ... in order of creation. An ID number above this threshold value is taken as the Z-machine address of the routine to which a rule has been compiled. In principle there could be a problem if any genuine rule had a Z-machine address so low as to clash with the range of rulebook numbers, but in practice the presence of the I6 library routines, the veneer, and other Z-machine impedimenta mean that this cannot happen.

RULE constant SPs have one FORMLESS reference: a booked_rule * pointer to the rule.

RULEBOOK constant SPs have one FORMLESS reference: a rulebook * pointer to the rulebook.

RULEBOOK_OUTCOME constants are similar values to possible outcomes of a rulebook, with a FORMLESS reference to a rulebook_outcome * pointer.

RULE_OUTCOME is a bit bogus as a data type: no variables or properties ever exist at run-time to hold data of this type. It represents the data type of the return code of a routine implementing a rule, and exists only evanescently on the run-time stack. We need it because we need a type name in order to parse the "outcome" notation in phrase definitions like:

To continue the action: (- rfalse; -) - outcome.

```
define RULE_TY 68
RULE_OUTCOME_TY
define RULEBOOK_TY 69
define RULEBOOK_OUTCOME_TY 70
```

¶23. `ACTION_NAME`. For those rare occasions where we need to identify the basic underlying action but none of the nouns, etc., thereto. At run-time, this stores as the I6 action number: e.g. `##Go` for the going action.

define `ACTION_NAME_TY 71`

¶24. `ACTIVITY`. Activities are also numbered, and this data type holds the identifying number of an activity. Names like "reading a command" evaluate to `ACTIVITY` constants, and the data type is mostly useful in order for the Standard Rules to define phrases which run activities.

`ACTIVITY` constant SPs have one `FORMLESS` reference: an `activity *` pointer to the activity.

define `ACTIVITY_TY 72`

¶25. `SCENE`. Scenes are similarly numbered and stored in their own data type: actually, they are for practical purposes a built-in enumeration type, as the `Types.i6t` specification shows.

`SCENE` constant SPs use the `index` to store the allocation ID number of the scene referred to. (That is, scenes are numbered upwards from 0 as they are created, and this is the number stored here. The first scene created, with number 0, is always the "Entire Game", defined in the Standard Rules: this furnishes us with a convenient default value.)

define `SCENE_TY 73`

¶26. `TABLE`, `TABLE_COLUMN`. Table names and table column names are both values at run-time. Tables are stored as their byte addresses in I6, table columns as code numbers in such a way that each different column name has its own number, regardless of the table it belongs to. (This is so that we can cross-reference between two tables, using a common column as a key.)

Constant `TABLE` and `TABLE_COLUMN` SPs each have one `FORMLESS` reference: a `table *` and `table_column *` pointer respectively.

define `TABLE_TY 74`
define `TABLE_COLUMN_TY 75`

¶27. `EQUATION`. And similarly for the name of an equation.

define `EQUATION_TY 76`

¶28. `RELATION`. The different relations can, again, be used as values at run time. This data type is the type of the parameter R in the phrase:

> To decide which object is next step via (R - abstract-relation) from (O1 - object) to (O2 - object): ...

(which is defined in the Standard Rules). Relation numbers are indexes to the table of relation information in the compiled I6 code.

Constant `RELATION` SPs have one `FORMLESS` reference: a `binary_predicate *` pointer.

define `RELATION_TY 77`

¶29. `UNDERSTANDING`. Again, no variables or properties have this type. It is used to refer to a token of parsing grammar for the I6 parser to handle, and needs to be a data type because literal text in double quotation marks must always result in a `VALUE` specification. The data type depends on context. When we parse grammar, text like "take [something]" comes out as `UNDERSTANDING`, whereas in other contexts it would be `TEXT_ROUTINE`. To make this flexibility possible, `UNDERSTANDING` needs to be a data type, not a family.

This type is also used in grammar tables, to hold the result of a grammar token. In that event there is one formless reference to a constant `UNDERSTANDING`: a `grammar_verb *` pointer.

define `UNDERSTANDING_TY 78`

¶30. `FIGURENAME`, `SOUNDNAME`. A resource ID number for a figure (i.e., a picture) or a sound effect in the eventual blorb, or for use in Glulx within the application.

define `FIGURENAME_TY 79`
define `SOUNDNAME_TY 80`

¶31. `EXTERNALFILE`. A `-->` array to a run-time data structure associated with an external file, read or written by the story file during play.

define `EXTERNALFILE_TY 81`

¶32. `TRUTH_STATE`. This is a boolean value type: it can have only two values at run-time, `true` and `false` in I6.

define `TRUTH_STATE_TY 82`

¶33. Group 3: Data types for block-sized values.

¶34. `INDEXED_TEXT`, added in August 2007, is the long-awaited flexible length, character-indexed string type, and was the first pointer-valued data type. See "Indexed Text.i6t" for details.

define `INDEXED_TEXT_TY 83`

¶35. `STORED_ACTION` is just what it says it is: a stored action, which can be tried later. Again, this is a pointer value; see "StoredAction.i6t".

define `STORED_ACTION_TY 84`

¶36. Strictly speaking there is no data type `LIST_OF`: it is a constructor, referring to the act of taking K and producing "list of K". But for many practical purposes we can treat it as a data type, since the block on the heap used to represent "list of K" is much the same whatever K is. See "Lists.i6t".

define `LIST_OF_TY 85`

¶37. The data type `INTERMEDIATE` is also fictitious: this is a different sort of composition.

define `INTERMEDIATE_TY 86`

¶38. And this is the starting point for the type interpreter to create further built-in types, of which there will only ever be few:

```
int next_Types_dot_i6_number = 87;
```

¶39. Now for the data types created by new kinds of value in the source text. These are given IDs from 100 upwards, as the following constant defines:

```
define BASE_OF_DATA_TYPE_IDS 100                    base value for KOVAs of new KOVs in the source text
define LOWEST_DESIGNED_TY (BASE_OF_DATA_TYPE_IDS)
define HIGHEST_DESIGNED_TY (next_free_data_type_ID-1)
define LOOP_OVER_DESIGNED_TYPE_IDS(var)
    for (var=LOWEST_DESIGNED_TY; var<=HIGHEST_DESIGNED_TY; var++)
define LOOP_OVER_DATA_TYPE_IDS(var)
    for (var=1; var<next_free_data_type_ID; var++)
        if (type_IDs_table[var].data_type_rules)
define LOOP_OVER_POSSIBLE_TYPE_IDS(var)
    for (var=1; var<next_free_data_type_ID; var++)
int next_free_data_type_ID = BASE_OF_DATA_TYPE_IDS;     next new kind of value gets this
```

¶40. The table. That gives us quite a mountain of type IDs, with various relationships between them. For instance, TEST_ACTION_SPC can only be used as a species ID, and only when subordinate to the family ID CONDITION_FMY. It turns out to be useful to record some details for each ID, which we do with the following structure.

```
typedef struct type_id_rules {
    int type_number;                                    the ID number which this structure describes
    int type_id_flags;                                  a bitmap of *_SPC flags for properties of species
    struct vocabulary_entry *parsing_name;              built-in types have one word names
    struct vocabulary_entry *parsing_plural;
    int word_ref1, word_ref2;                           but new kinds of value do not
    int plural_ref1, plural_ref2;
    char *source_name;                                  used in the debugging log: e.g. "NUMBER_TY"
    char *description;                                  used in Problem messages: e.g. "a number"
    char numerical_source_name[32];                     used to make a debugging log name
    int no_possible_specific_types;                     or 0 if not a family
    int main_type_for_which_this_is_specific;           or UNKNOWN if it isn't
    struct data_type_id_rules *data_type_rules;         or null if not a data type
    struct kind_of_value *kova_of_this;                 cached result of kova(T)
} type_id_rules;
```

The structure type_id_rules is shared with 7/kix.

¶41. SP contexts. Specifications are used right across Inform, but there are five main situations in which they turn up, as follows.

(1) As something which we expect to see when type-checking. For instance, if we are trying to match "award 5 points" against the definition of the phrase "award (N - a number) points", then the type we expect the middle word to have is `(G)VALUE_FMY/CONSTANT_SPC-NUMBER_TY`.

(2) As something we actually find when type-checking. For instance, the "5" is found as a `(A)VALUE_FMY/CONSTANT_SPC-NUMBER_`

(3) As a value or other construction to be compiled. For instance, the "5" found above would eventually be sent to `spec_compile` as a `(A)VALUE_FMY/CONSTANT_SPC-NUMBER_TY` specification.

(4) As an expression parsed when reading in the source text. Again, "5" is an example, but so is the entire phrase "award 5 points", which is parsed as a `(A)PHRASE_FMY/TO_PHRASE_SPC`.

(5) As the name of a type, which we parse when reading in a definition: for instance, "a number" would be parsed as a type and stored in a SP as `(G)VALUE_FMY/CONSTANT_SPC-NUMBER_TY`.

We define constants for these five contexts solely because, with type specifications being so complex, Inform takes the precaution of checking that they are correctly used: a precaution, that is, against bugs in Inform itself. We use these contexts to form bitmaps, so they are defined as powers of 2.

```
define NO_SPEC_CONTEXTS 8                    we store bitmaps of these in char (i.e. 8-bit) arrays
define TYPE_EXPECTED_SPCONTEXT 1
define TYPE_FOUND_SPCONTEXT 2
define COMPILED_SPCONTEXT 4
define PARSED_SPCONTEXT 8
define TYPE_PARSED_SPCONTEXT 16
```

¶42. Each SP has a pair of ID numbers attached: family and species. The following little structure is used to record in which contexts it is legal for a SP to exist with a given pair of ID numbers (M, S) attached.

```
typedef struct type_pair_rules {
    char legal_contexts;
    struct specification *observations[NO_SPEC_CONTEXTS];
} type_pair_rules;
```

The structure type_pair_rules is private to this section.

¶43. An even more minimal data structure, the need for which is explained below:

```
typedef struct single_integer {
    int the_integer;
} single_integer;
```

The structure single_integer is private to this section.

§**1. Starting up.** Early in Inform's run, we create the table, and populate it with details of the main and species IDs. We don't add the data type IDs yet, but we do signal the data type interpreter (see "Data Types.w") to get ready for that.

Altogether about 80 IDs – for main types, specific types and data types – are created in even the smallest run, and each new kind of value created by the source text adds another.

```
define INITIAL_ID_TABLE_SIZE 150          must be at least 50, to cover main and specific types
```

```
void make_type_IDs_table(void) {
    type_ID_enlarge_types_table(INITIAL_ID_TABLE_SIZE);
    type_ID_set_source_name(UNKNOWN, "UNKNOWN");
    type_ID_set_description(UNKNOWN, "something unknown");
    type_ID_permit_pair(UNKNOWN, UNKNOWN,
        PARSED_SPCONTEXT + TYPE_PARSED_SPCONTEXT + TYPE_FOUND_SPCONTEXT + COMPILED_SPCONTEXT);
    create_MATCHING_species();
    create_VALUE_species();
    create_STORAGE_species();
    create_CONDITION_species();
    create_COMMAND_species();
    data_type_initialise_type_interpreter();
}
```

The function make_type_IDs_table is invoked by a command in a `.i6t` template file.

§**2.** We want to store the table of details about type IDs as an array, not a linked list, for speed of access. But the size of this array has to increase as new type IDs are added – while main types and specific types are fixed, new data type IDs are added often, and we don't want to impose any upper limit on how many the user can make.

```
int extent_of_type_tables = 0;                                   call this number X
type_id_rules *type_IDs_table = NULL;                            1-dimensional array of X entries
type_pair_rules *table_of_observations = NULL;                   2-dimensional array of X^2 entries
```

§**3.** Accessing a two-dimensional array of a non-constant size means that we have to perform a calculation to look up the entry we want:

```
type_pair_rules *type_ID_pair_rules(int r, int s) {
    if (table_of_observations == NULL) internal_error("no table of observations");
    return &(table_of_observations[r*extent_of_type_tables + s]);
}
```

§**4.** So the table is dynamically allocated and expanded as need be, doubling in size whenever we break the bounds of the old one.

```
int type_ID_claim_new_ID(void) {
    if (next_free_data_type_ID >= extent_of_type_tables)
        type_ID_enlarge_types_table(2*extent_of_type_tables);
    return next_free_data_type_ID++;
}
```

The function type_ID_claim_new_ID is called from 7/data.

§5. Expanding the types table. The following enlarges the table, possibly from 0 entries (in which case the arrays are both NULL), possibly from an already positive size (in which case we migrate the existing entries to ensure their survival).

```
void type_ID_enlarge_types_table(int to_size) {
    int from_size = extent_of_type_tables;
    type_id_rules *tt;                                    the new larger type ID table
    type_pair_rules *tc;                                  the new larger table of observations
    ⟨Allocate new larger tables for the type IDs 6⟩;
    ⟨Transfer the contents of the existing tables to the new larger ones 7⟩;
    ⟨Initialise the new cells in the now-enlarged tables 8⟩;
    ⟨Free the memory holding the current type ID tables 9⟩;
    ⟨Make the new larger tables of type IDs the current ones 10⟩;
}
```

§6.

⟨Allocate new larger tables for the type IDs 6⟩ ≡

```
    if (to_size <= from_size)
        internal_error("type tables not increased in size");
    tt = (type_id_rules *)
        (I7_calloc(to_size, sizeof(type_id_rules), TYPE_TABLES_MREASON));
    tc = (type_pair_rules *)
        (I7_calloc(to_size*to_size, sizeof(type_pair_rules), TYPE_TABLES_MREASON));
```

This code is used in §5.

§7.

⟨Transfer the contents of the existing tables to the new larger ones 7⟩ ≡

```
    int i, j;
    for (i=0; i<from_size; i++)
        tt[i] = type_IDs_table[i];
    for (i=0; i<from_size; i++)
        for (j=0; j<from_size; j++)
            tc[i*to_size + j]
                = table_of_observations[i*from_size + j];
```

This code is used in §5.

§8.

⟨Initialise the new cells in the now-enlarged tables 8⟩ ≡

```
    int i, j;
    for (i=from_size; i<to_size; i++)
        type_ID_details_initialise(&(tt[i]), i);
    for (i=0; i<to_size; i++)
        for (j=0; j<to_size; j++)
            if ((i>=from_size) || (j>=from_size))
                tpr_initialise(&(tc[i*to_size + j]));
```

This code is used in §5.

§**9.** This is used when expanding the table, but not at the end of the run; our automatic memory manager takes care of deallocating the table then.

⟨Free the memory holding the current type ID tables 9⟩ ≡
```
    if (from_size > 0) {
        I7_free(type_IDs_table, TYPE_TABLES_MREASON);
        I7_free(table_of_observations, TYPE_TABLES_MREASON);
    }
```
This code is used in §5.

§**10.**

⟨Make the new larger tables of type IDs the current ones 10⟩ ≡
```
    type_IDs_table = tt;
    table_of_observations = tc;
    extent_of_type_tables = to_size;
```
This code is used in §5.

§**11.** Slots in the table are initialised (immediately after allocation) by the following:

```
void type_ID_details_initialise(type_id_rules *tidr, int i) {
    tidr->type_number = i;
    tidr->type_id_flags = 0;
    sprintf(tidr->numerical_source_name, "<type-%d>", i);
    tidr->source_name = tidr->numerical_source_name;
    tidr->description = "<a type which should not exist>";
    tidr->parsing_name = NULL;
    tidr->parsing_plural = NULL;
    tidr->word_ref1 = -1; tidr->word_ref2 = -1;
    tidr->plural_ref1 = -1; tidr->plural_ref2 = -1;
    tidr->no_possible_specific_types = 0;
    tidr->main_type_for_which_this_is_specific = UNKNOWN;
    tidr->data_type_rules = NULL;
    tidr->kova_of_this = NULL;
}
void tpr_initialise(type_pair_rules *tpr) {
    int i;
    tpr->legal_contexts = 0;
    for (i=0; i<NO_SPEC_CONTEXTS; i++) tpr->observations[i] = NULL;
}
```

§**12. Completing the built-in types.** Once the data type interpreter has finished creating data types from the template file `Types.i6t`, the built-in stock of type IDs is complete. (Other type IDs will probably arrive later as a result of the source text – by the built-in ones are done.)

That provides a useful opportunity to register single-word type names with the vocabulary banks so that they can be parsed in an efficient way.

```
void complete_type_IDs_table(void) {
    int i;
    for (i=0; i<extent_of_type_tables; i++) {
        if (type_IDs_table[i].parsing_name) {
            vocab_set_flags(type_IDs_table[i].parsing_name, BUILTINTYPE_MC);
            vocab_set_literal_number_value(type_IDs_table[i].parsing_name, i);
        }
        if (type_IDs_table[i].parsing_plural) {
            vocab_set_flags(type_IDs_table[i].parsing_plural, BUILTINTYPE_MC);
            vocab_set_literal_number_value(type_IDs_table[i].parsing_plural, i);
        }
    }
}
```

The function complete_type_IDs_table is invoked by a command in a `.i6t` template file.

§**13. Access to the table.** We can now assume that the table of type IDs exists, and we need to provide facilities to the rest of Inform, answering questions that anyone might have. Most basic of all:

```
int type_ID_exists(int t) {
    if ((t < 0) || (t >= next_free_data_type_ID)) return FALSE;
    return TRUE;
}
```

The function type_ID_exists is called from 7/spec.

§**14.** Note that `UNKNOWN` passes the `type_ID_is_family_ID` test, since it has exactly one possible species: `UNKNOWN`. Otherwise, the only cases which pass ought to be the `*_FMY` constants.

```
int type_ID_is_family_ID(int t) {
    if ((type_ID_exists(t)) && (type_IDs_table[t].no_possible_specific_types > 0))
        return TRUE;
    return FALSE;
}
```

The function type_ID_is_family_ID is called from 7/specv.

§**15.** Here `UNKNOWN` returns `UNKNOWN`, and otherwise t returns a value other than `UNKNOWN` if and only if it is a species ID.

```
int type_ID_get_family_of_species(int t) {
    if (type_ID_exists(t)) return type_IDs_table[t].main_type_for_which_this_is_specific;
    return UNKNOWN;
}
```

The function type_ID_get_family_of_species is called from 7/specv.

§**16.** The flags:

```
void type_ID_set_flag(int t, int f) {
    if (type_ID_exists(t)) type_IDs_table[t].type_id_flags |= f;
    else internal_error("tried to set type ID flags for nonexistent type ID");
}
int type_ID_test_flag(int t, int f) {
    if (type_ID_exists(t) == FALSE) return FALSE;
    if ((type_IDs_table[t].type_id_flags) & f) return TRUE;
    return FALSE;
}
```

The function type_ID_set_flag is called from 7/masp, 7/vasp, 7/stsp, 7/cosp and 7/cmsp.
The function type_ID_test_flag is called from 7/spec.

§**17. KOVA cache.** This is managed by the "Kinds of Value" section, and explained there.

```
kind_of_value **type_ID_get_kova_cache_location(int t) {
    if (type_ID_exists(t)) return &(type_IDs_table[t].kova_of_this);
    return NULL;
}
```

The function type_ID_get_kova_cache_location is called from 7/kov.

§**18. Source names.** Source names at first look like only internal conveniences. We want the debugging log to be legible and not to say what's going on in terms of ID numbers we would have to memorise, so we print text like `NUMBER_TY` rather than, oh, `68`. In fact, though, this is more than a debugging convenience, because certain I6 runtime activities need access to data type IDs too, and so we define them all as I6 constants with the same values in the I6 compiler run as they have now in the C run compiling NI. We also want to use them as constant names in the data type minilanguage, so we need to be able to convert back from source name to its ID number, too.

```
void log_data_type_ID(int id) {
    type_ID_write_source_name_to_file(dl, id);
}
void type_ID_write_source_name_to_file(OUTPUT_STREAM, int id) {
    if ((id <= 0) || (id >= next_free_data_type_ID)) {
        WRITE("ILLEGAL-SUBTYPE-%d", id);
    } else if (id == 1) WRITE("UNKNOWN");
    else WRITE("%s", type_IDs_table[id].source_name);
}
```

The function log_data_type_ID is called from 2/dl.
The function type_ID_write_source_name_to_file is called from 7/kov.

§**19.**

```
void type_ID_set_source_name(int id, char *d) {
    type_IDs_table[id].source_name = d;
}
char *type_ID_get_source_name(int id) {
    return type_IDs_table[id].source_name;
}
```

The function type_ID_set_source_name is called from 7/dti, 7/masp, 7/vasp, 7/stsp, 7/cosp and 7/cmsp.
The function type_ID_get_source_name is called from 7/kov and 9/rsdt.

§**20.** And logging:

```
void log_data_type_name(int t) {
    if (type_IDs_table[t].word_ref1 >= 0) {
        log_lowercase_dtid(t);
    } else {
        if (type_IDs_table[t].parsing_name != NULL)
            LOG("%s", vocab_get_exemplar(type_IDs_table[t].parsing_name, FALSE));
        else data_type_print_long_name(dl, t);
    }
}
```

The function log_data_type_name is called from 7/kov and 7/dim.

§**21.** Note that these routines assume that an invalid TSID can be detected by having a source name begin with an angle bracket: the one from `<type-N>` written in the initialisation code above.

```
int type_ID_get_ID_for_source_name(char *sn) {
    int t;
    for (t=1; t<next_free_data_type_ID; t++) {
        char *p = type_IDs_table[t].source_name;
        if ((p == NULL) || (p[0] == '<')) continue;
        if (strcmp(p, sn) == 0) return t;
    }
    return UNKNOWN;
}
void compile_I6_constants_for_typenames(OUTPUT_STREAM) {
    int t;
    for (t=1; t<next_free_data_type_ID; t++) {
        char *p = type_IDs_table[t].source_name;
        if (p[0] == '<') continue;
        if (t == UNKNOWN) WRITE("Constant UNKNOWN_TY = %d;\n", UNKNOWN);
        else WRITE("Constant %s = %d;\n", p, t);
    }
}
```

The function type_ID_get_ID_for_source_name is called from 7/dti and 12/cinv.
The function compile_I6_constants_for_typenames is invoked by a command in a `.i6t` template file.

§**22. The description of a type.** Each type ID has associated with it a textual description suitable for use in messages for the end user: so, not cryptic debugging-log-speak like `(G)STORAGE_FMY`, but text such as "a table entry".

```
void type_ID_set_description(int t, char *d) {
    type_IDs_table[t].description = d;
}
char *type_ID_get_description(int t) {
    return type_IDs_table[t].description;
}
```

The function type_ID_set_description is called from 7/dti, 7/masp, 7/vasp, 7/stsp, 7/cosp and 7/cmsp.
The function type_ID_get_description is called from 2/index and 7/kov.

§23. Single integers. This is a pretty foolish dodge. Registered excerpt meanings carry with them pointers to structures embodying their meanings. But for names of KOVs (see below) the only meaning we want is a single integer – because this acts as a key into the table of type IDs. It might seem more natural to register KOV names with a pointer to the table entry itself. But that's not safe, because the table moves around when being reallocated as the number of KOVs grows – this was discovered, er, empirically.

```
int sint_get(single_integer *sint) {
    if (sint == NULL) return 0;
    return sint->the_integer;
}
single_integer *sint_new(int t) {
    single_integer *sint = CREATE(single_integer);
    sint->the_integer = t;
    return sint;
}
```

The function sint_get is called from 5/candd.

§24. Names used in parsing. The type ID rules structure provides two alternative ways to specify the name of a type: as a word-range pair, used for types created in the main text, and as a single word, used for types built in. (Though the data type interpreter is able to make longer names if need be, the single word names are the most efficient to parse quickly, which is worth it for the commonly occurring type names.)

Because `type_ID_set_name` is used only when new KOVs are created in the source text, and none of the built-in types are made that way, any such textual name is registered with the `DESIGNED_TYPE_MC` meaning code. Because such names are registered with pointers to the relevant `type_id_rules` structure, whereas we want to deal with type IDs by their numbers, we need to provide a routine to translate back.

```
void type_ID_copy_name(int t, int *w1, int *w2) {
    *w1 = type_IDs_table[t].word_ref1;
    *w2 = type_IDs_table[t].word_ref2;
}
void type_ID_set_name(int t, int w1, int w2) {
    single_integer *sint = sint_new(t);
    type_IDs_table[t].word_ref1 = w1;
    type_IDs_table[t].word_ref2 = w2;
    register_excerpt_meaning(DESIGNED_TYPE_MC, 0, w1, w2,
        STORE_POINTER_single_integer(sint));
    make_plural_of(w1, w2, NULL);
    type_IDs_table[t].plural_ref1 = plw1;
    type_IDs_table[t].plural_ref2 = plw2;
    register_excerpt_meaning(DESIGNED_TYPE_MC, 0, plw1, plw2,
        STORE_POINTER_single_integer(sint));
}
vocabulary_entry *type_ID_get_singular_parsing_name(int t) {
    return type_IDs_table[t].parsing_name;
}
void type_ID_set_parsing_names(int t,
    vocabulary_entry *singular, vocabulary_entry *plural) {
    if (singular) type_IDs_table[t].parsing_name = singular;
    if (plural) type_IDs_table[t].parsing_plural = plural;
}
```

The function type_ID_copy_name is called from 2/index, 4/edoc, 7/kov and 7/data.
The function type_ID_set_name is called from 7/data.
The function type_ID_get_singular_parsing_name is called from 7/kov and 7/data.
The function type_ID_set_parsing_names is called from 7/dti, 7/stsp, 7/cosp and 7/cmsp.

§**25. Interface with data types.** Those IDs used to identify data types (in atomic KOVs) have far more information associated with them than main types or specific types have, but this information is stored in the form of a pointer to a structure managed in the "Data Types.w" section. Here we only manage the pointers connecting the type IDs table to these further structures.

```
int type_ID_is_data_type(int t) {
    if ((t<=0) || (t>=next_free_data_type_ID)) return FALSE;
    if (type_IDs_table[t].data_type_rules) return TRUE;
    return FALSE;
}
void type_ID_make_into_data_type(int t, data_type_id_rules *dtid) {
    if ((t<=0) || (t>=next_free_data_type_ID))
        internal_error("tried to register type id out of range");
    if (type_IDs_table[t].data_type_rules)
        internal_error("data type doubly registered");
    type_IDs_table[t].data_type_rules = dtid;
}
data_type_id_rules *type_ID_get_dtid(int t) {
    if ((t<=0) || (t>=next_free_data_type_ID)) internal_error("type id out of range");
    if (type_IDs_table[t].data_type_rules == NULL)
        internal_error("type id unregistered as data type");
    return type_IDs_table[t].data_type_rules;
}
data_type_id_rules *type_ID_get_dtid_or_null(int t) {
    if ((t<=0) || (t>=next_free_data_type_ID)) internal_error("type id out of range");
    return type_IDs_table[t].data_type_rules;
}
int type_ID_with_this_dtid(data_type_id_rules *dtid) {
    int t;
    if (dtid == NULL) internal_error("null dtid");
    for (t=1; t<next_free_data_type_ID; t++)
        if (type_IDs_table[t].data_type_rules == dtid)
            return t;
    return UNKNOWN;
}
```

The function type_ID_is_data_type is called from 5/candd, 7/kov and 7/specv.
The function type_ID_make_into_data_type is called from 7/data.
The function type_ID_get_dtid is called from 7/data.
The function type_ID_get_dtid_or_null is called from 7/data.
The function type_ID_with_this_dtid is called from 7/data.

§26. Checking SP invariants. NI contains detailed code to check that no improperly built SP lasts long inside it without an internal error being produced: so while the routines here have no practical effect on the work done by NI (and testing shows that they make no appreciable difference to speed), they do offer some assurance that many complex mechanisms in NI are at least getting some things right. Recall that there are a number of named contexts in which a SP can be used in NI: here, we give these names which can be used in any internal error messages which should turn up.

```
char *name_of_spec_context(int context) {
    switch(context) {
        case TYPE_EXPECTED_SPCONTEXT: return "type expected";
        case TYPE_FOUND_SPCONTEXT: return "type found";
        case COMPILED_SPCONTEXT: return "value compiled";
        case PARSED_SPCONTEXT: return "value parsed";
        case TYPE_PARSED_SPCONTEXT: return "type parsed";
        default: return "miscellaneous";
    }
}
void type_ID_permit_pair(int a, int b, int map) {
    type_ID_pair_rules(a, b)->legal_contexts = map;
    type_IDs_table[a].no_possible_specific_types++;
    type_IDs_table[b].main_type_for_which_this_is_specific = a;
}
```

The function type_ID_permit_pair is called from 7/masp, 7/vasp, 7/stsp, 7/cosp and 7/cmsp.

§**27.** "Observation" of a SP involves noting its first appearance, if any, and causing an internal error if it appears to be in the wrong place (or simply has an illegal pair of type IDs).

```
int observed_before = FALSE;
void type_ID_observe(specification *spec, int context) {
    int fmy = spec_get_family(spec), spc = spec_get_species(spec);
    int i, j, k, ix;
    ix=0; j=context; while (j != 1) { ix++; j = j/2; }
    if ((fmy <= 0) || (fmy >= 50) ||
        (spc <= 0) || (spc >= next_free_data_type_ID)) {
        LOG("Illegal type ID (context %d): %d/%d\n", context, fmy, spc);
        LOG("Error on: $X", spec);
        internal_error("type ID out of legal range");
    }
    if ((type_ID_pair_rules(fmy, spc)->legal_contexts
        & context) == 0) {
        LOG("SP ID combination illegal in context %s: %s/%s\n",
            name_of_spec_context(context),
            type_IDs_table[fmy].source_name,
            type_IDs_table[spc].source_name);
        LOG("Error on: $X (allows %04x)\n", spec,
            type_ID_pair_rules(fmy, spc)->legal_contexts);
        internal_error("Illegal SP ID combination");
    }
    if (observed_before == FALSE) {
        observed_before = TRUE;
        for (i=0; i<extent_of_type_tables; i++)
            for (j=0; j<extent_of_type_tables; j++)
```

```
                for (k=0; k<NO_SPEC_CONTEXTS; k++)
                    type_ID_pair_rules(i, j)->observations[k] = NULL;
    }
    type_ID_pair_rules(fmy, spc)->observations[ix] = spec;
}
```

The function type_ID_observe is called from 7/ttts, 7/cfsp and 7/tc.

§**28.** At the end of a run, we sometimes write a note about the specifications actually used into the debugging log. This is particularly useful if we need to find out whether certain combinations of family and species are ever observed in the wild, which we might do, for instance, with the following command:

```
intest.pl --compile-only --log=type-usage '--keep-log=SP used' all
```

...which concatenates the report from the following routine over all of the hundreds of test runs available. The resulting accumulated debugging log can then be passed through `sort`: alternatively, we could look for specific cases thus:

```
intest.pl --compile-only --log=type-usage '--keep-log=SP used: CONDITION' all
```

```
void report_pairs_observed(void) {
    int i, j, k, context;
    if (dl_this(TYPE_USAGE_DA) == FALSE) return;
    for (i=0; i<extent_of_type_tables; i++)
        for (j=0; j<extent_of_type_tables; j++)
            for (k=0, context=1; k<NO_SPEC_CONTEXTS; k++, context = context*2) {
                if (type_ID_pair_rules(i, j)->observations[k]) {
                    LOG("SP used: %s/%s in %s  ",
                        type_IDs_table[i].source_name,
                        type_IDs_table[j].source_name,
                        name_of_spec_context(context));
                    if ((type_ID_pair_rules(i, j)->legal_contexts
                        & context) == 0)
                        LOG("!!!!  ");
                    LOG("$S\n", type_ID_pair_rules(i, j)->observations[k]);
                }
            }
}
```

The function report_pairs_observed is invoked by a command in a `.i6t` template file.

§**29.** Similarly, we can write out a systematic picture of the legal type ID combinations into the debugging log.

```
void report_pairs_allowed(void) {
    int i, j;
    if (dl_this(TYPE_PERMISSIONS_DA) == FALSE) return;
    for (i=0; i<extent_of_type_tables; i++) {
        int flag = FALSE;
        for (j=0; j<extent_of_type_tables; j++)
            if (type_ID_pair_rules(i, j)->legal_contexts) {
                if (flag == FALSE) {
                    LOG("%s - family with specific types:\n",
                        type_IDs_table[i].source_name);
                    flag = TRUE;
                }
                LOG("    %s\n", type_IDs_table[j].source_name);
            }
        flag = FALSE;
        for (j=0; j<extent_of_type_tables; j++)
            if (type_ID_pair_rules(j, i)->legal_contexts) {
                if (flag == FALSE) {
                    LOG("%s - species of",
                        type_IDs_table[i].source_name);
                    flag = TRUE;
                }
                LOG(" %s", type_IDs_table[j].source_name);
            }
        if (flag) { LOG("\n"); }
    }
}
```

The function report_pairs_allowed is invoked by a command in a `.i6t` template file.

Kinds of Value 7/kov

Purpose

To manage the `kind_of_value` structure, representing the possible categories into which eventual I6 values can be placed; to determine which KOVs contain which others, and what their characteristics are.

Definitions

¶1. As we have seen, "type" is an enormous category inside Inform, taking in actual data as well as general descriptions of data, and actions and phrases as well as data. "Kind of value" is a much smaller category, and more like the idea of "type" in a C-like language.

The `kind_of_value` structure is always referred to by means of pointers, so that in practice a KOV is described inside Inform using a `kind_of_value *`. A `NULL` pointer means that the KOV is unknown. The structure pointed to unifies the four ways that KOVs are formed:

(i) Each data type ID, such as `NUMBER_TY`, makes an atomic KOV (a "KOVA"), such as "number".
(ii) Each kind of object, such as "vehicle", makes a KOVKO (a "KOV which is also a kind of object"). Note that "object" itself is a KOVA, not a KOVKO.
(iii) Each kind constructor, such as "list of", makes a new KOVCON out of existing ones: for instance "list of numbers".
(iv) Each intermediate result, partway through an arithmetic calculation, which can't be represented as a KOVA, is given a specially made KOVIV.

¶2. KOVs are static structures. Once created, their fields are never touched. It would be neat if there were exactly one KOV structure somewhere in memory for each different kind of value – and that is true for KOVAs and KOVKOs, but is not true for KOVCONs or KOVIVs, because it would be too much trouble to arrange. (In practice KOVCONs and KOVIVs are rarely needed, so even though they cause duplication, the amount of memory wasted is typically only about 2K.)

Therefore to see if two pointers `kov1` and `kov2` represent the same KOV, it's not good enough to test `kov1 == kov2`; we have to use the `kov_compare` routine.

define `MAX_KC_ARGS 1` *at present the kind constructors are unary*

```
typedef struct kind_of_value {
    int atomic_kov;
    struct world_object *atomic_kind;
    struct unit_sequence *intermediate_result;
    struct kind_of_value *kc_args[MAX_KC_ARGS];
} kind_of_value;
```

The structure kind_of_value is private to this section.

¶3. We keep track of the newest-created KOVA here, along with some statistics:

```
kind_of_value *latest_atomic_kov = NULL;
int no_kovas_created = 0;
int no_kovkos_created = 0;
int no_kovivs_created = 0;
int no_kovcons_created = 0;
```

---

§**1.** The four fundamental constructions. All KOV structures are obtained by one of the following. First, `kova(D)` returns the KOV for a value of data type ID `D`. This is something we need very often, so we create it only on the first request, and cache the pointer to it in the table of data about `D`; we can then use that same pointer on all subsequent requests.

Note that `kova(NUMBER_TY)` doesn't create the idea of "number", or bring the data type into existence, or anything like that: it simply returns a token which indicates that a number is meant rather than, say, a time.

```
kind_of_value *kova(int data_type_id) {
    if (data_type_id == UNKNOWN) internal_error("made unknown as atomic kova");
    kind_of_value **cache = type_ID_get_kova_cache_location(data_type_id);
    if (cache) { if (*cache) return *cache; }
    kind_of_value *kov;
    ⟨Create a raw KOV structure 5⟩;
    kov->atomic_kov = data_type_id;
    if (cache) *cache = kov;
    no_kovas_created++;
    return kov;
}
```

The function kova is called from 2/mem, 5/bp, 5/rel, 5/aph, 5/lit, 5/candd, 5/mlc, 6/simp, 6/tcpr, 6/asp, 6/cind, 7/data, 7/dim, 9/rsdt, 7/kix, 7/specv, 7/vasp, 7/stsp, 7/cmsp, 7/tc, 8/refpt, 8/creat, 8/mass, 8/knowp, 9/qty, 9/prop, 9/cmpbp, 10/qnbp, 10/list, 10/tab, 10/eqns, 10/libp, 10/bib, 11/act, 11/ap, 11/los, 11/av, 12/ph, 12/phtd, 12/phsf, 12/cinv, 13/gtok and 13/gprv.

§**2.** Second, `kovko(K)` returns the KOV for an object whose kind is `K`. Once again this is cached, so that each time we ask for `kovko(K)` for the same `K` we will get a pointer to the same structure.

```
kind_of_value *kovko(world_object *kind) {
    if (kind == NULL) internal_error("made null as atomic kovko");
    kind_of_value **cache = wo_get_kova_cache_location(kind);
    if (cache) { if (*cache) return *cache; }
    kind_of_value *kov;
    ⟨Create a raw KOV structure 5⟩;
    kov->atomic_kov = OBJECT_TY;
    kov->atomic_kind = kind;
    if (cache) *cache = kov;
    no_kovkos_created++;
    return kov;
}
```

The function kovko is called from 5/aph, 5/candd, 5/mlc, 6/aprop, 6/treec, 6/simp, 6/asp, 7/vasp, 7/tc, 8/creat, 8/mass, 9/mapbp, 9/pp, 10/list, 11/act, 11/av, 12/phtd, 12/stv and 12/rb.

§**3.** Third, `kovcon(C, K)` performs construction `C` on the existing kind of value `K` to produce a more elaborate one: for instance, `kovcon(LIST_OF_TY, kova(NUMBER_TY))` produces a KOV structure meaning "list of numbers". This is not cached anywhere, so a second request for the same thing will produce a different copy of the KOV, though with identical contents.

```
kind_of_value *kovcon(int constructor, kind_of_value *base) {
    kind_of_value *kov;
    ⟨Create a raw KOV structure 5⟩;
    kov->atomic_kov = constructor;
    kov->kc_args[0] = base;
    no_kovcons_created++;
    return kov;
}
```

The function kovcon is called from 5/candd and 10/list.

§**4.** Fourth, `koviv(US)` produces a KOV for the intermediate result given by the unit sequence US. Unit sequences are explained in "Dimensions", but for instance one might represent "area times pressure divided by velocity". Again, these are not cached.

```
kind_of_value *koviv(unit_sequence *ik) {
    if (ik == NULL) internal_error("made unknown as koviv");
    kind_of_value *kov;
    ⟨Create a raw KOV structure 5⟩;
    kov->atomic_kov = INTERMEDIATE_TY;
    kov->intermediate_result = CREATE(unit_sequence);
    *(kov->intermediate_result) = *ik;
    no_kovivs_created++;
    return kov;
}
```

The function koviv is called from 7/dim.

§**5.** These four constructions, and these four alone, have the power to create KOV structures, like so:

⟨Create a raw KOV structure 5⟩ ≡

```
    kov = CREATE(kind_of_value);
    kov->atomic_kov = UNKNOWN;
    kov->atomic_kind = NULL;
    kov->intermediate_result = NULL;
    int i;
    for (i=0; i<MAX_KC_ARGS; i++) kov->kc_args[i] = NULL;
```

This code is used in §1,2,3,4,1,2,3,4,1,2,3,4.

§**6. Comparison.** The following determines whether or not two KOV pointers represent the same kind of value.

```
int kov_compare(kind_of_value *k1, kind_of_value *k2) {
    int i;
    if (k1 == NULL) { if (k2 == NULL) return TRUE; return FALSE; }
    if (k2 == NULL) return FALSE;
    if (k1->atomic_kov != k2->atomic_kov) return FALSE;
    if (k1->atomic_kind != k2->atomic_kind) return FALSE;
    if ((k1->intermediate_result) && (k2->intermediate_result == NULL)) return FALSE;
    if ((k1->intermediate_result == NULL) && (k2->intermediate_result)) return FALSE;
    if ((k1->intermediate_result) &&
        (compare_unit_sequences(k1->intermediate_result, k2->intermediate_result)
            == FALSE)) return FALSE;
    for (i=0; i<MAX_KC_ARGS; i++)
        if (kov_compare(k1->kc_args[i], k2->kc_args[i]) == FALSE)
            return FALSE;
    return TRUE;
}
```

The function kov_compare is called from 5/aph, 5/litp, 7/dim, 9/rsdt, 7/kix, 7/vasp, 8/mass, 9/qty, 9/prop, 9/pp, 9/inf, 10/tab, 10/eqns, 11/ap and 12/cinv.

§**7. Quicker tests.** Three short forms. Firstly, if `D` is a data type other than `OBJECT_TY` then `is_kova(K, D)` is a quick way to test `kov_compare(K, kova(D))`, a test we need to perform often.

```
int is_kova(kind_of_value *kov, int data_type_id) {
    if (kov == NULL) return FALSE;
    if (kov->atomic_kov == data_type_id) return TRUE;
    return FALSE;
}
```

The function is_kova is called from 2/prob2, 4/iext, 5/rel, 5/aph, 5/lit, 5/tandv, 6/treec, 6/simp, 6/tcpr, 6/equal, 6/asp, 6/defer, 7/dim, 7/specv, 7/vasp, 7/stsp, 7/cmsp, 7/tc, 8/refpt, 8/creat, 8/mass, 9/qty, 9/prop, 9/pp, 9/provr, 9/inf, 10/list, 10/tab, 10/eqns, 10/bib, 10/fig, 10/sfx, 10/isin, 11/act, 11/ap, 11/av, 12/phud, 12/phtd, 12/cinv, 12/rb, 13/tfg, 13/gl, 13/gtok and 13/gprv.

§**8.** Now in principle `kova(D)` can be created for any type ID `D`, and not just data types, though this will generally only happen when problems have occurred. A careful test of a genuine KOVA, in such tricky cases, can be performed like this:

```
int kov_represents_data(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    if (kov->atomic_kind) return TRUE;
    if (data_type_is_constructor(kov->atomic_kov)) return TRUE;
    if (type_ID_is_data_type(kov->atomic_kov)) return TRUE;
    return FALSE;
}
```

The function kov_represents_data is called from 8/creat.

§**9.** `K` is a KOVKO if and only if `kovko_get_kind(K)` returns a non-`NULL` pointer. Note that `is_kova(K, OBJECT_TY)` is not quite enough, because `kova(OBJECT_TY)`, representing the KOV "object", is strictly speaking a KOVA and not a KOVKO.

```
world_object *kovko_get_kind(kind_of_value *kov) {
    if (kov == NULL) return NULL;
    if (kov->atomic_kov != OBJECT_TY) return NULL;
    return kov->atomic_kind;
}
```

The function kovko_get_kind is called from 2/index, 2/prob2, 5/aph, 6/aprop, 6/vars, 6/treec, 6/simp, 6/asp, 6/atoms, 8/knowp, 9/model and 10/list.

§**10.** KOVCONs are easy to detect:

```
int is_kovcon(kind_of_value *kov) {
    if ((kov) && (data_type_is_constructor(kov->atomic_kov))) return TRUE;
    return FALSE;
}
```

The function is_kovcon is called from 7/dim, 7/vasp, 7/tc, 10/tab and 11/act.

§**11.** Given, say, "list of numbers", the following returns "number"...

```
kind_of_value *kovcon_get_base(kind_of_value *kov) {
    if (kov == NULL) return NULL;
    return kov->kc_args[0];
}
```

The function kovcon_get_base is called from 7/stsp, 7/tc, 10/tab and 12/cinv.

§**12.** ...and the following returns `LIST_OF_TY`:

```
int kov_I6_construct_ID(kind_of_value *kov) {
    if (kov == NULL) return 0;
    if (data_type_is_constructor(kov->atomic_kov) == FALSE) return 0;
    return kov_I6_ID(kov->kc_args[0]);
}
```

The function kov_I6_construct_ID is called from 9/rsdt and 10/tab.

§**13. Weaker integer representations of a KOV.** Sometimes a KOV has to be stored as an I6 integer value at run-time. I6 is typeless, so some of the routines and data structures in the I6 template need these integer values to tell them what they are looking at. For instance, the `ActionData` table records the KOVs of the noun and second noun to which an action applies.

Clearly a single 16-bit integer can't faithfully represent the full range of KOVs. We could get closer to this if we used a trick like the one attributed to Ritchie and Johnson in chapter 6.3 of the Dragon book (Aho, Sethi and Ullman, *Compilers*, 1986), where lower bits of a word store `atomic_kov` for the underlying data and upper bits record KOV constructors applied to this.

But it turns out to be more fruitful to store the `atomic_kov`, thus recording a deliberately weaker version of the KOV. Any two lists look the same, because at run-time each is stored as `LIST_OF_TY`. All KOVKOs look the same – they all merge together as `OBJECT_TY`. This is positively useful, because –

Dogma. If a value v has KOV K, and we want to use it as a value of KOV W, and they are not KOVIVs, then

(a) if the `kov_I6_ID` of K is different from that of W then this is impossible;
(b) if the `kov_I6_ID` of K is the same as that of W then run-time code can tell from v alone whether this is possible.

For instance, if we know that the `kov_I6_ID` of v is `OBJECT_TY` then we can tell if it's a "vehicle" or not by testing the I6 condition `(v ofclass K27_vehicle)`. And if v is a `LIST_OF_TY` then it points to a block of data on the stack which includes the `kov_I6_ID` of the entries in the list.

It does not matter that KOVIVs do not conform to Dogma, because they are made to order, and are never assigned to storage objects like variables. That's what makes them intermediate.

```
int kov_I6_ID(kind_of_value *kov) {
    if (kov == NULL) return UNKNOWN;
    return kov->atomic_kov;
}
```

The function kov_I6_ID is called from 5/aph, 6/sch, 9/rsdt, 7/stsp, 9/qty, 9/prop, 10/list, 10/tab, 11/act, 12/cinv and 13/gprv.

§**14. Dimensions and scaling.** In theory, our polymorphic system of arithmetic allows us to add, multiply, etc., any KOVs according to rules provided in the source text. In fact, though, this only applies to atomic data types, and the dimensions system uses the following routine to pierce through the veil of the KOV and see the data type beneath. (Returning `UNKNOWN` implies that arithmetic cannot legally be applied to this KOV.) See "Dimensions" for much more on this.

```
int kov_get_dimensional_data_type(kind_of_value *kov) {
    if (kov == NULL) return UNKNOWN;
    return kov->atomic_kov;
}
int kov_is_dimensionless(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_dimensionless(kov->atomic_kov);
}
unit_sequence *kov_get_dimensional_form(kind_of_value *kov) {
    if (kov == NULL) return NULL;
    if (kov_quasinumerical(kov) == FALSE) return NULL;
    if (kov->atomic_kov == INTERMEDIATE_TY)
        return kov->intermediate_result;
    return data_type_get_unit_sequence(kov->atomic_kov);
}
int kov_scale_factor(kind_of_value *kov) {
    if (kov == NULL) return 1;
```

```
    if (kov->intermediate_result) return us_get_scaling_factor(kov->intermediate_result);
    return data_type_scale_factor(kov->atomic_kov);
}
```

The function kov_get_dimensional_data_type is called from 7/dim.
The function kov_is_dimensionless is called from 7/dim and 10/eqns.
The function kov_get_dimensional_form is called from 7/dim.
The function kov_scale_factor is called from 7/dim and 13/test.

§**15. Compiling default values.** When we create a new variable of a given KOV, but never say what its value is to be, Inform initialises it to the default value for that KOV, and similarly for other storage objects.

The following should compile a default value for K, and return
(a) `TRUE` if it succeeded,
(b) `FALSE` if it failed (because K had no values or no default could be chosen), and no problem message has been issued about this, or
(c) `NOT_APPLICABLE` if it failed and issued a specific problem message.

```
int compile_default_value(OUTPUT_STREAM, kind_of_value *kov,
    int w1, int w2, char *storage_name) {
    if (kov_get_default_value_of_type(kov)) {
        WRITE("%s\n", kov_get_default_value_of_type(kov));
        return TRUE;
    }
    we need to issue a problem message: try to find an appropriate one –
    if (kovko_get_kind(kov))
        ⟨The kind must have no instances, or it would have worked 16⟩;
    if (is_kova(kov, ANY_VALUE_TY))
        ⟨"Value" is too vague to be the kind of a variable 17⟩;
    if (kov_can_be_stored_in_variables(kov) == FALSE)
        ⟨This is a KOV not intended for end users at all 18⟩;
    – but failing that, we leave it up to the caller to say something
    return FALSE;
}
```

The function compile_default_value is called from 9/rsdt, 9/qty, 9/pp, 10/tab, 12/phtd and 12/cinv.

§**16.**

⟨The kind must have no instances, or it would have worked 16⟩ ≡

```
    quote_words(1, w1, w2);
    quote_object(2, kovko_get_kind(kov));
    quote_text(3, storage_name);
    handmade_problem(_P_(C7EmptyKind));
    issue_problem_segment(
        "I am unable to put any value into the %3 '%1', "
        "which needs to be a %2, because there is no %2 in the world.");
    issue_problem_end();
    return NOT_APPLICABLE;
```

This code is used in §15.

§17.

⟨"Value" is too vague to be the kind of a variable 17⟩ ≡

```
quote_words(1, w1, w2);
handmade_problem(_P_(C7KindlessValue));
issue_problem_segment(
    "I am unable to start '%1' off with any value, because the "
    "instructions do not tell me what kind of value it should be "
    "(a number, a time, some text perhaps?).");
issue_problem_end();
return NOT_APPLICABLE;
```

This code is used in §15.

§18.

⟨This is a KOV not intended for end users at all 18⟩ ≡

```
quote_words(1, w1, w2);
quote_kov(2, kov);
handmade_problem(_P_(C7BadVarKind));
issue_problem_segment(
    "I am unable to create '%1' with the kind of value '%2', "
    "because this is a kind of value which is not allowed as "
    "something to be stored in properties, variables and the "
    "like. (See the Kinds index for which kinds of value "
    "are available. The ones which aren't available are really "
    "for internal use by Inform.)");
issue_problem_end();
return NOT_APPLICABLE;
```

This code is used in §15.

§19. **Logging KOVs.** As always, we want a way of representing this fundamental data structure in the debugging log:

```
void log_kind_of_value(kind_of_value *kov) {
    int i;
    if (kov == NULL) LOG("NULL-KOV");
    else {
        if (kov->atomic_kind) {
            LOG("$O", kov->atomic_kind);
        } else if (kov->intermediate_result) {
            LOG("["); log_unit_sequence(kov->intermediate_result); LOG("]");
        } else {
            log_data_type_name(kov->atomic_kov);
        }
        if (!(logging_to_I6_text)) LOG("-KOV");
        if ((kov->atomic_kov) && (data_type_is_constructor(kov->atomic_kov)))
            for (i=0; i<MAX_KC_ARGS; i++)
                LOG("($u)", kov->kc_args[i]);
    }
}
```

The function log_kind_of_value is called from 2/dl, 9/prop and 13/test.

§**20. Creating new KOVAs.** The following is called in response to sentences like "Texture is a kind of value", and allocates a new data type ID for the new name ("texture").

```
kind_of_value *make_new_atomic_kind_of_value(int w1, int w2) {
    PROTECTED_MODEL_PROCEDURE;
    int d = new_data_type(w1, w2);
    if (d < 0) return NULL;
    latest_atomic_kov = kova(d);
    return kova(d);
}
```

The function make_new_atomic_kind_of_value is called from 6/asp.

§**21. Wrapper routines.** The whole of the rest of this section consists of routines which answer questions about KOVs.

These almost always have the form:

```
int kov_silly_question(kind_of_value *kov) {
    handle the NULL case somehow
    do something interesting to handle KOVKOs if the kind of object matters
    return data_type_silly_question(kov->atomic_kov);
}
```

Very often the question is such that the same answer applies to all KOVKOs, so that nothing needs to be done in that case.

§**22. Questions about origin.** Some KOVs are built in (in that the template file "Types.i6t" creates them, using the type interpreter), while others arise from "X is a kind of value" sentences in the source text.

Note that a KOVKO counts as built-in by this test, even though it might be a kind of object created in the source text, because at the end of the day "object" is built in.

```
int kov_is_built_in(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_is_built_in(kov->atomic_kov);
}
```

The function kov_is_built_in is called from 5/litp and 10/tab.

§**23.** A few types support modifying adjectives when created. These adjectives are created in "Types.i6t" file, and parsed here; in an ideal world there would be none of them, and we would simply use ordinary Inform adjectives.

```
int kov_parse_modifying_adjectives(kind_of_value *kov, int w1, int w2) {
    if (kov == NULL) return -1;
    return data_type_parse_modifying_adjectives(kov->atomic_kov, w1, w2);
}
```

The function kov_parse_modifying_adjectives is called from 8/refpt.

§**24. Questions about constants and notation.** Some KOVs have named constants, others use a quasi-numerical notation: for instance "maroon" might be a named constant for KOV "colour", while "234 kilopascals" might be a notation for a KOV where constants are not named.

```
int kov_has_named_constant_values(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_has_named_constant_values(kov->atomic_kov);
}
```

The function kov_has_named_constant_values is called from 5/rel, 8/creat and 9/qty.

§**25.** The following returns the compilation method (a constant in the form `*_CCM`, defined in "Data Types.w") used when compiling an `(A)VALUE/CONSTANT` specification of this KOV: in other words, when compiling an I6 value for a constant of this kind.

```
int kov_get_constant_compilation_method(kind_of_value *kov) {
    if (kov == NULL) return NONE_CCM;
    return data_type_get_constant_compilation_method(kov->atomic_kov);
}
```

The function kov_get_constant_compilation_method is called from 7/vasp.

§**26.** On reading "5 feet 4 inches specifies a height", Inform parses "5 feet 4 inches" into a `literal_pattern` structure and then calls this routine to attach it to the KOV "height". (Multiple patterns can be attached to the same KOV, and they become alternative syntaxes.)

```
void kov_add_literal_pattern(kind_of_value *kov, literal_pattern *lp) {
    if (kov == NULL) internal_error("can't add LP to null KOV");
    data_type_add_literal_form(kov->atomic_kov, lp);
}
```

The function kov_add_literal_pattern is called from 5/litp.

§**27.** And here we find the list of such notations.

```
literal_pattern *kov_list_of_literal_forms(kind_of_value *kov) {
    if (kov == NULL) return NULL;
    return data_type_list_of_literal_forms(kov->atomic_kov);
}
```

The function kov_list_of_literal_forms is called from 5/litp, 9/rsdt and 7/kix.

§**28. Questions about range and behaviour.** Unsigned comparisons are slower in the VM we're compiling for, so we use them only if we have to.

```
int kov_uses_signed_comparisons(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_uses_signed_comparisons(kov->atomic_kov);
}
```

The function kov_uses_signed_comparisons is called from 10/tab.

§**29.** See "Dimensions":

```
int kov_quasinumerical(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_is_quasinumerical(kov->atomic_kov);
}
```

The function kov_quasinumerical is called from 7/dim, 7/kix, 10/eqns and 13/test.

§**30.** See "Tables.i6t"; the issue is whether the value `IMPROBABLE_VALUE` can, despite its improbability, be valid for this KOV. If we can prove that it is not, we should return `FALSE`; if in any doubt, we must return `TRUE`.

```
int kov_requires_blanks_bitmap(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_requires_blanks_bitmap(kov->atomic_kov);
}
```

The function kov_requires_blanks_bitmap is called from 10/tab.

§**31.** The following is used only when the KOV has named constant values.

```
int kov_get_highest_valid_value_as_integer(kind_of_value *kov) {
    if (kov == NULL) return 0;
    return data_type_get_highest_valid_value_as_integer(kov->atomic_kov);
}
```

The function kov_get_highest_valid_value_as_integer is called from 5/rel and 9/rsdt.

§**32.** Is a variable allowed to have this KOV?

```
int kov_can_be_stored_in_variables(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_can_be_stored_in_variables(kov->atomic_kov);
}
```

The function kov_can_be_stored_in_variables is called from 7/kix and 12/phtd.

§**33.** Because of the way "let" variables are ambiguously defined – by initial value rather than by an explicit type description – it is not always clear what their KOV should be. When Inform reads:

```
let X be "look, it's [time of day]";
```

it sees that the initial value of X is a `kova(TEXT_ROUTINE_TY)`, but this is not permitted as the type of a "let" variable: it is upgraded to the more general `kova(TEXT_TY)`. The following routine takes the KOV K_I of the initial value and returns K_V, a suitable KOV for the "let" variable, or else `NULL` to say that the value cannot be stored in a "let". Provided K_V is not null, we always have $K_I \subseteq K_V$, so it is certain to be safe to store the initial value in the variable that results.

```
kind_of_value *kov_for_storage_to_hold(kind_of_value *kov) {
    int d;
    if (kov == NULL) return NULL;
    if (data_type_is_constructor(kov->atomic_kov)) return kov;
    if (kov->atomic_kov == INTERMEDIATE_TY) return kov;
    d = data_type_for_storage_to_hold(kov->atomic_kov);
    if (d == UNKNOWN) return NULL;
    return kova(d);
}
```

The function kov_for_storage_to_hold is called from 7/tc.

§**34. Questions about the default value.** This returns either valid I6 code for the value which is the default for K, or else `NULL` if K has no values, or no default can be chosen.

```
char *kov_get_default_value_of_type(kind_of_value *kov) {
    if (kov == NULL) return NULL;
    if (kovko_get_kind(kov)) {
        world_object *wo, *kind_wo = kovko_get_kind(kov);
        LOOP_OVER(wo, world_object)
            if ((wo_of_kind(wo, kind_wo)) && (wo->kind_flag == FALSE))
                return wo_get_I6_representation(wo);
        if (kind_wo == kind_room)                    for roomless texts used to rerelease I6 story files
            return "nothing";
        return NULL;
    }
    if (kov_uses_pointer_values(kov)) return "0";          meaning: not allocated on heap yet
    if (kov_is_an_enumeration(kov)) {
        quantity *q2;
        LOOP_OVER(q2, quantity)
            if ((kov_compare(qty_kind_of_value(q2), kov))
                && (qty_is_a_variable(q2) == FALSE))
                return qty_get_I6_representation(q2);
        return NULL;
    }
    return data_type_get_default_value_of_type(kov->atomic_kov);
}
```

§**35.** The following is used in the Kinds index, in the table showing the default values for each kind:

```
char *kov_get_index_default_value(kind_of_value *kov) {
    if (kov == NULL) return NULL;
    return data_type_get_index_default_value(kov->atomic_kov);
}
```

The function kov_get_index_default_value is called from 7/kix.

§**36. Questions about quantification.** Some KOVs are such that all legal values can efficiently be looped through at run-time, some are not: we can sensibly loop over all scenes, but not over all texts. We use the term "domain" to mean the set of values which a loop traverses.

```
int kov_compile_domain_possible(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    if (kovko_get_kind(kov)) return TRUE;
    return data_type_compile_domain_possible(kov->atomic_kov);
}
```

The function kov_compile_domain_possible is called from 6/defer and 7/kix.

§**37.** If the domain is a KOVKO, say "things", then we use a linked list compiled into the object tree for exactly this purpose. The list starts with the constant `IK2_First` (2 being the kind number for "things" in the usual arrangement), and then each instance of a thing has a property `IK2_Link` whose value is the next thing; this is `nothing` for the last in the list.

If it happens that no instances exist – unlikely for things, but often true of more unusual kinds – then a loop header which never executes the block following it is compiled.

If the domain `kov` is not a KOVKO, then we loop through the known constants which make up this kind of value; each KOV is allowed to provide its own loop syntax for this. For "time", for instance, it becomes a `for` loop running from 0 (midnight) to 1439 (one minute to midnight).

In all cases, we copy a valid schema to `sch` if the loop can be made, and return `TRUE` or `FALSE` to indicate success.

```
int kov_write_loop_schema(i6_schema *sch, kind_of_value *kov, int use_ix) {
    if (kov == NULL) return FALSE;
    world_object *k = kovko_get_kind(kov);
    if (k) {
        if (k->instance_list_length == 0)
            sch_write_to_existing(sch,
                "for (*1=nothing: false: )");
        else
            sch_write_to_existing_2d(sch,
                "for (*1=IK%d_First: *1: *1=*1.IK%d_Link)",
                k->allocation_id, k->allocation_id);
        return TRUE;
    }
    return data_type_write_loop_schema(sch, kov->atomic_kov, use_ix);
}
```

The function kov_write_loop_schema is called from 6/cdefp and 12/cinv.

§**38. Questions about run-time storage.** Recall that values are stored at run-time either as "word values" – a single I6 word – or "pointer values" (sometimes "block values"), where the I6 word is a pointer to a block of data on the heap. Numbers and times are word values, indexed texts (i.e., editable strings) are pointer values. Which form a value takes depends on its KOV:

```
int kov_uses_pointer_values(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_uses_pointer_values(kov->atomic_kov);
}
```

The function kov_uses_pointer_values is called from 9/rsdt, 7/cfsp, 7/vasp, 7/tc, 9/prop, 10/tab, 12/phsf, 12/stv and 12/cinv.

§**39.** A reasonable estimate of how large the heap block needs to be, for a pointer-value KOV, in bytes.

```
int kov_get_heap_size_estimate(kind_of_value *kov) {
    if (kov == NULL) return 0;
    return data_type_get_heap_size_estimate(kov->atomic_kov);
}
```

The function kov_get_heap_size_estimate is called from 9/rsdt.

§**40.** Some pointer-value KOVs have literal constants in the source text – lists, for instance. Others do not, because they accept their constants by casts from word values (indexed text, for instance, since any quoted matter written in the source is parsed as text – a word value).

```
int kov_has_pointer_value_constants(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_has_pointer_value_constants(kov->atomic_kov);
}
```

The function kov_has_pointer_value_constants is called from 9/rsdt and 9/prop.

§**41.** The following decides whether word-values of kind R can be cast into pointer-values of kind L – for instance, text values can be cast into indexed text, but rulebooks can't.

```
int kov_allow_word_as_pointer(kind_of_value *left, kind_of_value *right) {
    if ((left == NULL) || (right == NULL)) return FALSE;
    return data_type_allow_word_as_pointer(left->atomic_kov, right->atomic_kov);
}
```

The function kov_allow_word_as_pointer is called from 12/cinv.

§**42. Questions about copying and comparing.** For most word-value KOVs, it's easy to compare two values to see if they are equal: all we need is the `==` operator. But for pointer-value KOVs, that would simply tell us whether they point to the same block of data on the heap, whereas we need in fact to compare the blocks they point to. So the KOV system makes it possible for each individual KOV to decide how values should be compared, returning an I6 schema prototype to compare `*1` and `*2`.

```
char *kov_interpret_test_equality(kind_of_value *left, kind_of_value *right) {
    if ((left == NULL) || (right == NULL))
        return data_type_interpret_test_equality(UNKNOWN, UNKNOWN);
    return data_type_interpret_test_equality(left->atomic_kov, right->atomic_kov);
}
char *kov_interpret_store(int storage_class, kind_of_value *left, kind_of_value *right) {
    if ((left == NULL) || (right == NULL))
        return data_type_interpret_store(storage_class, UNKNOWN, UNKNOWN);
    return data_type_interpret_store(storage_class, left->atomic_kov, right->atomic_kov);
}
```

The function kov_interpret_test_equality is called from 6/equal.
The function kov_interpret_store is called from 6/equal and 12/cinv.

§**43.** And the following returns the name of an I6 routine to determine if two values of K are different from each other; or `NULL` to say that it's sufficient to apply `~=` to the values.

```
char *kov_get_distinguisher(kind_of_value *kov) {
    if (kov == NULL) return NULL;
    return data_type_get_distinguisher(kov->atomic_kov);
}
```

The function kov_get_distinguisher is called from 13/gpr.

§**44.** Can values of this KOV be serialised out to a file and read back in again?

```
int kov_can_exchange(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_can_exchange(kov->atomic_kov);
}
```

The function kov_can_exchange is called from 10/tab.

§**45. Questions about implicit casting.** Just one question, really. If K_F and K_T are kinds of value, what values do they have in common? `can_we_cast_kovs` returns

(a) `ALWAYS_MATCH` if $K_F \subseteq K_T$,
(b) `SOMETIMES_MATCH` if $K_F \supseteq K_T$, or
(c) `NEVER_MATCH` if $K_F \cap K_T = \emptyset$.

That exhausts the possibilities: the hierarchy of kinds is not a lattice, and if two kinds overlap at all then one must be a specialisation of the other.

"Casting" is using a value of one kind where another is expected – for instance, in C, writing `N = 'x';` where `N` is an integer variable. This is an implicit cast because no explicit conversion is requested: `N = (int) 'x';` would be explicit. Inform only has implicit casts; casting is always possible when $K_F \subseteq K_T$, sometimes possible when $K_T \subseteq K_F$, never possible when $K_F \cap K_T = \emptyset$.

To put this still a third way, we call `can_we_cast_kovs` when we believe we have data of a given data type (`from` below), and want to know if it is safe to use in I6 code where data of type `to` is expected. There are three possible answers: yes, no or yes but only subject to run-time checking.

The outer routine is just a logging mechanism for the real routine. Cases where $K_F = K_T$ are frequent and not interesting enough to be logged.

```
int can_we_cast_kovs(kind_of_value *from, kind_of_value *to) {
    if (kov_compare(from, to)) return ALWAYS_MATCH;
    LOGIF(TYPE_CASTS, "(Can we cast from $u to $u?", from, to);
    switch(can_we_cast_kovs_inner(to, from)) {
        case NEVER_MATCH: LOGIF(TYPE_CASTS, " No)\n"); return NEVER_MATCH;
        case ALWAYS_MATCH: LOGIF(TYPE_CASTS, " Yes)\n"); return ALWAYS_MATCH;
        case SOMETIMES_MATCH: LOGIF(TYPE_CASTS, " Sometimes)\n"); return SOMETIMES_MATCH;
    }
    internal_error("bad return value from can_we_cast_kovs"); return NEVER_MATCH;
}
```

The function can_we_cast_kovs is called from 5/aph, 6/simp, 6/tcpr, 6/equal, 7/cmsp, 7/tc, 8/mass, 8/knowp, 9/mapbp, 9/prop, 9/madj, 9/cmpbp, 9/vpbp, 10/qnbp, 10/list, 10/tab, 11/act and 12/phtd.

§**46.** KOV marker variables are special tricks used when matching phrase prototypes like this one:

> To add (N - value = kov reference 1) to (L - list of values = list of kov marker 1) ...

This matches "add 23 to L" if "L" is a list of numbers, but not if it is a list of times; that is, "N" can be any value, but "L" has to be a list of whatever kind of value "N" has. Clearly we can only achieve this if the KOVs noticed while checking "N" are still remembered somehow while checking "L", but we also don't want to assume anything about the order in which "N" and "L" occur in the prototype. So in fact we check phrase prototypes twice, in what we call pass 1 and then pass 2, and the KOVs we need to remember during this process are stored in "marker variables".

Phrase prototype matching isn't recursive, so we only need one set of KOV marker variables inside Inform. In fact at present "Types.i6t" uses only two at a time, so this is plenty:

```
define MAX_KOV_MARKERS 8

kind_of_value *kov_marker_variables[MAX_KOV_MARKERS];
int prototype_checking_pass = 0;
```

§**47.** With that background covered, here is the main routine:

```
int can_we_cast_kovs_inner(kind_of_value *to, kind_of_value *from) {
    if ((to == NULL) || (from == NULL)) return NEVER_MATCH;
    if (data_type_template_variable_number(to->atomic_kov) != 0)
        ⟨Deal separately with matches against template variables 50⟩;
    if (from->atomic_kov == NO_ENTRIES_TY) return ALWAYS_MATCH;
    if ((to->atomic_kov == OBJECT_TY) && (from->atomic_kov == OBJECT_TY))
        ⟨Deal separately with casting within the objects hierarchy 48⟩;
    if (data_type_is_constructor(to->atomic_kov))
        ⟨Deal separately with constructions 49⟩;
    return data_type_allow_cast(to->atomic_kov, from->atomic_kov);
}
```

§**48.** Here both our KOVs are `OBJECT_TY`. In each case either `atomic_kind` is set, and then we are dealing with a subset of the objects (say, all the vehicles), or it is `NULL` and we are dealing with the set of all objects.

⟨Deal separately with casting within the objects hierarchy 48⟩ ≡

```
    world_object *to_kind = to->atomic_kind, *from_kind = from->atomic_kind;
    if (from_kind == to_kind) return ALWAYS_MATCH;
    if (to_kind == NULL) return ALWAYS_MATCH;
    if (from_kind == NULL) return SOMETIMES_MATCH;
    if (wo_of_kind(from_kind, to_kind)) return ALWAYS_MATCH;
    if (wo_of_kind(to_kind, from_kind)) return SOMETIMES_MATCH;
    return NEVER_MATCH;
```

This code is used in §47.

§**49.** In general we are pretty strict with constructions. If $K_F \subseteq K_T$ then we will allow "list of K_F" to cast to "list of K_T", but we won't allow any "sometimes" outcomes: so a list of objects will not be allowed at the sometimes level to cast to a list of vehicles (say), even though sufficiently clever run-time code might be able to police this.

⟨Deal separately with constructions 49⟩ ≡

```
    int i;
    if (from->atomic_kov != to->atomic_kov) return NEVER_MATCH;
    for (i=0; i<MAX_KC_ARGS; i++)
        if (can_we_cast_kovs_inner(to->kc_args[i], from->kc_args[i]) != ALWAYS_MATCH)
            return NEVER_MATCH;
    return ALWAYS_MATCH;
```

This code is used in §47.

§**50.** The template variable number marks out the special matching KOVs described above; it's set in "Types.i6t". For all ordinary data types, this number is 0. For "kov reference 1" and "kov reference 2", it is 1 or 2; for the corresponding "kov marker 1" and "kov marker 2", it is −1 to −2.

⟨Deal separately with matches against template variables 50⟩ ≡
```
int vn = data_type_template_variable_number(to->atomic_kov);
if (prototype_checking_pass == 0)
    internal_error("KOV marker variable occurs outside phrase typechecking");
if ((vn >= MAX_KOV_MARKERS) || (vn <= -MAX_KOV_MARKERS))
    internal_error("too many KOV marker variables in phrase typechecking");
if (vn > 0)
    ⟨A KOV reference target is always achieved, and the KOV achieved is recorded on pass 1 51⟩;
if (vn < 0)
    ⟨A KOV marker target is always achieved on pass 1, but its value must be matched on pass 2 52⟩;
```

This code is used in §47.

§**51.** For instance, given our example:

> To add (N - value = kov reference 1) to (L - list of values = list of kov marker 1) ...

When the KOV of "N" is matched against "kov reference 1" for the first time, it is stored in marker variable 1; on both passes, the match is always successful. ("Kov reference" types match anything.)

⟨A KOV reference target is always achieved, and the KOV achieved is recorded on pass 1 51⟩ ≡
```
switch(prototype_checking_pass) {
    case 1:
        LOGIF(INVOCATIONS,
        "can_we_cast_kovs_inner: setting KOV marker variable %d to $u\n", vn, from);
        kov_marker_variables[vn] = from; return ALWAYS_MATCH;
    case 2: return ALWAYS_MATCH;
}
```

This code is used in §50.

§**52.** Meanwhile, matching "list of kov marker 1" begins by matching "list of...", which takes a recursive call to `can_we_cast_kovs_inner`. The top-level call checks that "L" is indeed a list of *something*, say boojums. The inner call then compares boojums against "kov marker 1". On pass 1 this is always a successful match – we can't be sure that "kov reference 1" has been set yet, which depends on which way round they are in the prototype. But on pass 2 we can be certain that "kov reference 1" has been set to the KOV K of "K", so now the token matches if and only if boojums are K.

⟨A KOV marker target is always achieved on pass 1, but its value must be matched on pass 2 52⟩ ≡
```
switch(prototype_checking_pass) {
    case 1: return ALWAYS_MATCH;
    case 2:
        LOGIF(INVOCATIONS,
        "can_we_cast_kovs_inner: checking $u against KOV marker variable %d (=$u)\n",
            from, -vn, kov_marker_variables[-vn]);
        if (can_we_cast_kovs_inner(kov_marker_variables[-vn], from) == NEVER_MATCH)
            return NEVER_MATCH;
        else
            return ALWAYS_MATCH;
}
```

This code is used in §50.

§**53. Questions about units and enumerations.** Let's start with uncertainly defined KOVs, and what happens to them. When we read "Colour is a kind of value.", "colour" is uncertainly defined at first. Later we read either "The colours are blue and pink.", say, and then "colour" becomes an enumeration; or "450 nanometers specifies a colour.", say, and then it becomes a unit.

```
int kov_is_uncertainly_defined(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_is_uncertainly_defined(kov->atomic_kov);
}
```

The function kov_is_uncertainly_defined is called from 10/tab.

§**54.** Here we test for being a unit or an enumeration:

```
int kov_is_a_unit(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_is_a_unit(kov->atomic_kov);
}
int kov_is_an_enumeration(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_is_an_enumeration(kov->atomic_kov);
}
```

The function kov_is_a_unit is called from 9/rsdt, 7/kix and 8/creat.
The function kov_is_an_enumeration is called from 2/lexi, 4/edoc, 5/rel, 9/rsdt, 7/kix and 7/specv.

§**55.** And here we perform the conversion to a unit. (We don't need conversion to an enumeration since that happens when new enumerated values are created – see below.) The return value is `TRUE` if the KOV was already a unit or was successfully converted into one, `FALSE` if it's now too late.

```
int kov_convert_to_unit(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    return data_type_convert_to_unit(kov->atomic_kov);
}
```

The function kov_convert_to_unit is called from 5/litp.

§**56.** The instances of an enumeration have the values $1, 2, 3, ..., N$ at run-time; the following returns $N+1$, that is, a value which can be held by the next instance to be created.

```
int kov_new_enumerated_value(kind_of_value *kov) {
    if (kov == NULL) return 0;
    data_type_convert_to_enumeration(kov->atomic_kov);
    return data_type_new_enumerated_value(kov->atomic_kov);
}
```

The function kov_new_enumerated_value is called from 9/qty.

§**57. Questions about properties.** Some values can have properties attached – scenes, for instance – while others can't – numbers or times, for instance. In general v can have properties only if its KOV passes this test:

```
int kov_has_properties(kind_of_value *kov) {
    if (kov == NULL) return FALSE;
    if (kov_is_an_enumeration(kov)) return TRUE;
    if (is_kova(kov, OBJECT_TY)) return TRUE;
    if (is_kova(kov, SCENE_TY)) return TRUE;
    return FALSE;
}
```

The function kov_has_properties is called from 7/kix, 8/mass, 9/pp and 9/vpbp.
